Lingual Goitre.—Henry R. Storrs concludes that lingual goitre is a tumor at the base of the tongue, arising from an accessory thyroid gland which may be found in the course of the development of the thyroglossal duct. It has all the characteristics of ordinary goitre. It occurs almost exclusively in women between the ages of fifteen and forty. It grows slowly, and may exist for years without causing any annoyance, until some unknown cause stimulates its growth and produces symptoms. These are functional and not constitutional, and consist of trouble in swallowing, breathing, and speaking, accompanied by frequent hemorrhages. The tumor is round or ovoid, elastic, and covered with a very vascular mucous membrane, and is almost never ulcerated. Dermoid cyst offers the only difficulty in differential diagnosis, but this is generally yellow, grows rapidly, pits on pressure, and has not the vascularity of goitre. Operation is the only radical cure. There are two ways of reaching the tumor, namely, through the mouth and through an incision in the suprahyoid region, the former being the best. The prognosis is good.

A Posterior Incision in Certain Appendicitis Operations.—John G. Sheldon describes an operation in which the appendix is reached through Petit's triangle. A vertical incision is made along the outer border of the latissimus dorsi and extends from the crest of the ilium upward. This exposes the outer border of the quadratus lumborum and the lumbar fascia and aponeurosis of the transversalis, which extends anteriorly from the outer border of this muscle. The second incision is made transversely, close to the iliac crest, through the lumbar fascia and transversalis, exposing the parietal peritoneum directly over the ascending colon and cæcum. This method is especially advantageous in treating an inflamed appendix or its most frequent complication, a localized abscess. In lean persons, the operation has few advantages over the method ordinarily employed. In obese patients the posterior operation is more rapid, and is less likely to be followed by hernia.

Repair of the Urethra by Transplantation of the Urethra of Animals.—J. Hogarth Pringle describes three cases, in which patients with defects of the urethra have been treated by grafting into their tissues portions of the urethra of the ox. Two of the patients were men who had sustained a complete and extensive rupture of the urethra in the perineum; while the third was a boy with hypospadias, in whom there was a deficiency of the floor of the urethra for the whole of the penile portion of the channel. The treatment of these three patients represents five operations in which portions of an animal's urethra, varying in length from five to thirteen centimetres, have been implanted with success; that is to say, the grafted tissue lived and remained a patent channel.

The Formation of an Artificial Vagina by Intestinal Transplantation.—James Fairchild Baldwin tells of a method he had intended to carry out in a patient whose entire vagina had sloughed away following her delivery by instruments and after craniotomy at term. A careful dissection was made upward between the bladder and rectum, but not a trace of vaginal wall could be found at any point. The uterus was finally reached, but no cervix could be made out; it seemed to have sloughed away with the vagina. Douglas' cul-de-sac was opened, and through this the lower segment of the womb could be quite thoroughly outlined. This opening was carefully packed and the patient sent to her room, with the expectation that forty-eight hours later a second operation might be made for the maintenance of

the new canal. She absolutely refused to have anything more done and passed from observation. The method he planned to carry out was to utilize for the lining of the new vagina the sigmoid flexure of the colon, or a loop from the lower end of the ileum . The abdomen was to be opened and the sigmoid seized at about its centre by a pair of forceps introduced from below through the new canal and drawn down to the perineum. The length of bowel thus drawn was to be detached by a transverse incision through the gut, but without injuring the vessels in the mesocolon, the continuity of the colon being at once restored by an anastomosis. One end of the vaginal loop would then be inverted and closed by a continuous suture, not penetrating the mucous membrane. By pulling up the fundus of the uterus until the cervix, or opening into the uterus, was exposed, the lower end of the bowel would be attached around the cervix so as to form a canal for the uterine discharges. Finally, the patient being placed in the lithotomy position, the loop of intestine still held by the forceps would be opened, the bowel cleaned, each limb of the loop packed with gauze, and the edges of the opening in the bowel attached to the surrounding skin. At the completion of this operation there would be a double vagina, each canal being approximately of the size of the colon, and with the nutrition positively provided for by the integrity of the mesocolon. At the end of ten days or two weeks the septum between the two vaginas could be easily removed by clamp pressure.

The American Journal of the Medical Sciences, Oct., 1904.

Acute Leukæmia in Early Life.—Frank Spooner Churchill presents the following conclusions: All cases of leukæmia are myelogenous in origin. As in adults, the acute variety is more apt to be of the lymphocytic type. The disease is rare in early, as well as in later life. It is probably more common than has been supposed, however, 22 cases of the acute or subacute variety having been reported since 1898, while previous to that date only seven cases are on record. The course in children differs from the adult type only in minor details, hemorrhages are fewer and less severe, and the lymphacytosis is more apt to be of the small variety. The disease is always fatal. It is suggested that injections of sera be used in the treatment of this disease. Experimental inoculations with leukæmic blood and with cultures of pathogenic organisms are desirable. These inoculations should be made directly into the bone-marrow. The administration of arsenic is useless. The record of cases treated with the *x*-ray thus far gives no promise of permanent help. The writer gives the detailed history of his own case, the patient being a boy aged four years.

Experimental Arthritis and Endocarditis Produced by a Streptococcus Isolated from the Blood of a Case of Rheumatism, Endocarditis, and Chorea.—Morris J. Lewis and Warfield T. Longcope report a fatal case of rheumatism, endocarditis, and chorea. The patient was a girl, eight years old. Before death a streptococcus was isolated from the blood. This microorganism, when injected intravenously, is moderately virulent for rabbits, and gives rise, with the greatest constancy, to a multiple arthritis which is rarely fatal. In one case, however, the arthritis was complicated by an acute vegetative endocarditis, and the rabbit died. It is only after a more or less definite incubation period of from 4 to 9 days that the onset of the joint symptoms is noticeable. Before this time the animals seem to be perfectly well. Swelling and tenderness in the ankles are usually the first indications of the joint involvement. There seems to be pain, also, for the rabbits move but little, and they limp when they are made to hop about. In certain cases the infection remains localized, while in others it spreads to practically all of the joints in the body. Small swellings may also develop upon the muscle tendons. The writers declare that the organism from its morphological and biological properties could not with any certainty be differentiated from the usual varieties of streptococcus pyogenes. They have not been able to investigate the question of pathogenicity for animals of streptococci from sources other than rheumatic fever.

Pulmonary Streptothricosis.—Aldred Scott Warthin and Herbert S. Olney have had an interesting case of this nature under observation. The patient was a farmer, aged 45 years. There was no family history of tuberculosis. Three years ago his trouble began with an attack of "la grippe," after which a moderate cough and expectoration persisted. He became much weakened and emaciated, and was so distressed with digestive disturbances that he was compelled to live upon a milk diet. He kept at work, however, until six months ago, when he was sent to Colorado with the clinical diagnosis of tuberculosis. He was examined again, and the clinical picture on the whole suggested a chronic bronchitis or broncho-pneumonia of tuberculous origin. The sputum which was collected for examination consisted of about one ounce of a yellowish-gray, nearly homogeneous, and somewhat gelatinous substance, containing large numbers of minute grayish granules. It was not stringy. There were no blood streaks in it, and it had no noticeable odor. No yellow elastic tissue was found. The small grayish granules proved to be masses of a filamentous organism, closely interwoven and freely branching. No tubercle bacilli could be found. When the organism was stained with carbol-fuchsin, the branching threads retained the stain after treatment with 25 per cent. sulphuric or nitric acids, although they gradually lost the color when washed in 95 per cent. alcohol. These threads stained beautifully with Gram's. The length of the branches varied greatly, though most of them were short. In specimens stained with carbol-fuchsin (acid decolorization) and by Gram's method, there was invariably present a filamentous organism showing true branching. In the carbol-fuchsin specimens the majority of the threads showed a beaded appearance, which seemed to be dependent upon the degree of decolorization. The beading was not so marked in the Gram specimens. The organism, according to the writer's belief, was evidently a streptothrix, morphologically identical with the ones described by Bughholz and Flexner. Cultural studies were not made of this organism, as the patient suddenly died. No autopsy could be obtained. The conclusion reached by the authors is that there is a distinct form of pulmonary infection clinically resembling tuberculosis, and caused by an acid-resisting streptothrix having a wide geographical distribution.

Tuberculosis and Heart Disease.—George William Norris bases his conclusions upon the study of 1,764 autopsies, 1,276 clinical histories, and a review of the literature. He believes that valvular heart disease exerts very slight influence, if any, either inhibitive or curative, upon tuberculosis, even if satisfactory compensation is maintained. Small hearts, either as the result of wasting or hypoplasia, are commonly found at tuberculosis autopsies, while large hearts are not often noted in uncomplicated cases. It is doubtful, however, whether smallness of the heart predisposes to pulmonary tuberculosis to a greater degree than can be explained by the general systemic underdevelopment and lack of resistance so common in such individuals. A large proportion of cases of stenosis of the pulmonary orifice die of pulmonary tuberculosis. A common result of tuberculous intoxication is arterial and endocardial thickening. Pericarditis, especially when chronic, is often due to the presence of the tubercle bacillus. Tuberculous endocarditis and myocarditis are rather rare. So is tuberculosis of the aorta. Fatty and fibroid changes in the cardiac muscle are common in pulmonary tuberculosis, a fact which explains the failure of certain heart stimulants, such as digitalis, to benefit these cases. The writer finally declares that he could accept the most absolute evidence only as a proof that either the coincidence of another pathological condition or the administration of a special remedy has conferred a benefit upon the patient.

An Unusual Ovarian Condition.—Lewis Schooler observed the case which he here describes. The patient was suffering with a tumor in the left side. This growth was gradually increasing in size. As medicinal treatment seemed to offer no relief, operation was resorted to. The incision was begun a little higher than the point usually selected for an ordinary ovariotomy. The uterus was found to be dragged upward and to the left, and the Fallopian tube felt double its normal size, and extended from the uterus to the enlarged and displaced spleen. The incision was extended upward to bring the spleen into view. It was six times its normal size, and looked like an old blood clot, only firmer. It was black and glistening. A bit of this organ was removed for examination, which confirmed the original diagnosis. Examination of the field showed that at the lower pole of the spleen there was complete and firm union of the spleen, ovary, and fimbriated extremity of the tube. Close inspection, indeed, was necessary to identify these structures, so close was the union. The tube, ligament of the ovary, and the upper edge of the broad ligament were hard and firm from the tension. They were divided between two ligatures, and the abdomen was closed. Healing took place by first intention. Four weeks after the patient had left the hospital she was found to be suffering from obstruction of the bowels. The condition improved at first, but later became so grave that a second operation was performed. The obstruction was found to be due to extensive adhesions almost the entire length of the descending colon. These adhesions were ligated at several points, and the bowel was freed and filled with salt solution. The uterus and spleen were both normal. The patient made a good recovery. The writer cannot explain how two organs, normally so far apart, became united. The patient had never suffered from malaria.

Studies upon the Capsule of the Kidney.—Haven Emerson has studied the capsule of the kidney of the dog, the rabbit, and the pig. The aim of his experiments has been to ascertain whether the capsule would allow or prevent

the absorption into the blood of salts in solution, and to determine the result of decapsulation of the kidney upon the animal and the organ. He believes that after decapsulation of the kidney a temporary relief from pressure may be hoped for, and if the conditions are proper, the vascular supply may be increased for a limited period. But there is a certainty of the formation of a quickly-growing, dense, and contracting capsule. There is also a probability of the establishment of a chronic interstitial nephritis in the majority of the cases, and a possibility, only, of any permanent increase of the renal blood supply. It is fair to state that the newly-formed capsule is efficient to protect the kidney from absorption from without, and from extremes of vascular pressure from within. The new capsule does not differ essentially from the original one, except in its tendency to persistent and uneven contraction. The writer believes that the possibility of attaining more than a temporary improvement of a diseased condition of a kidney by decapsulation is slight.

French and Italian Journals.

Typhoid Fever with Cutaneous Necroses in a Child of Ten Years.—Ley calls attention in this report to the power of causing necrosis, which is inherent in the bacillus of Eberth. The lesions caused by this bacillus in the intestinal follicles are clearly necrotic, but the development of gangrene elsewhere than in the intestines is rare. He cites the case of a girl aged ten years. The family and personal history were both excellent. The symptoms of typhoid began to show themselves on December 10. Profound weakness characterized the attack. Nine days after the first appearance of the disease rose spots appeared, and on the same day the writer was astonished to note the appearance of a spot of necrosis over the sacrum. The lesion was as large as a franc. In spite of the greatest care the lesion increased in size, and others of the same nature appeared in different parts,—on the thigh, the heels, and the toes. The formation of each gangrenous spot was preceded by congestion of the skin, and the development of a bulla filled with cloudy serum. Finally, a huge eschar developed in the skin of the abdomen. The general adynamic condition of the patient increased, and in spite of every effort death supervened. Autopsy was not allowed. It is interesting to note that a servant in the house contracted the disease, and died a few weeks later. She presented the same adynamic symptoms, and the same large plaques of disseminated cutaneous gangrene. Widal's reaction was obtained with the serum taken from a bulla, in the case of the first patient, although the serum was highly diluted.—*Revue Française de Médecine et de Chirurgie,* October 10, 1904.

A Study of The Variations of Astigmatism with Age.—Et. Ginestous briefly notes the history of the study of astigmatism, and then refers especially to the results of the recent researches in this subject made by Louis Sonder. Some of the conclusions reached by this investigator are as follows: Hypermetropic corneal astigmatism has a tendency to diminish with age. This tendency is the more accentuated as the hypermetropia is greater. Myopic corneal astigmatism has rather a tendency to increase. But the degree of increase is a little less than the degree of decrease in hypermetropic astigmatism. This tendency is more apparent in proportion as the fault in refraction is greater. In the defects of weak refraction the astigmatism, whether it be hypermetropic or myopic, does not undergo very sensible modifications. The differences that have been noted in examinations made at different ages, and which consisted sometimes of diminutions, sometimes of augmentations, prove that the cases do not conform to a fixed rule. The decrease in hypermetropic astigmatism appears to be due to partial contractions, prolonged and permanent, of the ciliary muscles. The increase in myopic astigmatism can be explained by the minimum of accommodation which is found in a myopic eye, and by the natural elongation of the eye. Sonder has examined most carefully 100 patients suffering with astigmatism; these patients had been examined 10 years or less before. He has thus been able to make these deductions from the comparison of the various examinations.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux,* October 9, 1904.

Contribution to the Theory of Autointoxication in the Pathogenesis of Death from Burns.—Alfonso Pirera brings forward a case of slight burn observed by him, resulting in death, to support the theory of autointoxication as the cause of such deaths. The patient was 12 years of age. She was scalded on the right cheek and neck over a surface only a few centimetres square. The symptoms were not severe at first, but after a lapse of some hours severe vomiting set in, with symptoms of acute intoxication, followed by heart weakness and death in collapse. Examination of the internal organs showed degeneration of the kidneys so severe that there was necrosis of many of the epithelial elements of the tubules. The liver cells showed a similar degeneration. The spleen was not much changed, nor were the lungs. The changes were such as are characteristic of acute phosphorus poisoning. He concludes that (1) Autointoxication is of the greatest importance in the etiology of death from burns, and is the result of the formation of toxic substances in the burned tissues. (2) The changes are characteristic of acute degeneration of different degrees from engorgement to necrosis. (3) In the kidneys the lesions are limited to the epithelia of the canaliculi, the glomeruli and capsule of Bowman escaping. (4) In the liver the lesions are unexpectedly severe, since the liver is an antitoxic organ par excellence. (5) The severity of the intoxication bears no relation to the extent of the burned surface.—*Giornale Internazionale delle Scienze Mediche,* September 30, 1904.

The Mechanical Treatment of Œdema.—Carlo Colombo considers that massage is the most effectual remedy for œdemas, in whatever location and in all circumstances. The established technique for this treatment does not seem to be fully understood. Pressure movements are the only ones that are useful in œdema. Pressure by the hand is to be used in œdema that is not too firm, and is situated in the limbs, especially the knee and foot. After placing the limb on a proper support the operator grasps the limb firmly with the palm of the hand and the palmar surface of the fingers, at the portion nearest the body; a progressively increasing pressure is exerted for thirty to forty seconds, a sulcus being produced in the swollen tissue. The movements are repeated just below the sulcus, and so on to the end of the limb. The skin of the limb will now have lost its tension, and the œdema have diminished. The movements are repeated until the œdema is reduced as much as is desired. When the œdema is more firm he uses pressure with a bandage three or four metres long and seven to eight centimetres wide. He begins at the end of the extremity in this case, bandaging the limb spirallyy, so that each fold is half covered by the next layer. The bandage is to be put on as tight as possible. After some seconds it is removed and again adjusted. An elastic bandage may be used with advantage. The pressure by the hand may, with advantage, precede that with the bandage.—*Rivista Internazionale di Terapia Fisica,* October 1, 1904.

Two Popliteal Aneurysms in the Same Patient.—Durand reports this interesting case. The aneurysm on the right side ruptured spontaneously. Gangrene of the left leg set in, and the writer extirpated the aneurysmal sac and performed an amputation below the knee, thus putting an end to the destructive process. On the left side the tneurysm was extirpated, with perfect results. The patient was a man of fifty-four years, with nothing of special interest in his history. It was in the first part of 1903 that the patient first noticed the existence of the two aneurysms, but as they did not trouble him, he paid no attention to them. In the first part of August, 1903, he felt a sharp pain in the right popliteal space. This area increased rapidly involume, and shortly after the dry gangrene of the great toe began to appear, gradually spreading upward. The writer emphasizes the fact that the correct treatment of popliteal aneurysms is extirpation. He calls attention to the results obtained in both of these aneurysms. Rupture of an aneurysm is not very common. Extirpation of the sac in this case of ruptured aneurysm enabled the writer to avoid amputation of the thigh. This unusual case demonstrates that extirpation is the method of choice as well in simple as in ruptured aneurysms.—*Lyon Médical,* September 11, 1904.

Painful Lipomata.—Debove describes a patient of sixty-nine years who had taken to bed, as she disliked even to move. She had been afflicted with painful lipomata for about 12 years, although her statements concerning the beginning of this malady were not very definite. The pain of these tumors is the most important symptom, and next to that stands the asthenia. A sort of mental debility is also noted in these patients. These tumors are not spontaneously painful, but on pressure only. They may be seen by simple inspection. They are covered by normal skin, and have a few blood vessels coursing through them. They are not adherent to the deep tissues. Some of them attain the size of a pigeon's egg. They are elastic, but are also resistant, like fibrous tumors. In this patient they are numerous on the forearm, in the upper two-thirds. They are not found on the hands. There is a mass on the back of this patient with all of the characteristics of a diffuse lipoma. These growths are also in the tissues of the abdomen. There is no trace of paralysis in this patient. The psychical troubles are very striking in this case. The mental state is very like that which is seen in certain forms of cerebral softening. The prognosis of this affection is not grave in respect to life, but it becomes serious when the psychical and physical weakness are considered, for these symptoms are sufficient to put the patient in bed for years before death.—*Gazette des Hôpitaux Civils et Militaires,* September 27, 1904.

Book Reviews.

A Treatise on Obstetrics. By Edward P. Davis, A.M., M.D. Second Edition. Philadelphia and New York: Lea Brothers & Company, 1904.

A comprehensive work in six parts, treating respectively of pregnancy, its diagnosis, physiology, pathology, and treatment; labor, the puerperal state; infancy, with a section on the diseases of infancy, including dentition and the infectious diseases; and lastly, the jurisprudence of obstetrics. This book has the disadvantages of its class. Where so much ground is covered in one volume, the detail is too great for a beginner's comprehension, and yet it is not great enough to satisfy a scholar. This is markedly true in the section devoted to the development of the embryo and the fœtus. The same holds true in the discussion of rare incidents, as hæmatoma of the vulva. The usual remarks are made, but the author's handling of the subject is not that of the master. The description of the mechanism of labor is very clear to those who already understand it. The nomenclature is simple, formally recognizing but two positions—first and second, and two presentations—vertex and breech. The book, as the author states, is well up to date in its descriptions of treatment and general technique. Being, in addition, fairly well written, and illustrated with 39 plates, some of them colored, and nearly 300 smaller figures, it will take a well deserved place among our books of reference.

Surgical Differentials. By J. W. Draper Maury, M.D., Rockefeller Institute Research Fellow in the Laboratory of Experimental Surgery, Columbia University, New York City. Illustrated. New York; James T. Dougherty, 409 and 411 West Fifty-ninth street, 1904.

This book was written for students preparing for the examinations of the various New York Hospitals. It does not claim to be a text-book, but only a guide to the proper selection and grouping of the facts learned from books and at clinics. The writer has been eminently successful in his endeavor to help the student; and the volume contains several very useful tables of differential diagnosis, schemes for the proper and complete answering of examination questions, and clear outline sketches, giving the maximum of useful information in very little space. We would recommend the student to get the book and use it during his third and fourth years, and not to wait till he is thinking of his hospital examination. Among the more important of the topics treated, are: inflammation, aneurysm, shock, sepsis, tuberculosis, syphilis, gonorrhœa, injuries of the head, the stomach, intestinal obstruction, fractures, dislocations, and hernia. Samples of examination questions of several of the New York Hospitals are appended. The author states that "in the opinion of over one hundred graduates who during the past six years secured hospital positions, the ability to apply the scheme (presented in this book) was the primary cause of their success."

The Principles of Hygiene. A Practical Manual for Students, Physicians, and Health Officers. By D. H. Bergey, A.M., M.D. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

This is a second edition of a book which first appeared some two years ago, and was here reviewed in these columns. While the book is much improved in its second edition, it is still open to many criticisms, previously justifiable. Chief among these is the fact that no man can write a book on hygiene thoroughly suited to be "a practical manual for students, physicians, and health officers." The requirements of these several classes vary and it would be better if Dr. Bergey had properly appreciated this fact and prepared his book accordingly to meet the needs of the particular class he desired to reach. Dr. Bergey's claim to supply all wants of the tyro and the expert within his 520 pages is comprehensive if not modest. He devotes some 65 pages to quarantine laws, and some sanitary laws of the State of Pennsylvania, which surely he does not expect his students to learn, and which certainly have no applicability to the duties of physicians and health officers of most towns outside his own state. He overloads the student with unnecessary matter, while the health officer who does not have an intimate knowledge of more than is given in this book must be regarded as scarcely competent for his position. The same applies to certain of his chapters, as those on military and naval hygiene—for few students will have any call for information on such technical matters, and those that do will derive little benefit from the meager information which he gives. On the whole, the book can be studied with advantage by students if considerable parts are omitted, while health officers and those better informed in hygiene will preferably resort to works of a more comprehensive character. Dr. Bergey's book is well written, and if condensed by one-third would make an excellent student's text-book, which is something needed at the present time. If further editions are to be forthcoming, it is hoped that he will recognize this fact and refrain from attempting to provide something to serve at once the purposes of the sanitary primer and of the encyclopædia.

Self-Propelled Vehicles. A Practical Treatise, with Illustrations. By J. E. Homans, A.M. New York: Theo. Audel & Company, 1904.

The large number of physicians who have come to realize the many advantages the automobile offers to them in their daily practise, and especially those who live remote from the larger cities, will appreciate the appearance of this book on Self-Propelled Vehicles—originally published in 1902, and now revised and largely rewritten, bringing it up to date. To the man who takes a personal interest in his automobile and who wishes to obtain an intelligent understanding of its workings—be it steam, gasoline, or electricity—this work will prove an admirable instructor and guide. The book opens with a chapter on the general principles of automobile construction, followed by an extensive account of the theory, construction, and operation of gas engines. Perhaps one of the most interesting features of the whole volume is the extensive chapter devoted to the description of leading types of gasoline vehicles, including the most important of American build. The chapter on electric vehicles—in fact, the whole subject of electricity, from the fundamental principles to its application to automobiles—is fully and clearly discussed. The merits of the several types of steam carriage are well set forth.

The book closes with a chapter on gasoline vehicle management, and one containing hints which will be found most useful and instructive, the various technical terms being readily interpreted by reference to the complete index at the end of the volume.

The book, on the whole, will appeal both to the mechanician and to the amateur, and, although many of the subjects treated are of a technical nature, nevertheless they are dealt with in such a way that the intelligent reader cannot fail to acquire a good knowledge of his subject.

Lectures to General Practitioners on the Diseases of the Stomach and Intestines. With an Account of Their Relations to Other Diseases and of the Most Recent Methods Applicable to the Diagnosis and Treatment of Them in General; also "The Gastrointestinal Clinic," in which all such Diseases are Separately Considered. By Boardman Reed, M.D. Professor of Diseases of the Gastrointestinal Tract, Hygiene, and Climatology in the Department of Medicine of Temple College Philadelphia; Attending Physician to the Samaritan Hospital; Member of the American Medical Association, American Climatological Association, American Academy of Medicine, American Electro-Therapeutic Association, Foreign Member of the French Société d'Electrothérapie, etc. New York: E. B. Treat & Company, 1904.

The author explains the publication of the above volume as being due to the desire of the profession to obtain a book which would give concise, practical, and easy methods of diagnosis and treatment of gastrointestinal disorders, the appropriate chemical tests such as could be performed by the general practitioner, and the means of determining size, position, and motility of the stomach, colon, etc., such as would be permitted by the patient and performed by the doctor without undue difficulty. To this end he has not included the historical introductions, the uncertain etiology, much of the pathology, and the usual bibliographical lists. With these omissions the work is fairly complete, and will probably be met by a large demand from those in general work who have not the time for more extensive reading. The author is clear and sound in his teachings, simplifies conditions as far as possible, and gives a good practical working knowledge, such as he has gathered from a large experience in his special field. The first part deals with the anatomical, physiological, chemical, and diagnostic data, the second with the methods of examination, the third with the methods of treatment, and the fourth part, which he names the "Gastrointestinal Clinic," with a consideration of the separate diseases.

On the mooted question of appendicitis, the writer holds conservative views regarding immediate operation. He strongly advocates the Ochsner method of rectal feeding and gastrointestinal rest, and in the less severe cases of chronic appendicitis claims that a cure may often result from purely medical means.

The work would have been more valuable to those to whom good surgical advice is not readily accessible if the author had been more explicit regarding the need and the elective time for operative interference in such cases, *e.g.*, as hematemesis, although this is a point to be settled as a rule by the surgeon. There was need of such a book written by a practical observer, who gives to the reader the easiest and most useful methods destined to be employed in general practice more and more in this rapidly progressive department of medicine.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, Held October 13, 1904.

David Bovaird, Jr., M.D., Chairman.

A Case of Sclerema Neonatorum.—Dr. Sara Welt-Kakels presented a boy, seven and one-half weeks old, who was brought to the Mt. Sinai Dispensary on September 12. The patient was born at full term. The labor was tedious, lasting 36 hours, the child finally being delivered instrumentally. It was asphyxiated at birth, and it was three-quarters of an hour before it started to cry. The child was restless, and cried whenever it was touched. The bowels were rather constipated and vomiting was frequent. The child was breast-fed. Two days before the child came under observation the mother noticed a hardening of the skin on the neck and upper arm. Examination revealed an induration of the skin along the entire back, from the neck to the coccyx, over the cheek bones, on the shoulders, on the sides of the chest, and the anterior aspect of the right and left femur. The skin in these regions was of a reddish-brown, livid color, band-like, and could not be raised in a fold; there was no pitting on pressure. The joints were movable. The organs of the chest and abdomen were normal. A tumor was situated on the right side of the neck; this was easily movable and rather tense to the touch; it caused no pain on pressure. It was probably of embryonic origin, the result of cystic dilatation of a branchial fissure obliterated at both ends. Dr. Welt-Kakels said that sclerema or scleroderma of the new-born occurred most frequently among children with feeble heart action, in the asphyxiated and premature. The disease was more commonly met with in foundling asylums, among bad hygienic surroundings. In America it was extremely rare. An interesting feature of the case under discussion was that when first seen the rectal temperature was 101° F. In most of the cases on record a sub-normal temperature was reported. The child was apparently improving under treatment, the main feature of which was hot baths.

Dr. William P. Northrup said he had seen but one case of scleroderma neonatorum, and that was many years ago, at the New York Foundling Hospital. That case formed almost a composite picture of the various descriptions of this condition found in the text-books. The sub-normal temperature was a marked feature of the case. The induration of the skin was first noticed on the cheeks; then on the neck and shoulders. Artificial heat was applied in every possible way, but it made no impression on the bodily temperature. After death, sections of the tissues were removed from different parts of the body, and hardened and stained in various ways and examined microscopically, but the results were absolutely negative.

The Influence of the First and Second Dentition Periods in the Etiology of Epilepsy.—Dr. William P. Spratling said it was his conviction that we were never justified in looking upon the convulsions of infancy and early life as harmless manifestations. Numberless convulsions appeared at this period that began as benign and sooner or later ended as such, but many others began as benign, sooner or later to end in established epilepsy. The speaker said he was led to make this statement after ten years' experience at the Craig Colony for Epileptics, during which time he had studied the etiology of the disease in nearly 2,000 cases. Infantile convulsions that appeared in connection with the first and second dentition often disappeared entirely for years, only to recur at some future time when the child was passing through a period of physiological stress, particularly like that which so commonly characterized the epoch of puberty. The lesson we often failed to learn was the necessity for constantly recognizing in such children the presence of the convulsive tendency. To keep the child free from convulsions in the future, this tendency should be borne in mind, and always respected. The question he particularly desired to discuss was whether difficult dentition alone, or acting in conjunction with a previously prepared organism, was ever capable of causing epilepsy. Many physicians of the present day denied that teething ever caused epilepsy or even epileptiform convulsions. From this view the writer dissented. He had long felt that in selected cases, the "stress" of difficult dentition was the touchstone in the causation of epilepsy.

In connection with his paper, Dr. Spratling exhibited a number of charts. Chart No. 1 gave the age for each year at the onset of epilepsy in 1,215 cases, from the first to the twentieth years, inclusive. These 1,215 cases, all under 20 years of age, represented 80 per cent. of all patients admitted to the Craig Colony up to the time these figures were made. One hundred and seventy-five of these patients, equal to more than 14 per cent. of the entire number, developed the disease during the first year of life. After passing the first year, there was a very decided and continuous decline up to and through the fifth year, there being only 33 in that year, or about one-fifth as many as during the first year. After leaving the fifth year, we entered upon the period of the second dentition, and there was a very decided rise in the number of cases through the sixth, seventh, and eighth years, 45, 69, and 67 cases, respectively, the number dropping to 55 during the ninth year. Chart II showed that epilepsy was present in 80 cases during the first month of life; the second month showed a decline to five cases and in the third month only three cases occurred. A notable increase took place during the fourth month, followed by a second decline through the fifth and sixth months, after which a very positive rise was noted during the seventh month, 20 cases occurring during that month, equal to 25 per cent. of the entire number. The sole fact of importance about the very notable rise during the seventh month was that it marked the beginning of the influence of the first dentition period. Chart III was made from a grand total of 3,523 cases, in all of which epilepsy developed before the twentieth year. Of these, 376 developed during the first year of life; these cases he ascribed to congenital causes, heredity, birth accidents, and the first dentition. Passing the first year, a continuous decrease was noted through the second, third, fourth, fifth, and sixth years, when only 127 cases out of 3,523 occurred. The seventh year showed an increase to 168, this increase continuing through the eighth year, and reaching 174. After this a fluctuating rate was noted until the twelfth year, when the stress of puberty began to be felt. The four years that covered the developmental period showed a vast increase in the number of cases, a grand total of 877 cases out of 3,523 occurring during those four years. Passing the epoch of puberty, the decline was sharp and continuous, so that by the time the twentieth year was reached the period had ended during which more than eight-tenths of all cases of epilepsy developed.

Dr. A. Jacobi said that convulsions were very frequent in early infancy, and should always be considered as serious occurrences. Dr. Spratling had emphasized the statement that the convulsions in infancy that led to epilepsy were the "teething convulsions," instead of referring to them, as Dr. Jacobi would have preferred to do, as convulsions occurring during the teething period, or convulsions that occurred from some cause or other while the child was teething. As a matter of fact, the process of teething began very early in fetal life, and the teeth were practically fully developed in the gums when the child was born. The actual eruption of the teeth generally occurred about the seventh or eighth month of life; sometimes earlier, sometimes as late as the twelfth or sixteenth or seventeenth month. This retarded protrusion of the teeth was not the fault of the teeth themselves, but was due to the general condition of the child. Such children were frequently rachitic, which meant an abnormal condition of the meninges of the brain. That was why we saw convulsions

simply on the basis of rachitis. In such children the convulsions were not the result of the teething, but of the peculiar condition of the child. Convulsions would not be looked for in a normal child during the dentition period. It was peculiar that so many convulsions occurred during the first month of life, because the reflex activity of the new-born was almost *nil*. The convulsions at that early age were not of reflex, but of cerebral origin, and in many instances were the result of hemorrhage. The blood-vessels of the new-born were very friable, and hemorrhages were not uncommon. Another cause was sepsis, sometimes of a very mild type. Premature ossification of the sutures of the bones of the skull might also give rise to epilepsy and paralysis. Dr. Spratling, in the history of his cases, had emphasized teething in the causation of the epilepsy, but had said nothing about other important factors, such as improper feeding, etc. Very recntly, Dr. Jacobi said, he saw a child in convulsions. The child was teething, it was true, but it had also been fed on sour-krout and frankfurters during the day. A single convulsion, from whatever cause, might produce hemiplegia and epilepsy. In most of the cases reported by Dr. Spratling the fathers were drunkards; in some, both parents were drunkards, and probably there were several generations of drunkards. Every case of epilepsy should be judged by its own history. Dentition could not be regarded as a general or even a frequent cause. The normal child would not suffer during dentition, excepting, perhaps, from a slight salivation, or a diarrhœa in consequence of swallowing so much saliva. In most cases, epilepsy dating from childhood resulted from local changes in the brain.

Dr. Charles G. Kerley said he agreed entirely with the remarks made by Dr. Jacobi, and he called attention to the fact that, according to the chart shown by Dr. Spratling, convulsions during the second year were of much less frequent occurrence than during the first year, in spite of the fact that teething was much more difficult during the second than during the first year. It was during the second year that the canines and molars were cut.

Dr. Floyd M. Crandall said that two questions were raised by Dr. Spratling's paper: first, the influence of dentition in producing convulsions, and, second, as to whether these convulsions that came on early in life developed into true epilepsy. The speaker said that while it seemed to him that teething exerted some influence on the child's condition, he had never been able to convince himself that dentition was the cause of convulsions in a healthy child. He had seen cases, however, in which children with rickets, bad digestion, bad feeding, added, perhaps, to bad heredity, had developed convulsions during the dentition period. One or all of these drawbacks had proved to be the straw that broke the camel's back. The convulsions of infancy were always to be looked upon as grave misfortunes to the child: in no instance should they be regarded as benign, and Dr. Crandall said he had long made it his practice carefully to look after these children, treating the rachitic condition, if there was one, regulating the diet, and guarding against every possible source of further convulsions, so that true epilepsy did not develop.

Dr. Spratling, in closing the discussion, said he had not tried to prove the assertion that dentition had a marked influence upon the development of epilepsy, but had simply brought the facts and figures before the members of the section. In many of the cases included in his list, there were doubtless other factors besides dentition in the production of the epilepsy. The speaker said he was aware of the fact that teething began during embryonic life, but the trouble did not occur while the tooth was in the gums, but when it began to cut through the gums; that was the critical period. His list did not include healthy, normal children, but diseased children; those whose constitutions were run down or who had a bad heredity. That was the class of children in whom convulsions developed and who ultimately might suffer from epilepsy.

Sequelæ of Cerebrospinal Meningitis—Dr. Henry D. Chapin said that of the 18 or 20 cases of cerebrospinal meningitis he had observed during the present epidemic a certain proportion of them had developed a neuroretinitis. In presenting a series of these cases before the New York County Medical Society last Spring he had mentioned this fact, and in the discussion that followed one of the ophthalmologists present said that this was a very unusual feature of the disease. Since then, Dr. Chapin said, he had had special attention paid to the examination of the eyes in these cases, and he had at present under his observation a baby of four months in which the cerebrospinal meningitis was accompanied by a marked neuroretinitis on the right side, and a slight one on the left. Dr. A. E. Davis, who had made the examination of the eyes, seemed to think that the neuroretinitis was a pecular feature of the present epidemic.

Dr. L. Emmett Holt said his experience showed that cases occurring in children under three years of age were almost invariably fatal. Two remarkable cases of recovery, however, fell under his observation. One of these was a boy of four years, who was taken suddenly ill; he was unconscious, blind and deaf, and for ten weeks had a continuous high temperature. At the end of that time consciousness slowly returned; then his improvement became more rapid, and he was now entirely well, with the exception of a certain degree of irritability. In connection with the treatment of cerebrospinal meningitis, Dr. Holt said he was impressed with the absolute futility of drug treatment. In the case he had just mentioned, potassium iodide had been given until the patient's stomach became disturbed. Inunctions of mercury were also tried, and for the pain morphine was given hypodermically. The feature of the treatment that apparently saved his life was the careful, constant attention to his nutrition. The pulse ranged between 130 and 150 until the temperature became normal; then it dropped suddenly, ranging for several days from 48 to 60. It appeared perfectly marvelous that this child should have recovered with perfect sight, hearing, and intellect. In the other case he had in mind, there was a high temperature for 84 days, and during the greater part of that time the patient was unconscious. The case gradually went on to complete recovery. In this instance, as in the other, life was also apparently saved by careful attention to diet and nutrition. Both patients became extremely emaciated, and probably would have died of exhaustion, as most of these cases did, had not the nutrition been so carefully looked after. In another typical case the patient had developed a secondary hydrocephalus, the child's head being enlarged two and one-half to three inches beyond what it should be for its age. The symptoms pointed to a persistent basilar exudate. As regarded the eruption, Dr. Holt said he saw it in a number of cases early in the course of the disease. In one instance it was so intense that the diagnosis of measles was made.

Dr. Jacobi said he had seen about 18 cases of cerebrospinal meningitis during the present epidemic. His death rate was between 30 and 40 per cent., which was less than he had expected. The eruption he had observed in very few instances. Deafness seemed to be a more prominent symptom than in previous epidemics or in the stray cases that were occasionally observed. Out of eight or nine patients that he had in his ward, three became hopelessly deaf. Why the eyes and the ears did not become more frequently affected the speaker said he was not able to say, because in practically every case the nasal mucus showed almost a pure culture of meningococci, and there was plenty of opportunity for them to spread. The nasal involvement was very marked during the present epidemic.

Dr. L. E. LaFétra said that in discussing the mortality of cerebrospinal meningitis, it was important to keep in mind the age of the patients. The speaker said he had seen 20 cases during the past summer, 18 at the Babies' Hospital and two at the Vanderbilt Clinic. The diagnosis had been confirmed by lumbar puncture in every case but one. Of

the 19 punctures made, there was a positive growth in the fluid drawn from 14. In four of the others there was no growth, but pus cells and an excess of fluid under pressure. Dr. Marple found a papillitis in several of the cases. Of the 20 cases, 11 were boys and 9 girls, the ages of the patients ranging from three months to three years. Eight patients were under one year old; seven were between one and two years; four between two and three years. The children had been ill for periods ranging from two days to three months before admission to the hospital; none of the cases developed in the hospital. In two instances there was another child in the family ill with the same disease. Six began with a cough. In ten there was a history of vomiting, which was usually accompanied by convulsions. Eight had convulsions and fever. The temperature ranged between 102° and 106°, according to the stage of the illness, and would at times fall to normal for long periods, to be again followed by a rise. There was rigidity of the neck in 16 cases; in three cases there was no rigidity at any time. In two cases the fontanelle was depressed; in two it never bulged. *Tache cérébrale* was present in 16 cases; not recorded in four cases. The pulse was irregular at some time in 13; regular in seven. It was irregular and slow in only one case, a child of three years. The respirations were noted as Cheyne-Stokes in one case; as regular in 13 and irregular in six. There was apathy and iritability in all cases. Kernig's sign was present at some time in 16 cases; it was absent throughout in four cases, of which three were fatal and one recovered. Babinski's sign was noted in one case. There was no record of Macewen's sign. Petechiæ were observed in three cases, and bilateral herpes in one case, an infant of seven months. Opisthotonus was present in 12 cases; absent in eight. Tremor was present in four cases. Wasting or marasmus was absent in all cases. The length of the disease varied from four days to four months. The earliest case began, according to the history, in January; 12 cases began in April and May. Death occurred in 16 cases; two were apparently completely cured; one case developed a chronic hydrocephalus and one was lost sight of. Of the two that recovered, one had the disease for three months and one for 43 days.

Dr. Northrup showed the temperature chart of a case of cerebrospinal meningitis in which death occurred after 135 days' illness. The patient was a girl, 14 years old, of a particularly robust type, who was very fond of horseback riding. Her illness came on suddenly. The eruption, the herpes on the lips, and the emaciation were prominent features of the case. Death occurred of exhaustion, in spite of every effort to increase the patient's ability to assimilate food. Dr. Northrup said that during the recent epidemic he had seen ten patients with the disease in private practice, and of these, eight died. Of the two that recovered, one went 107 days and the other 42 days. One was two years old; the other four. They had all the characteristic symptoms of the disease. Among the cases he saw at the hospital one child recovered, but was deaf, blind, and idiotic. The speaker said that the most marked peculiarity he had observed in the recent epidemic was the great variability and infinite variety of the symptoms.

Dr. William L. Stowell said that in one of the eight cases he had observed the patient recovered with an endocarditis. This began when the child had been ill about two weeks, and the endocarditis lasted about eleven weeks. The case went on to complete recovery. In another case, a child of 22 months, a choroiditis developed; this case died in convulsions after two and one-half months' illness. One patient recovered without any unusual manifestations or sequelæ. All the other children died. Dr. Stowell said that in a case which he saw during an epidemic several years ago there was apparent total blindness, but since then sight was gradually restored and was now practically normal, showing that atrophy of the optic nerve was evidently not complete. The mental condition of that child, however, was much impaired.

Dr. William M. Leszynsky said that during the recent epidemic he saw upwards of 30 cases, and the remarkable feature of the cases, to which one of the speakers had already called attention, was the variability of the symptoms. One patient, a boy of ten years, in whom the diagnosis was made only through lumbar puncture, had no rigidity, no loss or exaggeration of reflexes, and simply remained in a semi-conscious condition. He answered questions from time to time; his pulse was slow, his temperature subnormal, and death occurred in about four days. No autopsy was obtained. Another patient was a girl, who developed a lesion of the cornea, which probably was infected by herself, and which terminated in perforation and the loss of the eye. In this case the emaciation was so extreme that the skin ulcerated over the protruding pelvic bones. This patient also died. Dr. Leszynsky said he had made ophthalmoscopic examinations in all his cases as a matter of routine, and in only a few instances was an optic neuritis demonstrable. In several instances where a bad prognosis was given the patients made a complete recovery, without any sequelæ. He had not seen any cases of the fulminating type.

Dr. Northrup said he had seen one case of the fulminating variety in which death occurred within 20 hours after the onset of the disease. During that time the patient was a raving maniac. In another case, death occurred within 14 hours.

Dr. F. S. Fielder spoke of a case now in Bellevue Hospital which appeared to correspond to that referred to by Dr. Holt, in which there was a secondary hydrocephalus, with chronic basilar exudate. The child was taken ill about the 1st of May. The case was first supposed to be one of pneumonia, and from that drifted into cerebrospinal meningitis. On the 1st of June it was admitted to the Post-Graduate Hospital. The child was unconscious, and ran a very irregular, fluctuating temperature, ranging from 105° and 106° to normal. There was also diarrhœa and gastric irritability. Subsequently, Klebs-Loefiler bacilli were found in the nose and throat, and the patient was transferred to the Willard Parker Hospital. It remained there about five weeks in an unconscious condition, with marked retraction of the head and nystagmus, chiefly upwards, so that it was practically impossible to make an ophthalmoscopic examination. There was also contraction of the muscles of the arms, and the hands and feet were in a flexed position. The patient was subsequently transferred to Bellevue and now had some semi-lucid intervals. At the Post-Graduate Hospital, lumbar puncture was done several times. Four times the fluid withdrawn was clear, once it was turbid, and once bloody, but in no instance was the meningococcus positively identified. About the middle of September, lumbar puncture was again made and the meningococcus found in the serum. The child was still in the hospital and was believed to have a chronic basilar meningitis.

Dr. Henry Heiman referred to a few cases of cerebrospinal meningitis that occurred during the past summer in the wards of Dr. Koplik. One patient, after being under observation for over three months, developed symptoms of hydrocephalus with marked opisthotonus. This patient was treated by repeated lumbar puncture, the quantity of fluid withdrawn being gradually increased, up to 175 c.c. Most of the cases showed great fluctuations in the temperature. In one case seen in private practice, a boy of 16, the onset was of the fulminating character. Lumbar puncture was done, and a purulent fluid withdrawn. The meningococcus was found in this specimen. The boy made a complete recovery and had since returned to his home in Cuba.

Exemption for Fathers of Families.—The Czar has extended the decree originally exempting from service in the Far East reservists in the southern industrial districts who had more than three children, so that now its provisions cover the whole of European Russia.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held October 18, 1904.

Dr. CHARLES H. LEWIS, CHAIRMAN.

Specimen of Malarial Urine.—Dr. E. E. SMITH presented a specimen of urine which was passed during a paroxysm of malaria; it was very dark in color, due to the presence of oxyhæmoglobin. After the paroxysm had passed the urine became normal within two or three hours. The patient gave a malarial history, although no parasites were found in the blood. He said that the statement was usually made that the urine contained methæmoglobin during the paroxysm and not oxyhæmoglobin. When passed the specimen contained oxyhæmoglobin, although it soon turned to methæmoglobin.

Report of a Case of Appendicitis with Unusual Findings.—Dr. CHARLES H. LEWIS reported the case of a man, twenty-nine years old, who was admitted to St. Vincent's Hospital with the following history. Eight days prior to admission he had headache, anorexia, general malaise, nausea and vomiting. The vomiting was accompanied by pain over the epigastrium, which gradually extended and settled in the right hypochondrium. The patient described it as a severe, tight, oppressive pain, much increased on breathing. The patient was somewhat jaundiced. The temperature ranged between 104° and 100°, with irregular and sudden remissions. The prostration was great. On admission he was thought to have typhoid fever, and that diagnosis seemed to be warranted. On the first day of admission he could not sleep because of the pain, which extended over the whole abdomen. He complained of dull headache, constant thirst, depression of spirits, and felt very ill. The conjunctiva and skin were jaundiced. Petechial spots appeared over the abdomen and chest. The heart was pushed to the left and the breathing was shallow and intercostal on account of the painful diaphragmatic movements. The abdomen was moderately distended, and generally tender on pressure. There was muscular rigidity of both recti. The whole abdomen was uniformly tympanitic. The pulse was 96, temperature 103.2°, respirations 22, and leucocyte count 20,000. On the following day the temperature fell to 100°, the leucocyte count rose to 22,400, the jaundice became deeper, and the urine contained much bile. The case was then thought to be one of infective cholangitis, other biliary tract disturbance, or an intestinal toxæmia. Intestinal irrigations, anodynes and stimulants were given, but no new symptoms developed until death, which came three days later. At autopsy an abscess the size of a large orange in the cæcal region was found. The appendix was gangrenous and free in the cavity. The pelvis was partly filled with a sero-purulent fluid. There was a general peritonitis. The liver contained numerous abscesses, varying in size from a small pea to a hazelnut. The special points of interest were (1) date of beginning appendicitis, which ran on to abscess formation, its insidious onset simulating typhoid fever; (2) the multiple abscesses in the liver. He thought there was no doubt but that they were secondary and directly due to the appendicular abscess. (3) The situation of the pain in the epigastric and right hypochondriac region.

Dr. MORRIS MANGES said that in any case where a cholangitis was suspected the condition of the appendix should be investigated.

A Case of Filiaria Sanguinis Hominis.—Dr. MORRIS MANGES presented a patient, a laborer, twenty-five years of age, who had had some digestive trouble three and one-half years ago. About one year ago chyluria was noted. Three years ago he was in the Philippine Islands, when he noted some discolored urine. One year ago he was in Cuba, and six months ago, at Fort McKinley, filiaria was found. At present pains in the back and bladder appear about the middle of the night; he then passes white water, and is then all right and returns to bed. The filaria have only been found at these times. Dr. Manges presented a sample of the chylous urine. The microscopical examination of it showed fine points of emulsion, some red cells, and crenated white cells.

Two Cases of Duodenal Ulcer with Operation.—Dr. W. L. BAUER reported two cases in which the premonitory symptoms did not lead to a diagnosis of ulceration until perforation had actually occurred. In both cases operation was unfortunately deferred until general peritonitis had begun. Both patients died. The noticeable feature of the first case, besides the absence of all premonitory symptoms, was the close resemblance to gall-stone colic. In the second case, the history of distress after eating was suggestive of duodenal ulcer, but was obscured by the possibility of a simple alcoholic gastritis. In both cases the extreme severity of the pain was noticeable, as was the absence of hæmatemesis or melæna. In both cases the seat of tenderness was transferred after about twenty-four hours from the site of the lesion to the region of the appendix. This was presumably due to the gravitation of the ingested fluids into that region.

The Malarial Types of Infective Endocarditis.—Dr. WARREN COLEMAN of New York said that although cases of infective endocarditis simulating malarial fever had been reported from time to time for half a century, adequate attention had scarcely been given the subject. Such cases fell broadly into two groups, acute and chronic, the duration of the former being measured by weeks, of the latter by months. The following types of malarial endocarditis have been reported: double quotidian, quotidian, tertian, quartan, septan, mixed types, and irregular types. A single case might present during its course several of these types. The paroxysms might be identical with those of malarial fever. The onset also was often like a simple malarial attack. Dr. Coleman gave cases illustrative of the different types. He said that the diagnosis of a malarial form of infective endocarditis was often very difficult. Sometimes the heart gave neither signs nor symptoms. If the infective process had been grafted on an old valvular lesion there was not so much difficulty encountered, but the cryptogenic cases, or those giving histories of recent apparent malarial attacks, severely taxed the skill of the clinician. The patient may have been taking quinine, and attribute temporary interruptions to this drug. A complete examination of the blood would at once rule out malaria, but the presence of the malarial parasite did not necessarily exclude infective endocarditis. In this condition there was generally leucocytosis, the polynuclear leucocytes were increased, while in malaria, leucopenia was the rule except during paroxysms, and pigmented leucocytes were found in nearly all severe or fatal cases of malaria. The red cells showed much the same changes in both conditions. The recovery of the infective agent from the blood was often possible and always conclusive, provided no other nidus than the valves of the heart could be found. One notable feature of infective endocarditis was the strength of the patient between paroxysms. The classical picture of sepsis was lacking. The changes of type should be of much aid in diagnosis.

Dr. NATHAN E. BRILL asked if all cases of endocarditis were not infective. This pathological condition occurred in a great many diseases, and it was a well-established fact that endocarditis followed many bacterial infections, syphilitic, pneumonic, streptococcic, after scarlet fever, rheumatism, and many others. Although it had not been definitely determined that rheumatism was the result of any bacterial infection, many investigators had isolated a diplococcus usually associated with the disease, and he thought the bacterial origin of this might soon be determined. He referred to a patient seen in the wards of the hospital, who had erythema multiforme, tonsillitis, pains, pyrexia 103° to 104° F. One joint after another became involved. A petechial eruption soon followed the erythema multiforme, then appeared erythema nodosum. A blood

culture was made and diplococcus tenuis was found which, when guinea-pigs were inoculated, gave rise to arthritic pains and injured the valves. He asked how to explain such a case. It was an infective endocarditis. He deprecated the attempt to classify or to separate as distinct types clinical forms of a disease.

Dr. Morris Manges said that much confusion already existed in our classification of disease. He reported the case of a young woman, the daughter of a man from Trinidad, who was taken ill, and it was decided to take her to her home in Scotland. On the way she stopped in New York and he saw her. The diagnosis was very difficult. The blood was examined and looked suspicious, but could not be proven to contain malarial parasites. Of distinct value in making the diagnosis were the condition of the heart and a conjunctival petechia; in this case but one petechia was found. The rash did not appear until the patient reached her home in Scotland weeks afterwards. There was a decided leucocytosis. In acute cases he said one was easily misled, and the case he reported was one of the difficult ones to diagnose.

Dr. E. Libman believed that the cause of rheumatism had not yet been found, for it had not been proven that the diplococcus or streptococcus was the cause of rheumatism. In cases of mastoid infection one may have swellings of the joints, and such swellings may follow suppurations elsewhere. At present he thought it best to state that there was a group of cases resembling rheumatism clinically, due to a diplococcus or attended by a streptococcus infection. The diagnosis of endocarditis did not appear to him to be as simple as some supposed. The diagnosis may be made of bacteria in the blood on top of an endocarditis; there are cases of infections in the blood with a previous endocarditis, in which the bacteria did not affect the valves. This probably accounted for so many so-called cures of malignant cases of endocarditis.

Dr. Warren Coleman said he was following a precedent in regard to his treatment of the malarial types of endocarditis, for this type had been known for half a century. Because they are frequently mistaken for cases of malaria, it was well to emphasize the fact that there are cases of septic endocarditis which follow malarial attacks and paroxysmally. With regard to petechiæ occurring, he did not attempt in his paper to give the differential diagnosis as a whole, but only to differentiate malarial types from malaria itself.

The Present Status of the Clinical Value of Laboratory Tests as an Aid to the Practitioner.—Dr. John S. Thatcher said that the delight of medical work rested upon the variety of things it included, all the resources of nature being called upon to aid in the practice of medicine. In diagnosis there was no department of science that was not called upon, chemistry, physics, instruments of precision, biology, in fact, every department of science. As a result there was an enormous armamentarium in diagnostic work. He said he would attempt a brief review of the different kinds of assistance which the laboratory offered the general practitioner, some being old and some quite recent.

Examination of the Urine.—This was done for the detection of inflammatory or neoplastic conditions. We were also learning something regarding the clinical manifestations of abnormal metabolism, and the various forms of intoxications. Tests for sugar, acetone, indican, ethereal and fixed sulphates, uric acid, urea, the diazo-test, all throw some light upon changes in metabolism or intoxications. The determination of the ratio between the uric acid and urea was of value. The functional activity of the kidneys could be determined, although this did not seem to be of any great value in the ordinary practice of medicine.

Examination of the Fæces.—This gave interesting results, especially in those cases, so often seen at the hospitals, which gave all the appearances of pernicious anæmia; an examination of the fæces often revealed an abundance of eggs of intestinal parasites, and permitted a vigorous treatment, and elimination of the nematodes soon resulted in the cure of the patients. Testing for blood threw light upon certain diseases in which there had been slight hemorrhages in different parts of the intestinal canal.

Examination of the Blood.—The examination of the blood for hæmoglobin and red cells was not of great importance, because by simply looking at the patient one could, as a rule, readily tell whether the patient was anæmic or not. On the other hand, counting the leucocytes was very important, because it helped us very much in differentiating various diseases, such as typhoid fever, anæmia, malaria, sepsis, etc. This was especially valuable in differentiating the infectious diseases, such as scarlet fever from measles. Much was promised from the chemical examination of the blood when taken in considerable quantities. The bacteriological examination of the blood revealed much that was of diagnostic value. Blood could be obtained even from the spleen without disturbance to the patient; Dr. Osler had obtained blood from the spleen in more than 300 cases without injury to the patients. In typhoid fever blood so taken showed cultures of the typhoid bacillus in 90 per cent. of the cases. Blood cultures from veins had given many observers 80 per cent. positive results. One observer in forty-three cases of typhoid fever obtained positive results in every case. Better results were obtained with higher dilutions. The search of the blood for the pneumococcus had been successful, and this was best done with low dilutions. Positive findings in syphilis and rheumatism still remain *sub judice*.

The Diazo-Reaction.—This seemed to be more highly thought of now than formerly. In over 1,000 cases positive results had been obtained in over 80 per cent., and in fifty cases at the Johns Hopkins Hospital it was positive in 77 per cent. during the first week of the disease. In the second or third week of typhoid fever the diazo-reaction indicated that things were more serious. When found in pneumonia it gave a bad prognosis. It was to be regretted that the diazo-test was to be had in so many other conditions, yet the fact remained that finding a positive diazo-reaction in doubtful cases aided greatly in the diagnosis, especially if measles and certain forms of tuberculosis be excluded.

Widal Reaction.—In 5,000 cases collected by Brill, positive results were obtained in 98 per cent., and in a series of 100 cases collected consecutively by Dr. Tuttle, positive reactions were found in from 95 per cent. to 98 per cent. Since then the percentages had not been so high. In the presence of jaundice the Widal test often gave positive results. In doubtful cases of typhoid it was very strong presumptive evidence. He said that it had lately been modified by using an emulsion, a suspension of dead typhoid bacilli; this gave a test which could be used, and in solutions which could be kept for many months, and without any danger in carrying the solution about.

An examination of the spinal fluid was often profitable, although much of the work done so far that had been published was of little value. In exudations and transudations from the pleura and peritoneum the leucocyte count was of value, especially in making a diagnosis between tuberculous and other forms of exudates. Knowledge of infectious diseases was only advanced by bacteriological examinations. A correct classification of fevers by bacteriological work was the foundation upon which our knowledge of treatment must be based.

Dr. Andrew H. Smith said that the estimate placed upon the various methods of diagnosis seemed to militate against the general acceptance of them, and it meant that many men were in danger of losing their fine sense of diagnostic discrimination. The clinicians were likely to throw this work upon the laboratory men, and so neglect that close observation which was at the bottom of correct diagnoses.

Dr. W. Gilman Thompson said that the whole question was becoming quite a serious one, because it was leading to the development of an entirely new type of medical men,

who look upon the laboratory as the royal road to learning, and, in many instances, he thought it was a grave mistake. In making a diagnosis at the bedside one should keep to the ordinary methods, and not rely too much upon the results of laboratory work. Only experts should make the laboratory tests, and of this he was more and more convinced. He protested against making a diagnosis from a single examination of the gastric contents. He had seen many cases of tuberculosis in which the tubercle bacilli were not found until after four or five examinations were made.

Dr. Lewis A. Conner said that it had been his experience that the oldest and most widely known methods of examinations of the urine had given the most unsatisfactory results. He looked upon the ordinary urinary examinations as being almost valueless. Six out of ten patients in the hospital will show albumin and a few casts.

Dr. Louis Faugères Bishop said that what was very much needed was to have the clinical pathology more easily available, *i. e.*, so arranged that the examinations could be made by experts and without very great expense. He suggested that young men late from college might be given this work while waiting for practice.

New Instruments.

AN ADAPTATION OF THE HÆMACYTOMETER AND OUTFIT TO THE NEEDS OF THE PRACTICING PHYSICIAN.

By FRANK WILLIAM SMITHIES, M.D.,
CHICAGO, ILL.

However much or little the varieties of hæmacytometer, at present upon the market, may differ in construction, they all resemble each other in at least one important particular, namely, in their total unfitness for use by the physician in active practice. Blood-counting—especially the estimation of the white-cells—has become so great a factor in diagnosis that even in general practice the physician frequently finds it necessary to carry his "blutkörperzahlapparat" to the patient's bedside and secure the desired sample. It is then that, even with the best apparatus available, those difficulties are encountered which have led so many medical men to discard blood-counting as wholly impracticable for the busy physician. In the present state of affairs, he must carry his diluting fluids in small bottles, lying loose in his satchel, or in his several pockets; his puncturing needle is usually anywhere but at hand, and, finally, when, after various exasperating experiences, the desired blood has been obtained,

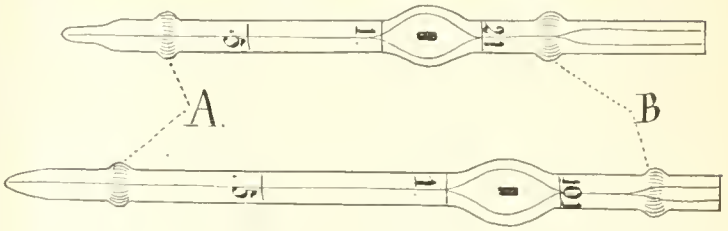

Fig. 2.—Tubes, showing glass rings A, B, near each end.

the last spark of scientific enthusiasm is extinguished by his having to carry his glass tubes back to the office, held carefully in one hand, while driving with the other. The tubes may not be returned to the case, for, if they are, the leakage that invariably occurs, particularly from the white-cell tube, is so great that all semblance of accurate dilution is lost. As a result, the count is utterly worthless—nay, it is often worse than this, for, if the leakage pass unnoticed, grave clinical mistakes may be made.

After many trying experiences along the lines above indicated, the writer has planned several modifications of the hæmacytometer and outfit at present in use. Briefly, they are:

1. A case of convenient size for pocket or satchel, containing everything requisite for obtaining samples of blood.

2. Hæmacytometer tubes, slightly modified in construction, to enable the adjusting of

3. Small rubber-caps, of peculiar structure, to close the ends of each tube, after the dilution of the sample blood, and thereby prevent leakage.

In detail, the outfit is constructed as follows:

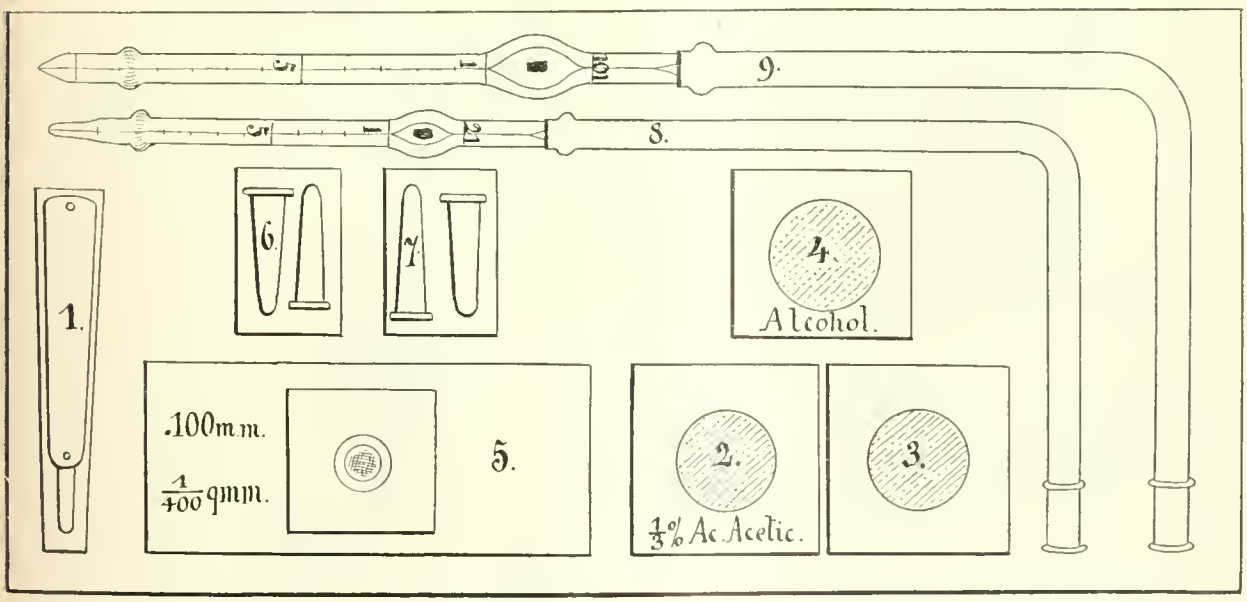

Fig. 1.—Plan of Case I. 1, Puncturing needle; 2,3,4, dilution caps; 5, counting slide and cover; 6, white-cell counter end-caps; 7, red-cell counter end-caps; 8, 9, counting tubes.

1. The case (Fig. 1) is of wood, leather-covered and velvet-lined. It is 8½ inches long, 4 inches wide, and about 1½ inches thick. It contains grooves for the glass and rubber-tubes and the counting slides, as do other hæmacytometer-boxes, but differs from them in having three wells, 1¼

inches square, into which fit small glass cups, with ground-glass stoppers and metal screw-caps, which are designed to hold the diluting fluids, viz., 1-3 per cent. acetic acid, Hayem's or other fluid, and dilute alcohol, for cleaning purposes. The acetic acid and the alcohol cups are so marked, the remaining cup

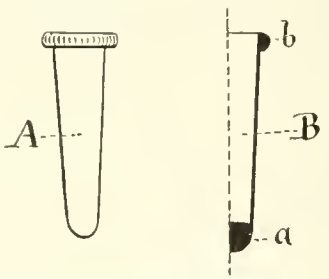

Fig. 3.—End-caps; A, outline of cap; B, sectional view, (*a*) solid rubber at blind end, (*b*) solid rubber edge.

is left unmarked, to be used at the pleasure of the owner. In addition to these wells, the case has a groove made to hold a folding puncturing-needle, and also two small grooves to carry the rubber end-caps, above mentioned. The snug relation of all parts is seen by consulting the illustration.

2. The counting-tubes (Fig. 2) are modified only externally. Three-fourths of an inch from each end of each tube is a raised ring of glass. This protrudes about one-eighth inch. Its purpose is to hold securely.

3. A small rubber cap (Fig. 3), made to fit closely over the ends of each tube. These caps are of thin but strong rubber throughout, except at their blind ends, where they are solid for one-eighth inch, and at the open ends, where the edges are thickened in the form of a band. The solid extremity acts as a pad to prevent snipping of the glass at the ends of the counting-tubes. It is also capable of being removed while the end-caps are being adjusted, and thus prevents back-flow into the tubes. The rubber-caps which are made to fit the red-cell tubes are colored red and those for the white-cell tubes are colorless. In this way the same caps are always used on the same tube, and even the slightest mixing of the diluting fluids is prevented.

The advantages of this outfit will be seen to be many and obvious. The physician has constantly at hand everything necessary for a blood-count. We have all seen cases—*e.g.*, is it typhoid fever or appendicitis?—when we would have given much to have had available at the bedside materials with which to secure blood for a white-cell count. With this modified hæmacytometer, the necessary dilutions may be made, the rubber-tubing removed, the rubber end-caps adjusted, the counting-tubes replaced in their case, and the drive to the office made in comfort, the practitioner knowing that his dilutions will still be accurate when he arrives there. It is to be hoped that the adoption of this modification will lead to the more general use of hæmacytometers, and that, as a result, much valuable material may thereby be added to the science of hæmatology.

7810 Lowe Avenue.

An Illustrious Colleague.—It is not generally known that M. Combes, the French premier, is a doctor by profession, and still retains his old copper nameplate "Docteur Combes" on the front door of his house at Pons. While not in active practice he never refuses his aid to such of his old townspeople who ask it, and he says he is more gratified by a victory over disease than by success in some political combat. He is also an ardent student of foreign languages and a devotee of the bicycle.

SOME SUGGESTIONS ON THE TREATMENT OF TALIPES.*

By M. M. EDMONSON, M.D.,
KANSAS CITY, MO.

The importance of this subject is emphasized by the fact that a very large proportion of the cases seen by specialists have been treated previously, in many cases three or four operations having been performed, and we also see aggravated cases in the adult that have never been corrected. These facts indicate very clearly that some of the essential features in the successful treatment of this deformity have not been overcome. I refer especially to Talipes varus and equinovarus, as these forms include a very large percentage of deformities of the feet. The cause of failure, I believe, has been due primarily to the incomplete reduction of the deformity at the time of the operation, either by tenotomy or forcible reduction by the Lorenz method, and, secondly, to the inability of the surgeon to prevent a relapse during the necessary period required by the weakened set of muscles to regain the power requisite for the performance of their natural function. In referring to the first cause of failure, I recall the emphasis laid on the necessity of overcorrection by my preceptor, Dr. Lewis A. Sayre. To attain this end we now have the experience of Dr. Lorenz to aid us, and its great value is especially shown in these cases, as it demonstrates the amount of force that we can safely use, if properly directed. A division of tendons alone is not sufficient, as all the tissues are contracted, and in moulding the foot by force all the tissues are stretched, to conform to the new position, so that we have much less tension than under the older method. However, if force is not sufficient we should cut and keep on cutting until the foot is overcorrected, so that little or no force is required to hold the corrected position. If inability

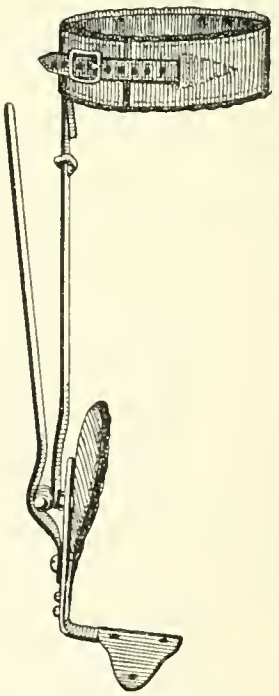

Fig. 1. Clubfoot brace.

to accomplish this has been the cause of failures in twenty-five per cent. of the cases, I believe fully fifty per cent. of the relapses are due to the ineffectiveness of the after-treatment. At this point I would emphasize the value of patience and persistence in the class of chronic cases that come within

*Read before the Hodge Medical Society, Butler, Mo., July 7, 1904.

the domain of Orthopedic Surgery. And no less would I emphasize the necessity of looking closely after the details of treatment, as the neglect of some

Fig. 2. Same child as in Fig. 3, before treatment.

apparently unimportant point may result in failure. The fact that it is not often a life or death matter does not justify us in the thought that we can operate again. The suffering incident to forcible correction, and the inconvenience to the family, should incite us to our best efforts. This applies to all cases in which there is a possibility of relapse, but more especially to cases of talipes. As it has been truly said that a "half cure in these is no cure."

In many cases the treatment is only begun when the foot has been corrected, for the muscles involved are not only weakened, but, from the malposition of the foot, are elongated, and the ligaments, fascia, and distorted bones must assume their proper relation and function before a cure is perfected.

If the above deductions as to the cause and frequency of relapse are true, then the form of retentive appliance we use should be of prime importance. To obtain the best functional results the following conditions should be met: (1) A mechanism that will hold the foot in its corrected position. (2) It should have free motion at the ankle, thus permitting exercise and development. (3) It should be simple in construction and made thoroughly durable.

Without in any way criticising the club-foot shoes and braces at present in use, I can only say that they have not met the requirements in my hands. When cases can be under one's direct supervision and the brace kept in good repair, they might prove satisfactory. But this is not feasible in a great number of cases, as it requires from one to two years before all danger of a relapse has passed.

About two years ago I had made the brace here pictured (Fig. 1). It consists of the main upright bar, with a universal joint at the ankle, bent at the lower end, and flattened out broadly to attach to the shoe. At the upper end it is fastened firmly to a band encircling the leg below the knee. Between the joint and the ankle and the lower end of the brace there is a strong steel spring, so riveted as to permit motion; this is curved out sharply to pass over the joint and extends to the upper end of the brace below the band, where it is held in position by a small sliding clamp. The size of the brace and the strength of the spring should be proportionate to the age and development of the child.

In the child in arms I use a sole of aluminum or German silver, strapping the heel and toes. In these cases if there is a tendency for the tendo Achillis to contract, an elastic running from the outside of the foot-plate to the uper end of the brace will prevent this. I have never found this necessary in the walking case, the weight of the body being sufficient to prevent contraction. As can be

Fig. 3. Child with clubfoot after the correction of its deformity and application of the brace.

readily seen, the important feature of the brace is the spring, which everts the foot, and in this position the ankle is more easily flexed.

Rialto Building.

Horseflesh Causes Typhoid.—It is reported that the origin of the typhoid epidemic which prevailed in Berne, Switzerland, during the latter part of the summer has been traced to certain horseflesh served at the cheap restaurant in the poorer part of the city. This horseflesh, it is said, was bought from the Bacteriological Institute, where the animal had been subjected to experiments with typhoid bacilli. The charge has created general indignation, and a searching inquiry into the whole affair has been demanded of the Berne sanitary authorities.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgement will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE BACTERIA OF THE STOMACH.

BY E. PALIER, M.D.,
NEW YORK.

UNDER the direction of Prof. Ficker of the Hygienisches Institut der Kgl. Universität, Berlin, I commenced at that institute a systematic series of researches into the bacteria of the stomach. Work in this field, it is true, has been done before, but it has been done in a desultory manner, and is of no practical value. From the work that has been done before one cannot tell what microbes are found in such and such a condition of the stomach, and it cannot thus be made use of for the purpose of clinical diagnosis.

Thus, Mathieu[1] refers to numerous bacilli that have been isolated from the stomach, but from the description given by the authors quoted by him one could not say precisely in what condition of the stomach the mentioned bacilli were found. According to Lesage, there are more microorganisms in hyperchlorhydria with alimentary stasis than in hypochlorhydria, a result which Mathieu thinks could not be expected theoretically, as the reverse might be expected *a priori*. My results will show how far they agree with the statement of Lesage.

The works on bacteriology are not more explicit on this subject. Thus, the statement is usually found in them that such or such a bacillus was found in a person suffering from dyspepsia; but as we know dyspepsia is not a disease, but only a symptom, the same as cough, for instance.

Without wasting any more space on quotations which will not clarify the matter, I will pass over to a description of the methods which I have employed and the results obtained.

In Berlin, my bacteriological examinations extended over six samples of gastric juice; but since then I have examined seven more, in all thirteen cases; and the results obtained have been so uniform in some respects that I feel justified in publishing them in spite of the comparatively small number of cases examined.* The samples of gastric juice examined in Berlin consisted of three cases of cancer of the stomach, one case of hypochlorhydria, or hypoacidity, as the Germans call it, and two cases of hyperchlorhydria, or hyperacidity, of the stomach. I will deal with these six cases first, and afterwards with the other cases which I examined later. The samples examined abroad were obtained from cases at the polyclinic of Prof. Ewald, and the clinical diagnosis was established there after long and careful observation; it can, therefore, be taken for reasonably certain that the clinical diagnosis was correct.

I will not, therefore, describe these cases in detail, but will only say that of the three cases of carcinoma ventriculi, one was in an old woman and one was in an old man, and tumors could be distinctly felt in the epigastric region. The third case was in a man of about 38 years, and the disease was in its incipiency. A tumor could not be distinctly felt in this case, but only some resistance and pain in the epigastric region. These are, indeed, cases which are frequently mistaken for gastritis anacida; but Prof. Kutner, at Ewald's clinic, arrived in this case at the diagnosis of carcinoma ventriculi after a careful study of the case, and I think we can accept this diagnosis as reasonably certain. The bacteriological findings in this case were similar to those of the other two cases, which is very interesting and important.

The case of hypochlorhydria was in a young chlorotic girl of nineteen, and the diagnosis was established also after careful observation. The two cases of hyperchlorhydria were in two middle-aged men, and were clear cases of chronic ulcer of the stomach.

The other samples of gastric juice which I subsequently examined I obtained from my own patients in New York, and these cases will be described in greater detail when we come to them. I shall first describe the methods used and the results obtained in the first six samples of gastric juice.

Cultures were made on neutral agar-agar and on gelatin, both in test-tubes and in Petri dishes. I shall first relate the results of the three cases of carcinoma ventriculi. On agar-agar in Petri dishes by smear, at 39° C., colonies of bacteria appeared in 24 hours; in 48 hours the colonies reached their full development. The same took place in agar slant test tubes by smear. In sugared agar by stab the culture grows along the whole stab, till the bottom of the tube, giving rise to a growth resembling a thick, coarse thread, and on the surface of the agar at the stab there is also an outgrowth. On gelatin, which, of course, must be kept at a lower temperature, there is no growth the first few days; but in sugared gelatin by stab there appear whitish points along the stab, at intervals. The growth is evidently very poor at a low temperature. On the top of gelatin at the stab there is a small growth. In plain gelatin, in Petri dishes, no growth at all the first few days, but later a few colonies appear. No fungi make their appearance in test tubes; but in Petri dishes in gelatin fungi appear in a week or so. On agar they do not appear at all. As the Petri dishes were opened for examination it is reasonable to suppose that the late appearing fungi were derived sooner from the air than from the inoculated stomach contents. I must say now that this absence of fungi in the cultures from all the three cases of carcinoma ventriculi is extremely characteristic, and is quite the opposite of what took place in all the samples examined, and this I consider of great importance; but I will revert to it again and deal with it more fully. As was said before, the bacterial growth is poor on gelatin, but is rich on agar-agar. The optimum of temperature is 39° C.

We shall now take up the several microorganisms which I was able to isolate. On agar in Petri dishes one can see by the appearance of the colonies that

*Since the above was written I have examined many more cases, and have found bacteriological findings similar to those described in the text.

there are several kinds of bacteria. Not to waste space on unnecessary description, I will say that in one case of carcinoma ventriculi the staphylococcus pyogenes aureus and in another case the staphylococcus pyogenes albus grew in abundant colonies in Petri dishes on agar. I have isolated them and obtained pure cultures in test tubes on agar slant.

In the third case—that of the middle-aged man mentioned above, in whom a distinct tumor could not be felt—colonies similar to those of the staphylococcus pyogenes albus appeared in agar, but the colonies were of a whitish-creamy appearance and much moister than those of the staphylococcus pyogenes albus. Unstained in a hanging drop, they were big, somewhat oval cocci, and appeared morphologically very much like the micrococcus prodigiosus, for which I was at first inclined to take them; the more so that some authors claim to have isolated this microbe from the stomach, though they don't say in exactly what condition of the stomach; and it is also stated[2] that this microbe sometimes loses its red color in successive cultures. But I have isolated the colonies in question and obtained pure cultures, and on examining microscopically the third generation they proved to be nothing else than staphylococci, which stained very well according to the method of Gram. In a fourth generation, which I subsequently obtained by reinoculation, many individuals assumed the shape of round diplococci. The creamy-whitish appearance of the colonies, the morphological form of the microbe of the third generation, and its being Gram positive, distinguish it sharply from *Micrococcus prodigiosus*, for which I mistook it for a while, and I have no doubt that it is a staphylococcus. I say *a* staphylococcus, and do not say *Staphylococcus pyogenes albus*, because, though it is very similar to this, yet its moist growth and big oval appearance in the first generation leads to the presumption that it is akin to the other, but has undergone some change, owing to the peculiarities of the medium from which it was obtained.

I said above that on sugared agar by stab, a rich colony grew at the top. In two cases I found the colonies to be typical staphylococci. In the third case, namely, that of the middle-aged man, the colony was the same as those found in agar in Petri dishes described above, viz., a moist, creamy growth, which, under the miscroscope, was seen to consist of big oval cocci. But in further cultures they also proved to be staphylococci.

In all the three cases of carcinoma ventriculi, then, staphylococci were found in great abundance.

This is also of great importance. Indeed, it is said that the presence of some pus globules in the gastric juice is a valuable sign in the diagnosis of carcinoma ventriculi, which, of course, must be taken in connection with other signs. The detection and identification of pus corpuscles in the gastric juice, however, is not an easy matter, unless the pus is in great abundance; but it is comparatively easy to make cultures and detect the staphylococci.

In one of the three cases there were a few colonies of yeast on agar-agar in the Petri dishes. It is usually stated that yeast is absent from the gastric juice of carcinoma ventriculi; this is indeed so in most cases, as yeast develops best in an acid medium, but as in carcinoma ventriculi there is usually a deficiency of HCl, there is also absence of yeast. But the fact is that in all cases of hyperchlorhydria, or even normal chlorhydria, I have been able to obtain yeast in cultures in neutral media, such as neutral gelatin and agar, as will be seen soon; and there is no reason why yeast should not occasionally be found in a stomach whose contents are neutral, or whose acidity is due to something else than free HCl. Besides, which is most likely in some cases, there may be some HCl, free or in combination, but the ordinary test may not be fine enough to show it, and yeast may thus develop. In a case diagnosed as one of cancer of the stomach, by Prof. Rosenheim of Berlin, at his polyclinic, there was also yeast present in the stomach contents, though the usual tests failed to show the presence of HCl. In two cases of hypochlorhydria soon to be described, there were also colonies of yeast. In short, yeast may be found in stomach contents which, by the usual tests, do not seem to contain HCl.

I will now take up the study of a microorganism about which a great deal has been said and written, namely, the so-called lactic acid bacillus, said to be found in cancer of the stomach. Boas[3] claims to be the first to have noticed it in the gastric juice of such patients, and claims that it is pathognomonic of this disease. He describes it in his book as a long bacillus, "sometimes motile, and sometimes non-motile." Riegel[4] also describes long bacilli, *Fadenbazillen*, found in the gastric juice of carcinoma ventriculi, and presents a picture of them as they appear in an unstained drop of gastric juice. Oppler,[5] a pupil of Boas, also lays stress on the presence of these bacilli in the gastric juice of carcinoma ventriculi, though he acknowledges that he was unable to obtain them in pure cultures. Kauffman[6] succeeded in obtaining them in pure cultures, and gives a rather incomplete description of them as they appear in pure cultures.

The bacilli in question assume in a drop of gastric juice a knee-shaped or elbow-shaped form, *i.e.*, two bacilli come together with their ends in opposition and form various angles.

I think it is absolutely needless to say that we can never identify any bacillus from the way it appears in a drop of fluid in an impure culture. A microbe to be identified must be first submitted to a series of tests. Many other bacteria assume the same form as the one in question. Thus, *Bacillus geniculatus*, *Bacillus scaber*, *Bacillus virgula*, found in cheese[7], morphologically resemble the so-called lactic acid bacillus of carcinoma ventriculi, as it is found in the gastric juice. Of course, no bacteriologist of repute would make a diagnosis of diphtheria, for instance, by simply examining under the microscope a drop of the exudate from a patient's throat. We are just as little justified in saying that we have such or such a microbe by simply examining a drop of the gastric contents under the microscope.

Boas's description of this bacillus as "sometimes motile and sometimes non-motile" is in itself indefinite. A bacillus is either non-motile or it is motile. A non-motile bacillus is always so, because it has no flagella; a motile bacillus is always motile in fresh cultures, though it may lose its motility in old cultures. The fact is, as is known to all, the motility or non-motility of a bacillus is one of the main characteristics by which it is identified. When, for instance, one should see a bacillus which in every particular resembles the diphtheria bacillus, except that it is motile, one should hesitate very much before pronouncing it a true diphtheria bacillus, which is known to be non-motile.

Without going any further into discussion, I will described the results obtained in cultures. It was said above that when a stab culture of the gastric juice of carcinoma ventriculi was made in a test tube of sugared agar, the bacterial growth extended along the whole stab and the top consisted of staphylococci. Breaking off the bottom of the tube, I expelled the mass, cut it open, and examined the bacteria from the bottom, and also made fresh cultures therefrom. The bacteria in a hanging drop present rod-shaped

individuals, some shorter, some longer, ranging from 2 μ to 6 μ in length, and about 0.5 μ in breadth. On the average, however, their length is about 4 μ. They do not form filaments, but are distributed singly or in very small groups. They do not appear to have spores, and are *always* non-motile, except occasionally a slight oscillatory motion. Frequently two of them come together with their ends in opposition, and form various angles, thus presenting a knee-shaped or elbow-shaped appearance. Similar bacilli are indeed seen in a drop of gastric juice of carcinoma ventriculi; but that these are the same bacilli we can only surmise, but we cannot affirm with certainty. The bacilli which I obtained in pure cultures are shorter than those which are seen in the gastric juice in question; but this may be due to a process of involution, as will be seen in another case.

I made successive cultures from the bacilli in question, till the sixth generation, and found that in grape sugared agar stab they grow along the whole stab, but from no outgrowth at the top. They also form some cracks in the agar, showing that they develop some gas. On agar slant by smear, the growth is extremely sparse. The colonies at the end of 48 hours at 39° C. are not numerous; they are fine, transparent and in size like pin points. When a stab innoculation into sugared agar is made from the agar slant, the growth again develops along the whole stab. This shows the bacillus in question to be an anaërobe, but since it slightly grows also on agar slant it is not a strict anaërobe. Its uniform growth in cultures, and its other peculiarities, soon to be described, show that we are dealing with a pure culture.

As to staining, it is stained easily by the ordinary stains, and is Gram positive. I have tried several times to bring out spores, but failed with the ordinary methods of staining. I believe these bacilli have no spores. In stained preparations their morphology is as follows: In the first and second generations they are of a rather straight, rod-shaped appearance, of the size stated above, with straight ends; but some of them assume a bent knee-shaped form, and some are even slightly curved. In successive generations the curved appearance predominates, so much so that some individuals are very much bent on themselves, and they look very much like the vibrio of cholera. I have found the same characteristics in all the three samples of gastric juice from carcinoma ventriculi, except that in one case, the first culture contained some very long individuals, which, however, underwent involution in successive generations.

Owing to the curved and knee-shaped appearance of this microbe, I think an appropriate name for it is *Vibrio geniculatus;* but in order to distinguish it from other geniculated bacteria, we may call it *Vibrio geniculatus ventriculi,* by which name I shall refer to it in the future.

I said that I found these bacteria in stab cultures; but I also isolated them from agar in Petri dishes. There they grow in fine, transparent, isolated, pinpoint colonies, nearly the same, in fact, as on agar slant. Under the microscope they are small, circular colonies, slightly opaque in the middle. Having thus isolated the bacillus in question from three cases of carcinoma ventriculi, I was for a while tempted to think, like the authors mentioned above, that it might in some way be the causative factor of carcinoma ventriculi, though *a priori* it is very unlikely. Indeed, it is very unlikely, and this objection has been raised before on similar occasions, that a microbe which grows with such comparative facility, in such a short time, should in any way be the cause of a disease which is more of a chronic than an acute nature. My further researches proved this objection to be true, as will be seen from the results obtained in other non-cancerous cases.

It will be remembered that among the first six samples of gastric juice examined there was one of hypochlorhydria. In this case I found the following: The gelatin in Petri dishes was overgrown in 48 hours with fungi. On agar, in Petri dishes, there appeared a few colonies of staphylococcus pyogenes aureus, colonies of oidium, and colonies which were similar to those of the vibrio geniculatus ventriculi described above. In sugared agar stab there was a growth along the whole stab, and a whitish abundant outgrowth at the top. On examining the growth at the top I found it to be an oidium, having the appearance of oidium lactis. On examining the growth from the bottom, after breaking the tube, I found it to be very similar to the vibrio geniculatus ventriculi, except that it has more of a straight than a curved appearance. It is also non-motile, is Gram positive, and evidently has no spores, as I could not bring out any by the ordinary methods of staining. On agar slant by smear they also grow in small, isolated colonies, though they are somewhat bigger than the colonies of the vibrio geniculatus carcinomæ ventriculi. The morphological appearance in the third generation, however, differed in this, that the bacilli in this case became smaller, lost their curved shape, had somewhat rounded ends and were lying in groups, forming little squares, having the shape of the bacillus mensentericus vulgarus. That it is not this bacillus can be seen from its cultural peculiarities.

In spite of some differences in the micro-organisms in question, after careful consideration I must say that they are evidently of the same type, which undergoes some change, owing to the peculiarity of the medium from which it was obtained. In two other cases of hypochlorhydria to be described soon, I also isolated a similar microbe. In order to verify the matter still further, I examined the bacteria developing in the putrefaction of food. As it would be out of the scope of this article to enter lengthily into the study of putrefaction, I will only say that in the putrefaction of meat I found in a drop of fluid examined under the microscope bacilli similar to the vibrio geniculatus carcinomæ ventriculi. In cultures I could isolate from the bottom of the tube in sugared agar stab a geniculate microbe, which was Gram positive. It differed only in this that it was slightly plumper in culture than the vibrio ventriculi. I found the same in putrefaction of egg albumin. Furthermore, I took a piece of cooked meat of about 2 c.c. and added to it in a test tube about 6 c.c. of filtered gastric juice from case C, to be described soon. The gastric juice in question, as will be seen soon, contained HCl, and reacted on congo paper well. After 48 hours, however, as digestion of the meat took place, the reaction on congo paper disappeared, and there appeared lactic acid in the test tube. On examining the fluid bacteriologically, bacilli similar to the vibrio geniculatus ventriculi were found. I repeated the experiment several times, and found it the same. If an excess of gastric juice is added to a piece of meat, and is again added 24 hours later, as digestion is taking place, so as to keep it strong enough to react on congo paper, these bacilli do not appear. By adding pepsine alone to meat and water in a test tube, similar bacilli appear in 48 hours, but few other putrefactive bacilli; whereas, by keeping meat and water alone in a test tube, about half a dozen kinds of bacilli soon develop there. If we add to a piece of meat a solution of HCl of about 2:1000, and add again a fresh solution a few days

later, so as to keep it strong enough to react on ordinary congo paper, few bacilli appear for a long time, and when they appear they are of a different nature, being similar to those which are found in hyperchlorhydria. The same when we use pepsin and HCl, provided we add a fresh solution of HCl as digestion takes place.

From the above simple experiments it will be seen that the vibrio geniculatus ventriculi will develop in any medium where there is a deficiency in HCl; or, in other words, it is rather a product of putrefaction or a putrefactive bacillus. But as will be seen from the above experiments, when there is a weak antiseptic present, such as a weak solution of gastric juice or pepsin alone, most of the putrefactive bacilli are hindered in their growth, and only the vibrio geniculatus ventriculi appears, which seems to be more resisting in this respect than the other putrefactive bacilli. Pepsin alone seems also to have some antiputrefactive power, as evidenced from the fact that when it is added to a test tube containing meat and water, only the bacilli in question appear at first, and the disagreeable putrefactive odor present in the tube containing only meat and water, as well as the many other microbes which appear soon are absent for some days, but do appear later, though not to such a great extent. The antiseptic power of pepsin, however, on the whole is very weak.

That is precisely what takes place in the gastric contents of carcinoma ventriculi. There are not found the many putrefactive kinds of microbes which are met with in the test tube containing meat and water alone; nor is there usually so much formation of indol in carcinoma ventriculi, as there is in unmitigated putrefaction. Evidently, then, either a trace of HCl, or the pepsin present, exercises some antiseptic powers in carcinoma ventriculi, as well as in hypochlorhydria.*

Now, Kauffman and Schlesinger[8] claim to have found the bacillus in question in 19 cases out of 20 of carcinoma ventriculi, and they wish to conclude therefrom that it is characteristic of this disease. Much as I would like to corroborate their statement, I think that from the facts stated above we must say that the presence of these bacilli show only a deficiency of HCl, and nothing else.

I went to such pains in dealing with the bacillus in question, because so much has been written about it, and in many polyclinics of gastrointestinal diseases abroad this bacillus is demonstrated and is said to be pathognomonic of carcinoma ventriculi.

Is it a lactic acid bacillus? Neither in the morphology nor in cultural peculiarities is the bacillus similar to the lactic acid bacillus of the laboratory, which is found in the fermentation of milk. The lactic acid bacillus of the laboratory forms on agar by smear a white pellicle, covering the whole surface, unlike the isolated, small colonies of the vibrio geniculatus ventriculi. Besides, their morphology is different, and the bacillus acidi lactici has spores.

Is it a lactic acid bacillus of another type? In my experiments on lactic acid formation, which cannot be dwelt on here, but which I will describe in another paper, I found that many bacteria, by their development, bring about lactic acid formation. That *Vibrio geniculatus ventriculi* does by its development help the formation of lactic acid I have found it to be a fact; but that it is not *the* lactic acid bacillus I am sure, for reasons which will be seen when we come to other cases of hypochlorhydria with the presence of lactic acid.

In addition to the vibrio geniculatus, I found in the cultures in Petri dishes a bacillus which seems to be the mesintericus vulgaris, and also a microbe which resembles the lactic acid bacillus mentioned above. But these latter have not been found in all the three samples examined. On milk the vibrio geniculatus ventriculi does not seem to have a coagulatory effect, for I could not succeed in coagulating sterilized milk with it.

To sum up, then, the bacteriological findings in these cases of carcinoma ventriculi: In all the three cases were found (*a*) staphylococci in abundance, and (*b*) the vibrio geniculatus; and all the three cases were marked by the absence of fungi or *Schimmelpilze* in cultures, of the kind that are usually met with in simple hypochlorhydria.

What is the cause of the absence of fungi? As will be soon seen, fungi were found in cases of hypochlorhydria; it cannot, therefore, be said that their absence in carcinoma ventriculi is due to the deficient acidity of the medium. Furthermore, as will be remembered, in a case of carcinoma ventriculi, I found a few colonies of yeast in the cultures, yet no moulds. In experimenting with the staphylococci, as to their effect on lactic acid formation, I found, contrary to the recent assertions that they do form lactic acid, that in certain media, such as cane and grape sugar, they not only do not by their presence increase the lactic acid formation, but, on the contrary, hinder it; which is not the case with many other microorganisms, especially the oidium lactis. In a watery solution of grape sugar, fungi and bacteria appear in a few days, and also lactic acid. But on addition of the staphylococci carcinome ventriculi, an amorphous precipitate forms on the bottom, and no lactic acid can be detected by the usual tests. And I surmised that the presence of abundant staphylococci in cancerous gastric juice was the cause of the absence of the fungi. To put the matter to the test, I exposed an open agar slant test tube of staphylococci, isolated from carcinoma ventriculi, before an open window for 24 hours; yet no fungi have appeared till now. It was contaminated by the micrococcus prodigiosus, the sorcina lutea and some other soprophytes, but not by fungi. When I leave in the same place other cultures, though they are well plugged with cotton, they invariably soon get covered with fungi. By oversight I had previously left for a long time another test tube of staphylococci from carcinoma ventriculi, among the abandoned cultures in the place mentioned above, and I noticed that it remained pure, whereas the other cultures were covered with mould. Furthermore, I inoculated a test tube of staphylococci ventriculi with the fungi from another test tube obtained from a case of hypochlorhydria, soon to be described under case 1, but no fungi appeared on the staphylococci. I am, therefore, inclined to the belief that the presence of staphylococci is a hindrance to the development of fungi. In the case of hypochlorhydria mentioned above, some colonies of staphylococci were found, and also fungi; but the staphylococci were few, and in sugared agar stab the top was covered, as said above, with oidium and not with staphylococci. Cultures of the vibrio geniculatus get easily contaminated with fungi, even when they are plugged with cotton.

The two cases of hyperchlorhydria, which, as will be remembered, form part of the six samples of gastric juice examined abroad, I will describe together with the other cases of hyperchlorhydria examined here, as the bacteriological findings were similar, and it will be best to describe them together.

In addition to the case of hypochlorhydria mentioned above, I examined three other samples of gastric juice of hypochlorhydria while here.

*The bacilli geniculati ventriculi give a slight indol reaction in some media.

The history of the three cases in question is briefly as follows:

Case I.—Man of 35, born in Austria; occupation, peddler; had been sick for about two years; previous history to illness in question negative. Physical examination, heart and lungs normal; stomach, bruit de clapotage or succussion sound till umbilicus, three hours after meals; slight tenderness on pressure at pit of stomach; no tumor palpable anywhere. Patient complains only of lassitude, weakness and heaviness after meals. Stomach contents, obtained one hour after Ewald-Boas test meal, amount to about 500 cc. and contain food rests from previous days. Absence of HCl, as seen by the negative reaction on congo paper, and presence of lactic acid, as seen from the positive reaction with dilute solutions of chloride of iron and with Uffelman's reagent.

Case II.—Man of 54, born in Russia; occupation, jeweler; had been sick with illness in question for 15 months; previous history, negative. Illness began with weakness in legs, pain in mouth, occasional swelling of tongue. Patient suffers from anorexia, and vomits occasionally. He is very cachetic, presenting a pale, waxy appearance. His legs are edematous, he is weak and cannot stand without support. Patient complains of pain in both sides. Physical examination: heart and lungs normal, palpation of abdomen shows no tumor, except slight tenderness in epigastrium; no succussion sound of stomach. Stomach contents after a test meal amount to about 20 cc. of rather pretty well divided food; no alimentary debris from previous days, but there is absence of HCl, and presence of lactic acid.

Case III.—Man of 44, tailor, born in Russia; claims to have been sick with present illness for 15 years; complains of cough, lack of appetite, heaviness after meals and general weakness. Patient is undersized and is very emaciated. Patient attributes his present illness to having slept 15 years previously at an open window, and having contracted a cold. Physical examination shows some transient moist rales at apex of both lungs; heart normal. Abdomen, succussion sound in stomach several hours after meal till below the umbilicus; slight tenderness in epigastrium, but no tumor could be felt anywhere. Owing to the great nervousness of patient stomach could not be emptied, but only a few cc. could be obtained for examination; but a great deal was left inside. Stomach contents showed absence of HCl and presence of lactic acid.

All the three cases are such in which one must be very careful how one excludes carcinoma ventriculi. Indeed, many cases which are diagnosed as simple gastritis anacida turn out to be carcinoma ventriculi. But in case No. 1 I am sure there is no malignant growth; first, from the history and physical examination of patient, and, secondly, because patient has greatly improved under treatment. Case No. 2 is a more difficult one. This case was kindly referred to me by Dr. A. J. Ronginsky, of New York. By another physician it was diagnosed as carcinoma ventriculi. But from the fact that the patient had been sick for 15 months, and no tumor could be felt, I think cancer can be excluded. Furthermore, an examination of the blood showed the red corpuscles in a condition of poikilocytosis and a few red blood corpuscles contained nuclei. I made the diagnosis of pernicious anemia. Subsequently I learned that the patient had previously been for some time in a hospital in New York and that the same diagnosis was made also there.

I cannot speak with so much assurance of case No. 3, the more so that I soon lost sight of the case. But I think that cancer can be excluded in this case also. I suspected tuberculosis; but a careful examination of the sputum failed to show any tubercle bacilli, I found, however, numerous streptococci. Cases No. 1 and No. 3, then, seem to me to be cases of hypochlorhydria, with atony of the stomach due to the general debilitated condition of the patients, or possibly the latter affection is due to the former. In case No. 2 the motility of the stomach seemed to be good, but there was hypochlorhydria, owing to the profound anemia.

We shall now see the results of the bacteriological examination of the gastric juice. In case No. 1 there were found an oidium, which appears to be the oidium lactis, and also long ramified mycelia. The oidium which I have generally found in these cases is from 10 to 20 μ long and about 5 μ wide. It has sometimes rounded, sometimes club-shaped extremities; and it sometimes has one or more nuclei, which are more refractive of light than the rest of the body. It is Gram negative, and herewith it can be distinguished from yeast, of which we shall soon speak, and which sometimes resembles it very much. In some cases the nuclei take the Gram stain, while the rest of the body remains unstained. In cultures on agar they form a whitish, thick layer, covering the whole surface. It is necessary to bear this in mind in order to be able to distinguish the oidium from the yeast, which is always found in hyperchlorhydria, and occasionally in hypochlorhydria.

The filaments found are very long and from 4 to 6 μ in width. They have septa and ramifications, which in most cases appear to be false; they appear very much like the cladothrix dichtoma of Cohn.[9] There is a diversity of opinion among authorities concerning the classification of fungi. Thus, according to Hansen, Zopf, De Bary, and others, the same species can assume various shapes,[10] and the oidium lactis can grow sometimes into long filaments. Grawitz[11] thinks that most of the fungi, including favus, tricophyton, and others, are nothing else than varieties of the odium lactis, though this view is generally not shared by authorities. All this will show how difficult it is to say precisely what these filaments are, whether they are only elongated oidii or they are something else.

From a practical standpoint, however, it is immaterial, for it can hardly be supposed that they are of any pathological importance. It is enough to state their presence in connection with the oidium lactis, and to know that they are usually met with in hypochlorhydria.

The oidium and the long filaments I found in three cases of hypochlorhydria out of the four. In case No. 1 I also found a bacillus which by its cultural and morphological peculiarities appears to be the vibrio geniculatus ventriculi.

But in case No. 2, which, it will be remembered, was that of pernicious anemia, I found no fungi, but a microbe very similar to the bacillus coli communis. It is a plump, oval bacillus, Gram negative, and grew at first in an abundant slimy growth on agar slant. It grows along the whole stab in sugared agar, which it cracks and gives rise to the production of an offensive gas, or gases. Furthermore, it coagulates milk. The only difference was that the bacillus in question was entirely non-motile in the first two generations, whereas the coli bacillus is, as is well known, endowed with some motility on account of its possessing a few flagella. But subsequently I made a third culture—that is, a third generation—and examined the bacilli in a hanging drop at the end of 24 hours, and found them quite motile. Furthermore, the third culture was not so slimy, but

assumed the appearance of typical coli bacilli, and the bacilli themselves became less plump and greatly resembled the bacilli of typhoid fever.

A bacillus very similar to it I have found in, and isolated from, the pulp of several samples of bread, both old and fresh; only the bread bacillus did not grow along the whole stab in sugared agar, but it gave rise to a discharge of an offensive gas. I did not carry this bacillus through many generations. In all probability the bacillus in the stomach of case 2 developed from the bread bacillus which the patient ingested. Indeed, Lehman[12] states to have isolated the bacillus coli communis from bread. I think I am justified in saying that this bacillus in passing into the intestines, which it can do, owing to the deficiency in HCl, may undergo some modification and become what is known as the bacillus coli communis. As the latter is such a common host of the intestines it must be introduced in some way, for we cannot reasonably assume that it originates *de novo* in the intestines. It is not, therefore, unlikely that it undergoes some change after it has been introduced into the alimentary canal, the same as it did in the third generation. The excessive fermentation and formation of gases which occur in some persons after the ingestion of an excessive quantity of bread can be easily explained by the presence of this bacillus, which multiplies very rapidly under favorable conditions. I must also add that patient No. 2 at the same time suffered from profuse diarrhœa and an examination of the stools showed them to be teeming with bacteria. But as I have not made cultures of the stools, of course, I cannot say what the bacteria were.

The bacillus in question greatly resembled in the first culture, because of the non-motility, the bacillus lactis ærogenes Escherich. But according to many authors,[13] this bacillus cannot be sharply divided from the coli bacillus. Its motility, however, in the third generation, I think, proves it to be the bacillus coli communis, which probably, owing to certain influences, was non-motile in the first two generations.

Case IV.—While writing these lines I examined another case of hypochlorhydria, which I will designate as case No. 4. It is that of a man about 28, who had been sick with what has been diagnosed by many physicians as asthma. A physical examination of the lungs revealed dry and moist râles scattered over both lungs, and the upper part of the right lung presented an exaggerated expiratory murmur. Patient in question gets frequent spells of asthmatic attacks. He feels heaviness after meals, and suffers from constipation. Physical examination of stomach shows *clapotage* to the umbilicus a few hours after meals. Stomach contents after test meal showed alimentary stasis with food rests of previous days. Patient is lean, and can easily be palpated, but no tumor is felt anywhere. Stomach contents show deficiency of HCl, as seen by the negative reaction on congo paper, and presence of some lactic acid, as seen by the positive reaction with solutions of chloride of iron. Bacteriological examination of stomach contents showed in sugared agar stab yeast and fungi at the top of the stab, and under it, along the stab, a bacillus like the vibrio geniculatus ventriculi, which was Gram positive. Its morphology, however, differed somewhat from the bacillus geniculatus in this that it presented a jointed appearance, as if it were a small chain of streptococci. That it was a vibrio, however, and not a streptococcus, could be easily seen from its cultural characteristics, as well as by observing its oscillatory motions in a hanging drop.

It will thus be seen in this case, as well as in the others of hypochorhydria, that the bacteriological findings of the stomach differed from those of carcinoma ventricula in this that there were only a few colonies of staphylococci in one case, but there were fungi present in all cases.

The interest in case No. 2 is that, though the vibrio geniculatus was absent, yet there was lactic acid in the gastric contents. But as was said above, with lactic acid formation I shall deal another time.

I will now consider the cases of hyperchlorhydria. Under these I include two cases which, as will be seen soon, the HCl can be regarded as normal in proportion, and they are, therefore, cases of chlorhydria, and not hyper, but the bacteriological findings in all cases were very similar.

The two cases of hyperchlorhydria from which the gastric juice was obtained and examined abroad were cases of old ulcer, and more need not be said about them. The three cases whose gastric juice was examined here were briefly as follows:

Case A was that of a woman of 35, with a history of pain in stomach after meals. No vomiting. She was pale, nervous, and more or less constipated. Stomach contents an hour after test meal amounted to a few hundred c.c., showing alimentary stasis. Excess of HCl, as shown by congo paper and by titration.

Case B.—A woman of 40, sick for several years; shifting pain in abdomen; is pale and nervous. Physical examination, slight tenderness in epigastrium on pressure, which, however, is not constant; no constant point of tenderness anywhere. Floating left kidney, some albumin in urine, but no casts. Stomach contents one hour after a test meal about 20 c.c of well divided food. Reaction on congo paper about normal.*

Case C.—Man of twenty, dental student, rather emaciated. Complains of weakness and heaviness after meals, but no pain in abdomen; very slight tenderness on pressure at the epigastrium. Physical examination: slight mitral murmur of heart, lungs about normal. Stomach contents, one hour after test meal, about 400 c.c., containing some alimentary rests from previous days, but food on the whole pretty well digested. Reaction on congo paper moderate. Titration with decinormal solution of sodium hydrate in the presence of phenolphthalein as indicator requires 6 c.c. of soda for 10 c.c. of filtered gastric juice; titration in presence of dimethylamidoazobenzol, known as Töpfer's solution, requires 4 c.c. of soda for 10 c.c. of filtered gastric juice.

Now if we use the German method of calculation, the total acidity would be 60, and the HCl would be 40, which is quite normal.[14] If we use the French method in comparing with HCl, the total acidity would be 0.365 x 6 = 2.190, and the HCl, 0.365 x 4 = 1.460 per thousand,[15] which is evidently about normal. There was thus an excess in the quantity of the gastric juice, but the quality was about normal.

The bacteriological findings in all these cases were similar in two things—they all yielded yeast and fungi, *Schimmelpilze*, in cultures. As to the bacteria of the schisomycetes class, they were as follows. In the cases examined abroad, I found in cultures sarcinæ of the lutea type. I could not see any bacteria in a hanging drop. In the three cases examined here I did notice a few bacteria in a hanging drop, but they were very few in Case A, which, it will be remembered, had an excess of HCl, and were a little more numerous in cases B and C. In

*I tested the congo paper which I have with various solutions of HCl and found that it gives a faint reaction with a solution of 1:1000, and a marked reaction with 2:1000.

cultures the colonies of bacteria of A developed only about five days later; in B and C they developed in about three days. In case C there were also sarcinæ lutea, and in addition there was a small, slightly motile bacillus which grows in Petri dishes on agar in white circular colonies, under the surface at first, then it reaches the surface. It liquefies gelatin, and gives rise to a strong ammoniacal odor. The same bacillus I found in B and C. It gives rise to a strong ammoniacal odor in agar also. It is Gram negative, but is well stained with diluted fuchsin.

This bacillus seems to be endowed with great vitality. I kept an imperfectly filtered sample of gastric juice from C for about three weeks, and then on examination I still found this bacillus in a hanging drop, and in cultures on agar, colonies of them developed in three days. Since I found them also in case C, which did not present any symptoms of pain, nor was it a grave case, for patient has greatly improved under proper diet and other treatment, I do not think the bacteria in question are of any pathological significance. Similar bacilli appear in a test tube of meat with HCl, as mentioned above.

As to fungi and yeast, these were found in all the five cases. As was said above, authorities are not in accord regarding the classification of fungi; and it is said that the penicilium, aspergillus, and mucor, may grow on the same hypha, they being only varieties of the same species.[16] But the fungi in hyperchlorhydria are different from the long filaments met with in hypochlorhydria, described above. In the former the ramifications are real; they are also thinner, and many have spores at the end of the numerous branches. But the spore formation varies in successive cultures and in various media of the same fungus obtained from the same stomach. In one culture there may be a bunch of spores at the end of a branch, in another no spores at all, in another again only a few spores along the branches. Again, I saw, in gelatin, the spore formation was like that of the aspergillus niger, which was formed on barley and water kept in a test-tube. I was at first inclined to the belief that the fungi were rather of the aspergillus type, though sometimes they resemble the penicilium. On further study of the subject, however, I believe that the fungi in the cases in question are nothing else than filamentous outgrowths of yeast cells, and are analogous to the nerve fibers, for instance, which are outgrowths of nerve cells.

I intend to consider the yeast and fungi of chlorhydria in a separate paper, as the subject is too vast and important to be considered here, and almost nothing has been written about it before. I will therefore limit myself here to the following brief remarks: On making cultures from some of the cases above mentioned on gelatin by smear, the gelatin soon covers itself with a white pellicle and soon gets liquefied. Under the microscope, round corpuscles and mycelia are seen. Similar corpuscles can be noticed in test tubes containing meat and gastric juice or meat, a solution of HCl and pepsin, when digestion had set in. I made smear cultures on agar in Petri dishes from a gelatin culture from case C, and obtained superficial, big, waxy colonies, which soon got dry and covered with slight cracks. From the periphery of some of these colonies long filaments grow out. On examining the colonies under the microscope, they appear brown and studded with lacunæ, and on closer examination the cellular arrangement is seen. On examining the filaments at the periphery, it is seen that they emanate directly from the colonies in question, and on close inspection the filaments, which are branched, present a jointed appearance, as if they consisted of a number of cells joined together. I took all that for fungi with their spores, and looked for yeast colonies, but in vain. I stabbed up the middle of a colony under the microscope and made a smear culture on an agar slant test tube, and obtained waxy colonies, which, on confluing, form a waxy, dryish cover on the agar. Under the microscope, they present rather circular corpuscles, about half the size of ordinary red blood corpuscles. On staining them according to the Gram method they take the Gram stain very well.

I stabbed up the periphery, that is, the filaments, of the same colony on the Petri dish from which I obtained the cultures just described, and made another culture on an agar slant test-tube, and got colonies which assume the form of little knots of down, and on confluing they present a feathery appearance. Under the microscope, they consist of cells and long filaments, all of which take the Gram stain.

Now, I have cultures of saccharomyces cervicæ, obtained from the cultures of Prof. Dr. Ficker of Berlin, and in old cultures they also present a network of filaments, which, however, show constrictions right along on both sides, thus demonstrating the cellular origin of the filaments. The cells and fibers are here also Gram positive, only the cells are larger, nearly the size of red blood corpuscles. I am, therefore, rather inclined to think that the filaments, or fungi, in the cases in question are outgrowths of the yeast cells, which are of the saccharomyces variety. As to their more detailed characteristics and their rôle in general, this will be considered separately, at another time, as said above.

From the above it will be seen that the gastric juice in hyperchlorhydria does contain some microorganisms; but that it contains more than in hypochlorhydria, as said by Lesage, who was quoted above, does not seem to be the case. Furthermore, it will be seen that the normal gastric juice is antiseptic with regard to some microorganisms, especially those of putrefaction, but it is not a universal antiseptic. In speaking of the antiseptic properties of gastric juice, we must first determine the proportion of HCl contained therein. How a certain gastric juice will act on a certain microbe, we can tell only by experiment, but not *a priori*.

To sum up, then: Carcinoma ventricula is bacteriologically characterized by the following trio: (1) the presence of the vibrio geniculatus ventriculi; (2) the presence of numerous staphylococci; and (3) the absence of fungi, that is, mycelia. In none of the other cases have I met this combination. In simple hypochlorhydria the vibrio geniculatus ventriculi may be found; but any other microorganism may also be met with, either alone or in combination with it.

In hyperchlorhydria, or chlorhydria, yeast and fungi, or rather mycelia, are met with, and also occasionally sarcinæ, and a small bacillus which is Gram negative, and in cultures discharges an ammoniacal odor. In subacidity of the stomach, when the acidity is only subnormal but not negative, with alimentary stasis, I usually found yeast, mycelia, and the vibrio geniculatus.

For clinical purposes one needs to make cultures only in a test-tube of sugared agar by stab, and on slant agar by smear, leave them at 39° C. for forty-eight hours, or in summer in the room temperature, then examine them as stated above. Ordinary neutral culture media are good enough, no acid media being necessary or advisable, as claimed by some.

Some precaution is necessary, however, in obtaining the gastric juice for bacteriological examination. The stomach tube should previously be thoroughly

rinsed, better still, if possible, sterilized in boiling water, and the receptacle for receiving the stomach contents should also be sterilized. It is preferable to get the sample for examination after some of the stomach contents have already escaped, as one is thus not so liable to get the first part, which may come from the œsophagus. The receptacle containing the sample for examination should be immediately closed, and the examination should be conducted under sterile precautions.

The bacteriological examination of the stomach contents should become as much routine work in clinical medicine as is that of the sputum.

ARE THERE OTHER CAUSES OF MALARIA THAN MOSQUITOS?*

By JUNIUS L. POWELL, M.D.,
MAJOR MEDICAL DEPARTMENT, U. S. ARMY.

During the month of August last, I was called upon by the authorities of the War Department to furnish a report on various sanitary conditions relating to the Post of Fort Hamilton, New York Harbor. Besides the water supply, its nature, source, etc., etc., the excreta, and their method of disposal, information relative to "mosquitos, their presence or absence at the post, source, usual time of arrival, appearance, varieties, hours of the day when most active, connection, if any, with existing diseases, and measures employed for their destruction," constituted an all-important requirement of the order in point.

About the same time I was requested by the courtesy of Dr. P. B. Porter, recording secretary of the "Medical Association of the Greater City of New York," on the suggestion of the President, Dr. T. E. Satterthwaite, to contribute a word in the discussion on the subject of "Tropical Diseases," which would take place at its meeting on October 10. While it has been impracticable, owing to exacting official duties for me to devote as much time to the preparaof a paper on as extended lines, as the members of this society may have been led to anticipate, I shall present to them that part of my report relating to the mosquito problem, as based on my observations and studies, made at the Post of Fort Hamilton. The following is the extract, in part, from the report:

"The mosquitos of this locality have been a subject of interesting study, but in all my investigations I have been able to discover but two varieties, viz.: the common Atlantic coast *Culex sollicitans*, as described and illustrated by L. O. Howard, of the Department of Agriculture at Washington, and the *Culex pungens*. There has been all along absolute uniformity in the physical appearances of these respective varieties. In but one single instance have I been able to find a specimen that accorded in any way with the description given of the different varieties of *Anopheles*. This one I killed about two o'clock P.M. in my own quarters, in the middle of July. It was a small black insect, smaller than the varieties mentioned, with smaller head, and distinctly mottled wings, two spots on the front margin of each wing. I had no opportunity to observe its attitude while in a resting position. Believing that there must be others of the same breed in the neighborhood, I had specimens brought to me from every part of the garrison, but all these turned out to be *Culex sollicitans* or *C. pungens*, and just here I will mention that the latter were the first to appear during the month of May, but the former, while later in their on-coming, have become vastly more numerous, and the greatest period of activity in either case is in the early morning and in the evening. In my hunt for the alleged malaria disseminating variety, I had the enlisted men of the different organizations bring me specimens that had succeeded in getting inside the mosquito nets that hung over their bunks at night. They all proved to be *C. sollicitans* or *C. pugens* without exception. The further expedient was then adopted of collecting samples of standing water from various sources for the purpose of hatching out whatever eggs might be deposited therein. In due course each sample produced its larvæ, pupæ and fully developed insects, by the hundreds, without a single *Anopheles*. In the instances of the larvæ, they answered in their behavior to the description given by Howard and Manson, but while the vast majority that were propagated in the incubation jars, 'came to the surface to breathe, thrusting their (long) breathing tubes through the surface layer and holding their bodies at an angle of about forty-five degrees with the surface of the water,' characteristic of the *Culex*, there were others, though vastly less numerous, that 'habitually remained at the surface, their bodies resting not at an angle, but practically parallel with and immediately below the surface film, so that portions of their bodies as well as their (short) breathing tubes were practically out of the water,' a feature peculiar to the larvæ of the *Anopheles maculipennis*, according to the previously quoted authorities. My investigations and experiments thus far have led me into a fog of perplexities and contradictions, but this fog becomes still more dense when I revert to the fact that from May 28 to the present date, September 1, I have had ten cases of tertian intermittent fever to treat among the enlisted men of this command, *all but three being from the same company organization*. Only two of these cases ever had the disease before. The Eleventh Battery of Field Artillery furnished seven of the cases, and not until July 16 did a case occur in any other organization.

"Last year between May 1 and September 30 there were twenty-nine cases of malarial fever reported on my return, but I have not stopped to sift out those cases that were readmitted to the sick report one or more times, on account of the recurrence of the disease, a circumstance which would make the total number of cases appear larger than it really ought to be, and which, for accuracy, should, as second or third admissions, as the case may be, be eliminated from consideration. The same rule holds, however, with reference to the Eleventh Battery, for from the twenty-nine cases reported from all the organizations, the battery furnished twelve. The barracks for this company are located on the highest elevation in the post, and off to the southern boundary. They overlook the Dyker Meadows, a more or less salt marsh, and are situated but a short distance from the Post dumping grounds. They are also

*Read before the Medical Association of the Greater City of New York, October 10, 1904.

near the battery stables. These latter facts are stated for whatever value they may possess, if any, in elucidating the problem of cause and effect, in connection with the disease under consideration. Eager for an explanation of the situation as I have described it, it was natural I should turn to the locality of the Eleventh Battery in search for the much-dreaded *Anopheles*, but, as already stated, from none of the many samples of water that I collected there or in the immediate vicinity was I able to hatch out a single insect that varied in the slightest particular from the *Culex sollicitans* or *C. pungens*. Thus confronted by an equation, the factors of which I could not make agree, I was somewhat in the attitude of one of our learned Congressmen, of national renown, who once found himself in a situation so embarrassing that he was unable to determine 'where he was at.'"

But what does all that has been recited in this report go to show? Does it mean that there are *other* methods of conveyance of malarial disease to the human organism than through the medium of the mosquito? I own the facts here recited point much that way. For one to rise up in this day and generation and suggest the least scepticism on the subject of the almost universally accepted views concerning the rôle played by the little diptera in the dissemination of disease would sound to many almost like heresy, but until, by further investigation, I can remove the doubts that now hang over my mind, I fear I will have to admit that its present status is that of "unstable equilibrium."

As has already been stated the first appearance of the pests at this post is during the month of May, being determined largely by the character of the season, with reference to temperature, moisture, etc. Towards the end of September they make their exit.

Unhappily there are numerous water holes just outside the reservation that afford ample breeding grounds, wherein the females may deposit their eggs. Inside the Fort, a quantity of filling in has been done at certain points, and all the residents of the reservation have been impressed, as far as possible, with the importance of permitting no vessels containing water to stand about the kitchens or elsewhere, where the mosquitos may find access to them and deposit eggs.

Returning to the old-time underground cisterns that have been referred to, one being located at the rear of every set of officers' quarters and a few elsewhere, I quote a recommendation of mine relative to them, made in my Sanitary Report for September, 1902, as follows: "Attention is invited to the fact that there are numerous underground cisterns about the post, which, aside from the fact that they belong to a past era, fulfil no good or useful purpose, inasmuch as the garrison is provided with an excellent and abundant water supply from the Brooklyn system. Indeed, the presence of these cisterns, under existing conditions, is considered contrary to sound sanitary principles. On account of the lack of the use of the water that is collected in them from the water shed of the post buildings, during periods of rainfall, it stands without removal for indefinite periods, and every inspection that I make of them leads me to believe they are the breeding nests of hordes of mosquitos. It is respectfully recommended that the cisterns referred to be filled up, and their supply pipes, leading from the roofs be diverted into the main drains." So much for the official report.

Pending action on the foregoing recommendation, crude petroleum was, at stated intervals, poured over the surface of the water in each cistern, which in time caused a manifest decrease in the swarms of the insects that had infested the immediate vicinity of the officers' quarters. This diminution was due, of course, to the destruction of the larvæ, from which full grown mosquitos had formerly been developed. Returning now to the suggestion that mosquito inoculation is not the only means by which malarial disease is conveyed to man, it may be interesting to quote from Munson's "Hygiene," published as late as 1901. He says: "It is true that the mosquito is undoubtedly capable of transmitting the malarial plasmodium, but it has not been shown that inoculation by this insect is the only means of producing this affection. Much evidence has been accumulated during the past—if the diagnosis be accepted as accurate—to show that drinking water drawn from certain sources is productive of malaria. In this connection a case recorded by Bourdin is instructive. This writer states that 800 French soldiers, in good health, were embarked on three ships bound from Algiers, to Marseilles; all arriving at the latter port on the same day. On two vessels there were 680 men, presenting not a single case of sickness among them. On the third vessel there embarked 120 men. Of the latter, 13 had died during the short voyage, and of the 107 survivors no less than 98 were affected with malarial fever. Among the crew of the ship not a case of malarial fever had occurred. On investigation it was shown that the water on the two first ships was pure and good, while on the unhealthy ship the water had been taken from a marsh and had an unpleasant taste and odor. *This water, however, had not been used by the crew of the ship.*" This is the old, old story of the *Argo*, familiar no doubt to every member of this association, but it is a noteworthy fact that the author cited thinks proper to introduce it in his valuable volume, even though as high an authority as Ross claims there is but one medium of conveyance for the *materies morbi*. But let us quote further. In *American Medicine* of July 23, 1904, "L. Chenisse combats the idea that mosquitos should be regarded as the only basis for the etiology of malaria and yellow fever. First of all, the geographic distribution of the *Anopheles* does not always correspond with the distribution of malaria. The disease has even completely disappeared in localities where mosquitos still remain numerous. On the other hand, there are regions profoundly infected with malaria, where it is impossible to discover any *Anopheles*. Epidemics of malaria have occurred under the influence of late and abundant rains, without the intervention of mosquitos." Again, Major G. H. Fink, I. M. S., commenting on the experiments at Main Mir, which are discussed in the *Journal of Tropical Medicine* for August, 1904, pertinently affirms that "whence malaria comes remains a mystery," and this, too, while confessedly appreciative of the work and investigations of Major Ronald Ross. But a still more important announcement comes from one who may be considered as the very author and finisher of the mosquito theory, Sir Patrick Manson, who at the eleventh International Congress of Hygiene and Demography at Brussels, September 2-8, 1903, stated that he "did not believe mosquitos to be the sole cause of the disease, but that some other factor, evidently as yet unknown, existed." The preference, so to speak, that the disease has manifested at Fort Hamilton, for one organization, the Eleventh Field Artillery, over all the rest, is a notable fact. The entire population on the reservation drinks the same water, and I am advised by Brooklyn practitioners in the vicinity of the reservation, that malarial fever does not cut a conspicuous figure in the nosological classification amongst their clientele. Finally, in the face of all that has been said, does it not appear that the etiology of malarial disease is as yet far from being definitely and conclusively settled?

THE RATIONAL REDUCTION AND FIXATION OF MAXILLARY FRACTURES.

By WILLIAM J. LEDERER, D.D.S.

INSTRUCTOR IN ORAL SURGERY AT THE NEW YORK SCHOOL OF CLINICAL MEDICINE; FORMER DEMONSTRATOR OF OPERATIVE DENTISTRY AT THE NEW YORK COLLEGE OF DENTISTRY; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, SECTION OF STOMATOLOGY; MEMBER OF FIRST DISTRICT DENTAL SOCIETY, STATE OF NEW YORK, ETC.

It is surprising how large a percentage of the cases of maxillary fracture, after union has taken place, present asymetry of face and faulty articulation, inasmuch as both these sequelæ can almost invariably be avoided. It is true, to reduce and fixate a broken inferior maxillary bone is rather difficult; also to give it physiological rest, as it gives attachment to a number of powerful muscles and is a much used part of our anatomy; however, by the employment of the double arch interdental splint and proper bandaging, very happy results can be obtained.

Although fractures of the inferior maxillary bone do not occur very frequently, the construction of the bone is such that it presents some points of weakness, which offer little resistance to direct force applied to them. Although it is one of the heaviest bones of the head, having no osseous union with the skull, but really being an appendix to the same, a blow directly applied to the mandible will exert its full force upon the bone without its momentum be-

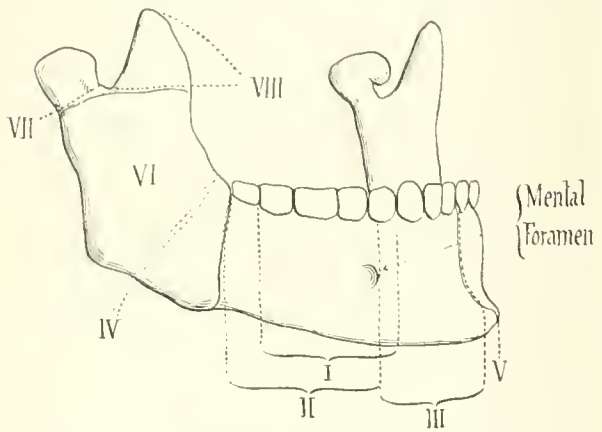

Fig. 1.—The usual seats of fracture.

ing diffused to other parts; especially if the blow comes unexpected and the mouth be open. Evolving from six centers of ossification, also produces many weak areas, and besides being tunneled by a large canal with large entering and exit foranima, also contribute to points of weakness.

According to Dr. F. D. Weisse, professor of Oral Surgery at the New York College of Dentistry, the frequency of fractures of the inferior maxilla, as to location, can be tabulated as follows: (1) Between first bicuspid and second molar teeth, most frequent. (2) Between mental foramen and third molar. (3) Between mental foramen and symphysis. (4) At ramus (angle). (5) At symphysis. (6) Body of ramus. (7) Neck of condyloid process. (8) Coronoid process. (See Figure 1.)

Fractures of the superior maxillary bones are very rare and if they do occur they as a rule are of the comminuted type. The reason for this is obvious. The superior maxillæ are part and parcel of the skull and force applied to them will radiate and become diffused over the whole surface of the skull. If a comminuted fracture obtains it is caused by great crushing force, otherwise, though cerebral concussion may obtain, the superior maxillæ are rarely fractured.

The symptoms of maxillary fractures are: (1) Altered physigonomy. (2) Deformity. (3) False point of motion. (4) Pain. (5) Crepitus. (6) Lack of function, fixedness of jaw. (7) Increased salivation. (8) Pain in swallowing. (9) Faulty articulation of the teeth.

Of course, there are many cases which do not present all these symptoms; thus, a fracture may obtain at the symphysis and not show any deformity, but it will give a false point of motion and crepitus will be felt. At times a patient will present with a much swollen face and the positive diagnosis of maxillary fracture can only be made after a very careful examination, as an impacted third molar will at times produce similar symptoms and the

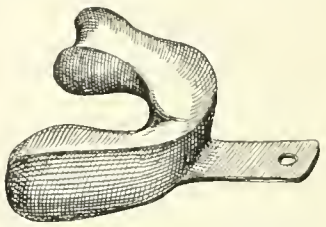

Fig. 2.—Impression-cup for the lower jaw.

tissues being much swollen, neither false point of motion nor crepitus can be felt.

The prognosis is favorable. The treatment consists in the reduction of the fracture and the coaptation and fixation of the parts, affording the jaw perfect rest till union has taken place. The mouth should be carefully washed, spiculæ of bone and dislodged teeth removed, and the buccal cavity be put into as aseptic condition as possible.

The patient is then anæsthetized and an impression of both jaws is taken by means of "modelling compound" (a combination of gum damar, French chalk, stearin, and coloring material, much employed by dentists). This is preferable to plaster, as it hardens faster and gives a fairly clear impression. This compound is placed into a dental impression cup, Fig. 2, and the cup containing the compound, which has been softened in hot water, is placed on the jaw and firmly but evenly pressed down, so as to embed the teeth in the compound. The cup is held in position till the compound is chilled, which can be hastened by irrigating the floor of the mouth with cold water. The cup is now removed without jerking and placed into cold water to thoroughly harden the compound. An impression of the opposite jaw is now obtained in the same

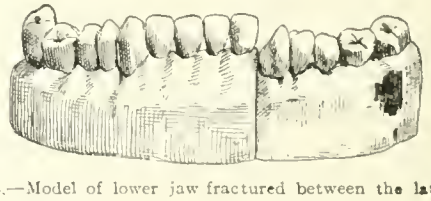

Fig. 3.—Model of lower jaw fractured between the lateral incisor and the cuspid teeth.

fashion. The patient is now dismissed, after a bandage has been applied.* Models of the jaws are now made by pouring softly mixed plaster into the impressions and permitting the plaster to set. After the plaster has thoroughly hardened the cups are immersed in hot water again and the plaster models can easily be separated from the again softened compound impression. Now, two models have been obtained, one of the healthy jaw and one of the fractured bone, in its abnormal, misplaced condition, Fig. 3.

*If the impressions are handed to a dental mechanic he will construct the splint, if necessary, in 5 or 6 hours.

The solution of continuity of the bone is now reproduced by sawing the model in two along the lines of fracture, with a scroll saw, and the fractured model is coapted and then fixated by means of a little soft plaster, so as to articulate with the model of the opposite jaw. Fig. 4.

Thus a model of the fracture is obtained as it should present after union has taken place. According to these models a splint is made in wax, embracing both the upper and lower teeth, high enough so as to separate the jaws about three-

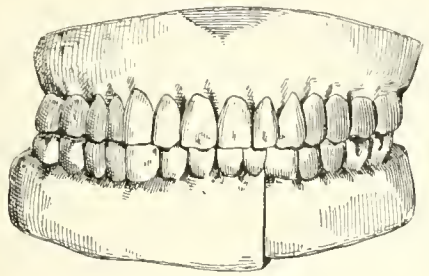

Fig. 4.—Models articulated.

quarters of an inch, with an opening in the center to permit the introduction of fluid food. (Fig. 5.)

This wax splint is now reproduced in rubber or tin; the patient is again anæsthetized, preferably not with nitrous oxide, as this does not permit complete muscular relaxation, and the splint is introduced into the mouth, first embracing the healthy jaw. The fractured maxilla is now forced into the other half of the splint and a double roller bandage applied. The double roller is preferable to any other head bandage, as the patient cannot remove it, a great advantage in children; it positively does not slip, and it can be secured without pins.

The patient is put on fluids and such diet that need no mastication. The mouth is kept as clean as possible by antiseptic washes, and the splint can be removed from time to time to cleanse it. To

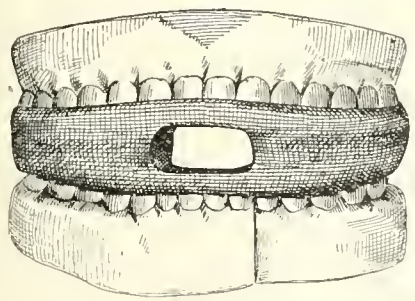

Fig. 5.—Splint in position.

illustrate the efficacy of this splint, the writer quotes one case from actual practice.

Some years ago the writer was asked to see a case of compound multiple maxillary fracture in a patient at Bellevue Hospital, with the following history:

The patient, a boy six years old, had fallen from a third story window to the ground and sustained a fracture of the left leg and forearm, also contusions about the head. He was sent to the hospital, and after the leg and arm were attended to, the maxillary fracture was discovered. The fracture was one of very rare occurrence, it was compound, multiple in character, and the lines of fracture extended through the body of the inferior maxilla between the central and lateral incisor teeth *on both sides* of the median line. The submental tissues exerted tension on the small fragment carrying the central incisor teeth, and drew it downward and backward. (Fig. 6.)

The house surgeon attempted to coapt and fix the parts by wire sutures, but this proved futile. One of the senior class students of the New York College of Dentistry was sent to construct a splint for the case, which was done as described. The splint was put into the mouth and a bandage applied, but the central portion of the bone would not go into place. As soon as the bandage was tightened, the two lateral halves of the body would approximate and push the central portion further down.

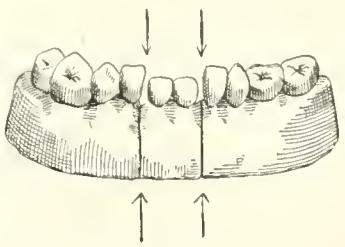

Fig. 6.—The lines of fracture.

The writer was asked to see the case. The difficulty here was to get fixation of the parts. This I attempted by constructing a single arch splint, embracing only the lower jaw, of silver, and by cementing this on all the teeth of the lower jaw, hoping thus to keep the central fragment in position. This, however, proved a failure, for the temporary teeth offered but little surface for attachment, and also was it impossible to get the cement to set properly, as moisture could not be excluded long enough, in spite of damming of the salivary ducts. Also was the boy very violent, and insisted on working the splint loose as soon as his nurse turned her

Fig. 7.—The chin-cap.

back. The problem to be solved here was twofold, first, to construct a splint which the boy could not remove, and, secondly, to get counterpressure from below the chin to keep the central portion in position.

A third splint was constructed, of the double-arch variety, this time of tin, to make it heavy. This was placed into the mouth under anæsthesia, the central portion of the bone was pushed into place, and an impression of the chin was obtained. According to a model of this chin, a chin plate was made, also of tin, extending beyond the lines of fracture laterally, and going above the mental protuberance and behind the genial tubercles. (Fig. 7.) This was padded with a little gauze and applied to the chin.

A tightly fitting skull cap was made of coarse linen, also a cap fitting over the chin. These were

held together by a strap and buckle on each side, which could be drawn tighter at will.

The splint was now forced into the mouth, the central portion forced into position, the padded chin plate placed over the chin, and the whole covered with the linen chin cap, which in turn was padded with cotton to get close adaption. The linen chin cap was strapped to the skull cap, and thus the much desired end was accomplished. There was

Fig. 8.—Apparatus in position—*a*, double-arch splint ; *b*, opening for feeding ; *c*, metal chin-piece ; *d*, gauze padding inside of chin-piece ; *e*, cotton padding outside of chin-piece ; *f*, linen chin-piece attached with straps to the skull-cap.

coaptation, perfect fixation, and perfect rest. (Fig. 8.)

The boy made a splendid recovery. I saw him subsequently, and he had a good serviceable jaw. Had other means been employed, necrosis would have occurred in the central portion of the bone, and he would not only have been deformed for life, but articulation would have been badly interfered with.

This case illustrates the value of the interdental splint in one of the most difficult forms of maxillary fracture imaginable, and I believe this form of splint is better than any other, as it is less encumbersome to the patient, it is more easily kept clean, as it can be removed, and above all, it actually fixes the parts as they should be kept, and gives the jaw perfect rest.

150 East Seventy-fourth Street.

Affections of the Facial Nerve in Diseases of the Ear.—C. Zimmermann finds that a great variety of causes may produce facial nerve lesions in ear maladies. A predisposition thereto may be given by anatomical abnormalities as the dehiscences of the Fallopian canal (especially at the projecting ridge), variations of the lumen, and thickness of its walls. Congenital palsies are the consequence of insufficient development of the petrous bone, and are generally associated with malformations of the external ear and other parts of the skull. The family type of facial paralysis is generally owing to stenosis of the Fallopian canal. Paralysis may follow affections of the auricle and external meatus, or, as a reflex from zoster, external otitis and cerumen middle-ear inflammation may also produce it if they subject the nerve to pressure. It follows both acute and chronic otitis media. Other causes are local tubercle and syphilis, caries and necrosis of the petrous bone, new growths, trauma (accidental or surgical).—*Archives of Otology.*

THE STUDY OF SPRAIN AND ITS TREATMENT BY MASSAGE.

By GUSTAF NORSTROM, M.D., Stockholm, New York.

Does what we know of the pathological action of massage, authorize us to declare that its employment in a sprain is rational? If we were supplied with neither statistics nor facts, could we assume that massage would be serviceable in the treatment of its immediate and consecutive consequences, and that it would facilitate its cure.

Sprain is a popular term denoting a morbid condition of traumatic origin, whose exact nature is not well determined. As a general rule the joint itself is more or less affected in the form of an acute or subacute inflammation (traumatic synovitis). Sometimes sprain is only an acute tenosynovitis, affecting the sheaths of the tendons of the extensors, of the flexors of the foot, the peroneus longus, and other muscles.

Pathological anatomy teaches us but little. We have succeeded by the aid of Bonnet's experimental researches[1] and by analysis of the symptoms in arriving at the conclusion that in slight cases there is a stretching of the ligaments, whereas in the more severe cases there are tears, ruptures of blood vessels, and sanguineous extravasations. The most frequent clinical phenomena are the following: At the beginning ecchymosis, pain and physical weakness; later inflammatory conditions, effusion of serum, periarticular œdema, and stiffness of the joints. Nearly all are caused by the same etiological factor, viz., primary sanguineous effusion. The blood acts as an irritant. It hinders the reunion of tissues, and calls forth unequal reactions. We know, as Mosengeil's experiments have shown, that massage hastens absorption. Frictions properly performed on a joint, promote the passage of the fluids into the absorbing vessels and by the same manipulations diffusion throughout the body is facilitated. It is possible, says Philippeaux,[2] to transform a circumscribed and thick effusion into a general infiltration, or rather, into a large thin sanguineous mass extending from the extremity of the limb towards its base and disseminating throughout the subcutaneous cellular tissue where veinous and lymphathic radicles are found. These, as we know, are the active changes in interstitial absorption. Thus we perceive that massage is absolutely indicated in sprain. It was used long before the mechanism of its action was understood.

Poteau said that sprains could thus be cured almost instantaneously. "We do not know," said he, "what accounts for the failure surgeons generally experience in a trifling undertaking, inasmuch as it is left to inexperienced people who do succeed."[3] This has been pointed out by several writers: "Massage," says M. Duplay, in treating of a chapter on sprains,[4] "has most often been left to bone-setters," and Hüter adds that this has been the foundation of wealth to them, and if they have a greater reputation in treating joint diseases than the physicians, it is because these ignore the rational practices of their treatment. The reproach is to a certain degree merited. The truth is that one has heard massage vaguely spoken of, and therefore distrusts it. The success obtained by empirics, lauded beyond measure, has perhaps been more injurious than useful to the treatment; they have had striking failures because the indications were badly interpreted and because they left luxations without reducing them, or prevented the union of fractures. Boldness and a certain amount of dexterity alone do not suffice to prevent such accidents.

"In performing massage slowly, prudently and gently," says Mullier, "you cure without provoking any pain, contrary to the 'bone-setters.' I was told by an officer in my regiment, who had been massaged by the man of Thelus, that the pain was generally so intense as to be beyond description.[5] Bonnet relates the case of a man treated by a young and 'clever' masseuse for sprain of the knee. He was cured after one séance; but the operation was so merciless that the patient fainted three times during the procedure. If a woman's hand," says Mullier, "can inflict such pain, what term shall we apply to the martyrdom the patient has to suffer when he is massaged by a robust peasant, who is convinced that he cannot use too much force in performing his duties?" Many surgeons hesitate to use massage, which is left to empirics, who cure or harm at random. There is only one way to overcome this indifference, and that is by proving that with the help of massage we can cure much quicker and better than by immobilization or similar procedures. I have often had instances of it. A person, for instance, makes a false step which produces a tibiotarsal sprain. He is carried home, if the accident happens outside of his house, and every attempt to take a step and rest on the foot produces the most excruciating pains, causing the patient to cry out loud. It frequently happens that these pains are so diminished after the first séance, which has already reduced the swelling and other inflammatory symptoms in a marked degree, and the patient experiences such a relief that he feels disposed to walk. This produces the most excellent effect on the patient and gives him a great deal of courage to stand the pain at all subsequent séances. Another has only a slight sprain. He cannot walk and he is obliged to stay in bed. Compresses wrung out of cold or hot water are applied and the leg is immobilized for several weeks by a bandage of gauze, or even plaster-of-Paris. The same person suffers another sprain of the same severity in the same joint, and he is cured within twenty-four hours by massage. Isn't this sufficient proof of its utility? We have stated that as far as our personal experience went, it was in favor of treating sprains by massage. We have also seen that masters who have studied joint diseases think favorably of it. In France, the country in which massage was first applied in the treatment of sprains, physicians hesitated a long time before it was, as is the case nowadays, generally adopted. In other countries, particularly Germany, it has gained much ground in the last few decades, and in none of them does it seem to meet with absolute reprobation.

To what are we to attribute the effects of massage? Those who do not hesitate to admit that they borrowed the procedure from "bone-setters" would never have made this confession had they not been able to support their boldness by statistics. If they had been unable to prove that by means of massage one effects a more rapid and permanent cure than by any other means, then they would have added two or three examples and only commented on them. Opposition would soon have arisen, and one would not have failed to apply to them the saying, *Testis unus, testis nullus.*

The earliest French statistics are all in favor of massage; those of other countries are likewise favorable. They were compiled by specialists, physicians in hospitals, and military surgeons, whose prime motive was to enable their men to perform duty as soon as possible, statistics pure and simple, in which facts are recorded without any comment or definite object in view. One of the best known is the one compiled by Péan, and published in his "Lecons de Clinique Chirurgicale."[6] The observations on sprains by him number 61, and they were located as follows: Wrist, 3; knee, 3; spine, 2; tibiotarsal articulation, 52; metatarso-phalangeal, 1. In all these cases, the treatment was based on the same principle: immobilization. The patient had to stay in bed during the whole time he was in the hospital.

When it seemed necessary, Péan placed the limb in a splint, or gutter, applied compresses wrung out of hot water, and later, if the affection persisted, the plaster-of-Paris cast. Let us omit the two cases of sprained spine reported. The minimum duration of their stay at the hospital was three days (only in one case), and the maximum forty-two days. Altogether, however, 919 days of treatment were necessary for 58 patients. This averages a little more than a fortnight for each. In all these cases we have only had to deal with typical sprains without fractures or concomitant luxations. The patient came into the hospital immediately after the accident had occurred. Only once did it happen that the patient had suffered for four days. In the two most serious cases, which demanded 28 and 42 days respectively, complete cure had even then not been established. After the removal of the dressing one of the patients still had perimalleolar œdema; another one articular stiffness which considerably impeded the movements of the joint.

The treatment by immobilization was vigorously adhered to as long as it seemed necessary; consequently the results were not very satisfactory, inasmuch as it took a fortnight to cure an ordinary uncomplicated sprain, treated immediately after the occurrence of the accident. As an additional factor we may mention that during all time the cast remained, the patient was obliged to walk with crutches.

In order to claim success, a few simple, but indispensable precautions are necessary. We ought never to act blindly, but know what we have in view and what we are doing. The more recent the effusion is, the less time passed after the injury, *i. e.*, the more acute the inflammatory process is, the more easy is the absorption, and the sooner a cure will be effected. Unluckily this fact is not admitted by all physicians.* One allows the exudate to become organized, and as a last resort massage is used to repair the prejudice caused by other curative measures. The patient is suffering, the joint is tumefied; how could mechanical medication possibly be thought of? It is entirely out of consideration to think that massage, if properly performed, is the best anesthesia that we have at command. It is, furthermore, the quickest way of overcoming effusions in the joints or in the teno-synovial sheaths and infiltrations of the cellular tissue.

All patients are not cured in the same length of time. I have obtained excellent results after 24 hours; at other times it took me a fortnight or more. I had to deal with identical affections, and no complications existed. This difference in time to effect a cure always depends upon the length of time intervening between the accident and the séance, as well as upon the seriousness of the case.

Postponement may sometimes become dangerous.

* I may here mention that when I settled in Paris many years ago, it took a very long time before I was able to convince the French medical body that just in the acute arthropathies—traumatic or not—we had the best results with massage, although, strange to say, one felt generally disposed to admit its efficiency in that kind of traumatic synovitis which we call sprain. It was feared that in interfering in these cases by massage, even when applying that relatively mild form of it that we call effleurage, one would increase the inflammatory condition, and instead of benefiting the patient by such treatment, make a bad thing worse. This is further proof how difficult it is to overcome old, deeply rooted prejudices.

We see from the report of Bizet that some amputations performed on officers' legs fifty years ago were due to delayed treatment of sprains. We ought never with scrofulous persons allow an articular affection to become chronic. The initial phenomena disappear, the tumefaction diminishes, motion partly returns; but what is the result of all this? Very often a white swelling. We know that the duration and progress of arthropathies often depends upon the constitution of the individual, and that it is not wise to let an articular effusion under such circumstances go too far and assume a chronic form.

Massage ought, then, to be applied in sprains. In the hands of empirics it has produced unexpected results. A lot of technical maneuvers have arisen. Every healer has his own rules, and only confidence in these. But this confidence is absurd. We are face to face with various predispositions, and complex processes. No two cases are ever alike. How, then, can an unalterable method be employed in all cases? If we have to deal with a recent sprain it is not convenient to imitate the man of Thelus or the strong woman Bonnet has spoken of.

Progressive inflammations and exaggerated sensitiveness demand very slight friction—that is to say, effleurage. A diminution in the inflammatory condition is followed by a disappearance of the hyperæsthesia, as by massage the irritated extremities of the nerve filaments are relieved of the pressure caused by a liquid effusion in the interstices of the tissues.

Massage cures absolutely. Neither blood nor serous fluid remains behind in the tissues, provided that the divided parts are quickly brought together. Experience has shown that the reunion of subcutaneous wounds takes place more rapidly than that of open ones. If immobilization alone is resorted to something will always remain behind, and this would be sufficient to produce an acute attack in cases of even slight future accidents. One might call this a relapse, but it is not. It is a new affection in an organic territory, which has become the seat of less resistance in consequence of anatomical changes which were not anticipated nor prevented.

The indications are quite different in old cases. Here we have to deal with infiltrations, more or less chonic, and indurations. Effleurage or slight frictions would be of no use. Here powerful frictions are indicated. It is only by this means that cicatricial retractions can be cured. Passive movements are likewise indispensable, but it is above all patience, on the part of the patient as well as on the part of the physician, that we need. It is sometimes only after several weeks' treatment that we are enabled to restore all the functions of the joint that was apparently immobile forever. I do not wish any one to have to treat a neglected sprain in a person suffering from rheumatism. Diathesis and local affection are then combined. Sometimes it is claimed that the sprain was improperly treated. At other times that rheumatism accounts for the inflammation of the joint. All this may be true. The result, however, is an infirmity which seems to defy the best of treatment. This malady may nevertheless be overcome if we have full confidence in the efficiency of our method, and if applied most energetically and perseveringly.

Even in Pott's fracture it is most important to massage the always complicating sprain in the tibiotarsal joint. Indeed, this is more important than the massage for the fracture itself. It has been applied with great benefit for the last years, particularly in France. There this method has in these as well as in other cases of fracture gained more and more favor, owing to the many communications presented on this subject by its principal champion, Prof. Lucas Championnière, surgeon of St. Louis Hospital.

Of several cases of this kind I was called upon to treat, I mention here one that I saw in Paris many years ago. I do this in order to show the different results obtained by the modern and ancient method of treatment in this kind of fractures. The patient being a foreign ambassador, and at the same time a man advanced in years, I obtained here a complete cure without any complication, after only three to four weeks of treatment, by merely applying an ordinary bandage and massaging twice a day, particularly the complicating sprain.

In an identical case, which happened some few years later, and in the same city, to a representative of another power, an eminent surgeon of Paris was called. He applied, as had always been customary, a plaster-of-Paris bandage which kept the leg immobilized for five to six weeks. The result in this case was that when the bandage was removed the fracture had healed, but when the patient tried to walk he felt the joint, which was the seat of the sprain, as well as the joints of the toes, quite stiff, and there was, furthermore, what almost always happens with old people under these circumstances, an effusion in all the small tarsal joints. I heard that five months after this accident he was still disabled.

Walking, if possible, after a tibiotarsal sprain in slight cases, right away, and in more complex ones, after very few days, when we suppose that the healing of the ruptured parts has at least begun to set in, does not cause the inconveniences that were formerly ascribed to it. It was feared that by doing so the congestion of the tissues would be increased, the process would spread and be aggravated. This possibility, however, is not so threatening as was entertained. In slight cases we do not run any risk, according to my experience, if we allow the patient to use his foot from the start very moderately when for some reason or other he desires to do so. In regard to more severe cases, although I am not in favor of immobilization, I do not believe in passive and particularly active movements too soon. It is better to advise the patient two or three days' rest if it is possible. At the end of this time the patient will be allowed to take a few steps, but not to take long and fatiguing walks. In sprains, with rupture of the ligaments, the patient may not be permitted to walk, until we may suppose that the first act of the healing process is terminated.

If we have to deal with sprains in the lower extremity, application of a well-fitting roller bandage, after every séance of massage, is necessary, otherwise the œdema will reappear in walking. Judgment must be issued in massaging to prevent violent maneuvers. These are particularly injurious when the articular ligaments are torn or when fractures of the bones or lacerations of the periosteum coexist.

Passive movements should not be neglected. At first slight extension is exercised. Later on, when the inflammation has diminished, this may be increased. It is a wise plan to postpone passive movements if one has reason to suspect that the ligaments are torn to some extent, as was the case with some of my patients.

Case I. *Slight Sprain of the Tibiotarsal Joint.*—Massage. Walking possible after only one séance. Mrs. M., Paris, 46 years. Sprain after a false step. Pain immediate and sufficiently sharp to prevent her from taking any step. I was called some hours after the accident, March, 1889. Tibiotarsal region

slightly tumefied. Slight effusion in the above joint as well as in front of the malleoli (tenosynovitis in the sheaths of the extensors). No ecchymosis thus far. Screams at the slightest examination. No movement, active or passive possible. No malleolar fracture. Effleurage during half an hour. Immediate relief. Foot more supple and less painful. Tumefaction almost gone, and the effusion distinctly decreased. Felt so much better that she got up and tried to walk. She did as well as she could. When in the afternoon the following day I returned to give her another séance of massage I was greatly astonished to see her come downstairs and to tell me that she had been able to sleep during the last night, and that she was just now making her preparations to return to St. Germain, in the neighborhood of Paris, where she was living. She felt almost entirely well, and promised to return if necessary. Examination of the foot showed only a scarcely perceptible amount of effusion in the tibiotarsal joint. No tumefaction. Passive and active movements almost normal and not attended with any pain. The same lady told me that during the last two years she had twice suffered a sprain in the same joint, and presenting exactly the same phenomena. She was treated by absolute rest, medicated compresses, and application of an elastic bandage; but she was not cured in six weeks.

Case II. *Acute Traumatic Arthritis from Sprain in the Right Knee.*—Cure after 12 sittings (6 days). M. G., 35 years old, fell from his horse in October, 1880, and tore his knee (internal lateral ligament stretched, the knee having been turned inwardly). He had to be brought home in a carriage. I saw him the same day with an ice-bag on his knee. Tumefaction and redness; the slightest contact and spontaneous movements provoked extreme pain. Performing massage for three days (effleurage), every sitting lasting twenty minutes. The pain and sensitiveness has entirely disappeared, and the patient was able, without too much difficulty, to support himself on his leg. Complete cure after six more séances (two a day), the last ones in form of real frictions.

Case III. *Acute Traumatic Arthritis from Sprain of the Elbow.*—Massage. Cure. December 30, 1881, M. de Sch——,[2] in jumping over a heap of sand, fell in such a way that his hand struck the ground, the arm, as he believes, in slight flexion in the cubital joint. On my arriving the following morning the tumefaction of the joint was very marked, and he complained of a great deal of pain at the slightest movement. Posteriorly to and on each side of olecranon process there was distinct fluctuation. These regions were extremely sensitive to touch. The patient could not sleep on account of the pain. The forearm was in a position midway between flexion and extension. Passive and particularly active movements quite restrained. The hand in pronation, and movements of supination impossible. After causing the greatest part of the œdema to disappear by means of massage I found that the muscles about the elbow, although swollen and quite painful to the touch, were not the seat of any lesion. Massage, very painful at the beginning, was performed twice a day. The immediate effects were quite satisfactory, and the following night the patient was able to step. January 1 the patient has less violent and the manipulations are more easily tolerated. January 2. Passive movements, at least, to a certain degree possible. Tumefaction has greatly diminished, and there is only a slight fluctuation left. No more sensitiveness of the muscles of the forearm. January 4. Passive and active movements no longer painful, and possible to a normal degree. The hand remains no longer immobilized in pronation. Can put on his coat himself. January 11. I received a letter from the patient, who has left Paris, in which he says he can use his arm and his hand as well as before the accident.

Case IV. *Sprain of the Right Shoulder.*—Massage. Rapid cure. Mr. N., Paris, fell down a flight of stairs. He fell upon his right hand, the corresponding arm extended in order to gain support. Immediately felt a sharp pain in the shoulder region. This increased towards evening. Not able to make the slightest movement with the arm. Ice-bag followed by application of an elastic bandage. As there was no improvement the following day, I was called. Movements of the right scapulohumeral joint were almost suppressed. The patient was able to lift the arm a little, but he could not move it forwards nor backwards. The passive movements were also quite painful and very limited. He was not able to take his food without the aid of another person. No tumefaction, no ecchymosis. Distinct effusion in the shoulder joint. Effleurage—increasing force—for half an hour. The following day already marked improvement. Was able to move the arm without too much pain, the third day the movements more extended and much less painful. Slight passive movements. The fifth day complete cure, only slight impediment remaining in the active movements.

When we have to deal with the sprains of a large joint the tibiotarsal joint for instance, it is wise to apply at the end of treatment a linen bandage in order to give more steadiness to the joint and prevent relapses. It has to be worn for some days.

Sprain is one of those affections which gives the clearest indication for massage. It may be used in all cases, whatever its seat may be, whether immediately after the accident or later on. It is the only means of preventing serious disturbances or hastening the repair of those already existing. The method is essentially curative and wholesome. One might assume that the treatment of sprains occupies a prominent place in the statistics of scientific masseurs. My experience, however, leads me to believe the contrary. In the perusal of the notes I have taken since the commencement of my practice in Paris up to this date, I find 193 cases embracing 67 tibiotarsal, 24 femorotibial, 15 elbow, 52 radioulnar joint,* 24 wrist, 7 phalanges.

This is not much during more than twenty years of experience, and I am inclined to think that most of my colleagues who practice this same specialty might have remarked the same. There exists in large cities like this prejudices as in the country. An accident happens in the foot joint. The person has suffered neither a fracture nor luxation. Everybody congratulates him, and is on the point of telling him to get up and walk on. If he does not do this at once they attribute it to a little indolence or faintheartedness. A friend or a neighbor comforts him, and tells him the name of a practitioner who cures sprains, and he is asked to come. The great majority of simple sprains are treated in this way.

When I ask patients who come to me two or three weeks after the accident, or even still later, why they do not come before, I only obtain an evasive answer, and conclude an empiricist was consulted previously. This one often only eases the pain a little, diminishes the congestion and the swelling, and enables the patient to walk. If the case is an

* All these belong to an affection known as lawn tennis elbow, which is caused by extreme pronation of the forearm, with the arm in flexion.

ordinary one, it is a brilliant success; if it is a more serious one, it is quite another matter.

When patients apply to me on the same day or a day after the accident, I nearly always succeed in curing them after a treatment lasting from two to six days. When they came to me later it took of course a longer time, and they were sometimes only definitely cured after several weeks, when the disease had taken a chronic course. The objection may be raised that the rapidity with which results terminated in using massage are only relative; that, while some sprains were cured in a few séances, others require a treatment extending sometimes over several weeks, and that we meet with the same conditions as when treated by immobilization. No doubt a long time is sometimes necessary to attain a cure, but no mention is made of the fact that these cases were exceptionally severe ones, and that they were exceptions to the general rule. My countryman, Dr. Berghman, one of the most staunch supporters of Metzger's method, records the case of a sprain in which 52 séances were required to obtain a cure. But it must be granted that he had to do with an exceedingly serious and complicated case. When subcutaneous rupture of the ligament takes place in sprain no modification in the treatment is called for, except that the patient's movements be postponed somewhat. This rupture is by no means a contra-indication to massage, as the latter can only exercise a curative influence upon it, as it hastens the healing and restrains the complicating inflammation within due limits. I am glad to see that such an eminent masseur as Dr. Kleen,[7] as well as other specialists of massage, entirely share my opinion in this respect. It is in relation to sprain that massage was first spoken of. The works of the first French observers, Metzger's Thesis, the first memorials on this subject, emanating from the school of Amsterdam, all treat of massage for this affection, and let us not forget that Boudins, Malgaigne, Volkmann, Hüter, Duplay, and so many other physicians of repute, have insisted on the inconveniences which neglected and improperly treated sprains can produce.

In all sprains massage is the surest and simplest remedy, and the only rational treatment to be employed. Even under unfavorable circumstances, when we see the patient a long time after the accident, when more pronounced and anatomical disorders, or functional disturbances, have set in, we may still with perseverance overcome them. In acute or subacute cases I have already mentioned, in the beginning of the sitting, quite gentle strokes in the shape of effleurage ought to be applied, in order to occasion the least possible irritation and not too much pain. If after a few minutes of treatment the tension in the tissues is noticeably decreased, then we may use a little more force. Not until the treatment is further advanced and inflammation has become less intense is it advisable to introduce real frictions into the treatment.

The sittings ought to be the first days protracted —*i. e.*, of at least twenty minutes' duration—as in the acute cases of synovitis—and should, furthermore, when possible, take place several times daily, particularly on the first and second day after the accident. Such a procedure reduces the length of the cure to a considerable degree.

To sum up the treatment:

(1) At the initial stage in the presence of classical phenomena, including a great deal of pain, effleurage. (2) When the pain has decreased a great deal, frictions and passive movements; later, active movements. Walking at the beginning ought not to be permitted. (3) In all sprains of the lower extremities, after every séance, application of a gauze bandage, a precaution all the more indicated when the patients are allowed to use their legs and walk. (4) In order to prevent real relapses as well as to prevent the inflammation taking on a chronic character, the treatment ought to be kept up until complete restitution has taken place.

EXPERIMENTS TO DETERMINE THE VALUE OF OXYGEN IN COMBINATION WITH THE DIFFERENT GENERAL ANÆSTHETICS.*

By JAMES T. GWATHMEY, M.D.,

NEW YORK,

ANÆSTHETIST TO GOUVERNEUR, THE NEW YORK SKIN AND CANCER, AND CHARITY HOSPITALS.

My attention was first drawn to this subject by the remarkable and to me unwarranted difference, that Mr. Hewitt in his most excellent work on anæsthetics makes between nitrous oxide and oxygen and nitrous oxide and air on the one hand, and chloroform and oxygen and chloroform and air on the other. In the first instance, he states: "It is now established beyond all doubt that by employing certain percentages of atmospheric air with nitrous oxide a better form of anæsthesia can be obtained than with the undiluted gas, and that by using oxygen instead of atmospheric air, a still better form of anæsthesia is obtainable."

In referring to chloroform and oxygen he dismisses the subject in a few lines, saying he has had no personal experience with it, as it seems to offer no special advantages. Theoretically, oxygen *is* indicated with every anæsthetic and at all times. Normally for every volume of inspired air 4.8 per cent. of oxygen is abstracted, 4.3 per cent. of carbonic oxide is added. When narcotized the blood becomes more and more venous from two causes: (1) Any obstruction to the entrance of air into the lungs; (2) the blood not taking up from the air its usual supply of oxygen.

We also know that asphyxia is produced more by the diminution of oxygen than by the increased amount of carbon dioxid. According to Patton, Rumph found a decrease of 40 per cent. of carbonic oxide eliminated in the respiratory exchanges, and Richet found a decrease of 50 per cent. in the elimination of carbonic oxide in chloralized dogs. Bert's experiments with chloroform show a progressive diminution in oxygen absorbed and of carbonic oxide given off. Lorrain Smith has shown that dyspnœa from change in the gaseous composition of the blood may be due to a deficiency of oxygen.

Richet states that blood which contains an anæsthetic in solution preserves, when shaken with air, its full ability for fixing oxygen. Irregular forms of breathing may also occur from too little oxygen, as in the close administration of volatile agents; or from carbonic oxide dyspnœa, as in rebreathing during the administration.

It might be as well here to refer briefly to the his-

* Read at a meeting of the Surgical Section of the New York Academy of Medicine, October 7, 1904.

tory of nitrous oxide and oxygen. As this special combination has been so fully experimented with and practically demonstrated by Hewitt and others, it would have been superfluous for me to attempt anything further. In 1868 Dr. E. Andrews, of Chicago, published accounts of several cases in which, by mixing oxygen with nitrous oxide, he had obtained a more satisfactory form of anæsthesia than with nitrous oxide alone; but his observations failed to attract the attention they deserved. Paul Bert in 1878 again drew attention by a series of experiments to this form of anæsthetizing. In his concluding remarks on nitrous oxide and oxygen, Hewitt states that those patients who otherwise might evince symptoms of embarrassed breathing at the acme of ordinary nitrous oxide anæsthesia, are certainly less likely to do so in the presence of oxygen, and that no fatalities have been recorded with this anæsthesia.

The object of giving oxygen instead of air with nitrous oxide, is to be able to replace the high per cent. of useless nitrogen in the air by a corresponding amount of useful nitrous oxide, the percentage of oxygen remaining the same. Cyanosis and other evidences of diminished blood oxygenation will thus be prevented.

Chloroform and oxygen anæsthesia was first introduced by Neudorfer of Vienna in 1886. He excluded all air and used a tightly fitting face-piece. Bertel stated before the St. Petersburg Medical Society that a more rapid and successful anæsthesia follows its use, and that it is practically free from risk.

Kreutzmann used a Junkers chloroform inhaler for this method, allowing oxygen instead of air to pass through the chloroform. The *British Medical Journal* of January 25, 1896, states that the number of cases in which chloroform and oxygen have been employed by either of these plans, has been too few for any definite conclusion to be drawn as to its value. If, as is claimed, it lessens excitement, vomiting, and after headache, and robs chloroform of much of its danger, it does a great deal and deserves further trial and careful study.

Different surgeons and anæsthetists have from time to time recommended the Junker inhaler and the vapor method of giving chloroform. A few of them have further stated that oxygen is preferable to ordinary air on account of its minimizing the after-effects of the narcosis. But no experiments have been made or reasons given up to this time, as to why we should use oxygen instead of atmospheric air with the different anæsthetics. As the main object of this paper is to state (and I hope prove) a new principle, still it might be wise to pause here sufficiently long to note a very glaring defect in the Junker chloroform inhaler as sold and used in Great Britain and elsewhere to-day.

This inhaler has a closed mask, with an expiratory valve. In pumping the vapor to the patient there is no possible method of determining whether or not said patient is getting a sufficient supply of it at each inspiration. If the amount is insufficient, a terrific and needless strain is placed at once upon both heart and lungs, which if repeated, could easily bring on a train of asphyxial symptoms that it might not be possible to check. This has been remedied (in my cat inhalers) by placing a very small, thin, and easily inflatable rubber bag next to the inhaler, and by keeping this two-thirds full, this danger is eliminated. The principle that I have deduced from my experiments in this, *oxygen increases the value of all anæsthetics as regards life, without decreasing their anæsthetic effect.*

The experiments of Priestly and others, with which you are all familiar and as cited in Dr. Wallian's translation of Demarquay's work on Pneumatology, of placing small animals under two different receivers, one filled with oxygen and the other with air, show that those under the oxygen receiver survived twice as long as the others; also, that the death of birds in oxygen was not accompanied by convulsions, as those that died in air; also, that the heart retains its irritability for several hours when death takes place in oxygen.

Demarquay immersed two kittens in water and kept them there until they had lost consciousness and were completely asphyxiated. One had previously been confined for twenty minutes in a glass case containing two parts of oxygen and one of air, the other had breathed only atmospheric air. On removing them from the water there was only a slight movement of the lower jaw. At the end of a minute and a half the superoxygenated kitten arose and totteringly walked around and made an uneventful recovery. The other partially recovered at the end of fifteen minutes, but died the next day. These experiments were repeated a number of times, but always with the same result.

The above experiments, illustrating the value of oxygen as compared to air, have been practically paralleled by me in using them with the various anæsthetics. Regardless of the anæsthetic used, animals have lived twice as long with oxygen as when air was used. They usually die quietly with oxygen, and in convulsions with air. With oxygen their hearts also continued to beat longer after respiration ceased. I may add here that the heart always continued to beat a variable length of time after respiration ceased, whether air or oxygen was used, and with all anæsthetics. I have also been more often successful in reviving them after death when oxygen was used, than with air. I have not allowed them to come to and noted the after effect, but as I constantly use oxygen in my private practice with both chloroform and ether, I can state absolutely that it reduces the after effects to a minimum.

In my experiments I have used a closed mask with an expiratory valve, with the light rubber bag already referred to, just behind the mask. I have used exactly the same amount of anæsthetic (ʒvii) and have also attempted to so regulate the flow of air and oxygen that the technique in each instance would be the same. In order to determine the difference in toxicity of the drugs used, the time was taken from the application of the mask to the stoppage of the heart. As the toxic effects came on so rapidly, observations on the pulse and respiration and blood pressure were of little value. These will be reported in a subsequent paper, when the methods of anæsthetization will be entirely different. To make these experiments valuable and as accurate as possible, I have killed over one hundred cats altogether, and have recorded the average time. In selecting the feline subjects for these experiments I have not deemed it necessary to enter into details of the exact weight, age, size and physical condition of each animal. I have, however, endeavored to select for each comparison animals as nearly alike in all essential respects as possible. The results have, as will be seen from the table, varied in accordance with individual characteristics and conditions; but the result as a whole is seen to uniformly and invariably confirm the claim that the use of oxygen in connection with any form of anæsthetic, practically eliminates the percentage of danger which has hitherto been recognized as inseparable from the practice of anæsthesia.

Twenty-six cats were killed with chloroform and air, the average time being nine minutes, the shortest

time three minutes, the longest seventeen minutes. Thirty-eight cats were killed with chloroform and oxygen, the average time being twenty-one minutes, the shortest time five minutes, and the longest one hour and a half.

With one part chloroform and two parts ether I killed thirteen cats in all, six with air and seven with oxygen; the average time with air was nineteen minutes; with oxygen thirty-five minutes. The shortest time with this mixture and air was fifteen minutes, the longest time thirty minutes. The shortest time with oxygen was sixteen minutes, the longest one hour and ten minutes.

With ether and air twelve were killed, the average time being nineteen minutes, the shortest time fifteen, the longest thirty-three minutes. Seven were killd with the same anæsthetic and oxygen, the average time being thirty-five minutes, the shortest twenty-five and the longest one hour. With anæsthol six were killed altogether, three with air and three with oxygen, the average time with the first combination being nineteen minutes, with oxygen fifty-six. The shortest time with air was ten minutes, the longest twenty-six; the shortest time with oxygen fourteen and a half minutes, the longest one hour and fourteen minutes; but too few experiments have been made with it to admit of a comparison with the other general anæsthetics; however, it is improved more than any of the others by oxygen, its value being nearly three times as great as when administered with air.

From the above it will be seen that chloroform and oxygen is more than twice as safe as chloroform and air, and is also safer than any of the other general anæsthetics with air. This means that instead of a very high mortality, chloroform and oxygen is now as safe as ether. But all of the other general anæsthetics are also increased in value by oxygen.

From the above data it will be seen that the principle stated in the first part of this paper is true, viz., *oxygen increases the value of all anæsthetics as regards life, without decreasing their anæsthetic effect.*

I have to thank the Kny-Scheerer Co. and the Walton Oxygen Co. for efficient assistance.

NOTE.—After the reading of this paper, three cats were anæsthetized, with the following results: Chloroform and air, death in twenty minutes; ether and air, sixteen and a half minutes. At the end of fifty-one minutes, the cat anæsthetized with oxygen and chloroform was breathing regularly, when, at the request of the chairman, the anæsthetic was stopped. Oxygen was administered for a few minutes, and the animal made an uneventful recovery.

CONGENITAL ABSENCE OF VAGINA; OPERATION.

BY A. E. ISAACS, M.D.,

NEW YORK.

ASSOCIATE PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; SURGEON BETH ISRAEL HOSPITAL.

MRS. A. S., age 26, married three years, consulted me April 17, 1904, regarding inability to have coitus, and with the object of having something done to permit of fulfilling that marital function. She never menstruated, never had any vicarious bleeding nor periodic pains. She had married the man of her own choice in preference to the one her parents wanted her to marry. Coitus was impossible, and attempts were painful, though she claimed she had sexual desire and gratification from the attempt. She said that during the contact the vulva became moistened with her own secretion.

Her general appearance and development is that of the normal female except that she has a double thumb on one hand. The breasts are well developed, labia majora and minora, urethral orifice, hair on mons and labia are all normal. The orifice of the vagina is covered in by skin from the inner reflections of the labia minora. Pressure with the finger on this area allows of its deepening about a half inch beyond the labia minora. This she says has not been so originally, but is the result of a stretching done by a midwife and of attempts at coition. The pain she complained of is due to some tenderness at the fourchette. A rectal examination disclosed no evidence of the presence of the uterus and ovaries. The subsequent examination under anæsthesia previous to operation, made by Dr. A. Brothers and myself and members of my house staff, revealed no evidence of the presence of any rudimentary uterus or ovaries. There was found a fibrous band running across the pelvis from side to side between the bladder and rectum, very likely the remains of undeveloped Müller's ducts.

As she was anxious to have something done solely for the sake of permitting coitus, I undertook to do what I could to construct a canal, though I had my misgivings as to results. The generally advised procedure is dissection between the bladder and rectum for two to three inches and utilization of the neighboring skin for flaps to cover in the raw surface, or utilization of redundant vaginal tissue from

another patient, or Thiersch skin grafts for the same purpose. These procedures did not appeal to me as giving hope of satisfactory results, especially as even their advocates were not enthusiastic regarding their success. Plastic work with flaps from the same patient would not supply enough to cover in sufficient surface for an orifice of large enough calibre, even if the flaps would stay where they were put and unite primarily, which in itself could hardly be expected. Vaginal tissue from another patient could not be obtained in sufficient quantity, and even if it could would have little chance of becoming vitalized. The objections to Thiersch skin grafting as a lining for the cavity would be the impracticability of thoroughly covering the vault and sides and keeping the grafts in place during the necessary manipulations.

I thought that if I could preserve a circle of tissue *in situ* to form the vault and push it up to its new position by loosening its adhesions as deeply as necessary, I could then, while holding the vault in its position by pressure inwards with a glass vaginal dilator, apply Thiersch skin grafts to the circumferential gap produced, first on one side, then on the other by tilting the dilator from side to side, and because of the limited movement of the dilator necessary, not disturbing those grafts already put in place.

I proceeded on these lines, making first a circular incision through the mucous membrane, beginning just below the urethra in front, crossing over to and including almost the whole labia minora on either side and from there well outside the vaginal orifice and on to and across the perineum. This gave me quite a large circle of skin that when loosened and pushed up into place sufficed not only for the top of the cavity, but for a small distance down on the sides as well. Its attachments were loosened up freely whenever they were found to interfere with its being pushed up into place, until the whole length of the glass dilator, fully three inches, entered the newly made canal. Now, while holding the dilator in, under tension against the vault, by tilting it to one side and retracting the margin of the orifice in the opposite direction, the gap of raw surface, one part at a time, was approachable for placing the Thiersch grafts. These were taken from the patient's thigh and immediately placed in position.

From the time the grafting was begun until the end of the operation the dilator was held in position under tension against the vault and then strapped in place with long strips of adhesive plaster over the buttock and abdomen to prevent disarrangement of the grafts. This dressing was maintained with the patient perfectly quiet on her back for five days, the bladder being catheterized and the bowels retained. On the sixth day the dilator was removed for cleansing purposes. It was then replaced for three days and subsequently removed daily for a vaginal douche.

The adhesive plaster becoming troublesome, was replaced in the second week with a McIntosh uterine supporter arrangement, the rubber bands of which were adjusted to hold the glass dilator in the vagina under tension. With this she was able to walk around.

The grafts all took nicely except at the upper angles of the incision in the labia minora, but this had cicatrized over by the end of the second week. The dilator was kept in the vagina for eighteen days, and so long as it was retained it necessarily kept the cavity from contracting. It was then removed and no further dressing applied.

At the end of the third week the patient was allowed to leave the hospital with instructions to report in a week, which she did. On this examination I found a vagina freely admitting two fingers for two and a half inches, and with a little pressure almost three inches, without causing any pain. She was instructed that she might now fulfil her marital duties and to report back again.

On August 1, over three months after operation, examination showed a canal of sufficient calibre to admit two fingers for two and a half inches. The patient stated that coitus was natural and conditions satisfactory.

Structural Alterations of the Thyroid Produced by Phosphorus and Arsenic in the Treatment of Goiter.—Luigi Macaggi details experiments entered into by him with reference to the effects of phosphorus and arsenic on the thyroid of dogs. In cases of exophthalmic goiter in man it has been found that the amount of iodine in the gland is 90 per cent. less than normal, while the phosphorus is markedly increased. The administration of phosphoric acid causes the iodine to increase, while the phosphorus decreases. The probable effect of the phosphorus is to increase the activity of the gland. At the same time, the size of the tumor decreases, especially in hyperplastic and vascular goiters, and in Graves' disease. In his experiments the drugs were injected into dogs, and after death the bodies were examined. Microscopically, in both cases, the glands were much congested and reddish, and the superficial veins were markedly injected. The lymphatic glands were filled with colloid material. In the thyroid there were some areas of fumefied epithelium, more transparent and stained with difficulty. In more rapid cases there was fatty degeneration of the epithelium. In slower cases, the contents of the glandular utricles were decreased, and there was an increase of colloid material in the lymphatics. In acute cases of poisoning with arsenic or phosphorus there is therefore an increase and a migration of colloid material toward the lymphatics, while in subacute cases there is a lessening of the colloid and an atrophy of the epithelium.—*La Riforma Medica.*

Some Symptoms and the Leucocyte Formula in Acute Poisoning by Mushrooms.—Umberto Gabbi reports three cases of poisoning by mushrooms that he has carefully observed, and in which the examination of the blood was carefully made. Two of the patients recovered, the other died. All commenced with severe and violent vomiting, and the stomach became dilated, the liver and spleen enlarged. The vomiting was bilious in character and was regarded by the author as indicating a true overaction of the liver in the effort to eliminate the poison. The arterial pressure was lowered, while the pulse was somewhat increased in frequency. The fungus eaten was believed to be *Agaricus virosus*, which contains muscarine and amanitine. Muscarine is an arterial depressant. The blood examination showed increase of hæmoglobin, slight leucocytosis, marked polynucleosis, and many large mononucleated cells. The polynucleosis he interprets as due to an organic reaction against the poison, rapid, marked, and lasting.—*La Riforma Medica.*

The Suprapubic Transverse Incision.—Vertes says that the Pfannenstiel incision has been found very satisfactory at Döderlein's clinic in Tübingen. In pelvice operations it possesses many advantages over the vertical incision, particularly in the diminished risk of ventral hernia, and in the greater ease with which the lateral portions of the pelvis can be reached. It is well adapted to replace vaginal operations, since the scar is concealed beneath the pubic hair, and is, therefore, not disfiguring. These facts are illustrated by the statistics of the clinic. In 1903 the median incisions were to the transverse incisions in the ratio of 2.8 to 1, and twice as many laparotomies as vaginal operations were done. In the first half of 1904 the transverse incisions exceeded the vertical incisions in the ratio of 1.4 to 1, and laparotomies were three times as numerous as vaginal operations.—*Zentralblatt für Gynäkologie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, November 19, 1904.

THE NATURE OF CARCINOMA.

SURROUNDED by the whitening bones of many shattered theories, the Sphinx of modern medicine still turns an inscrutable countenance upon her questioners, but undaunted by the fate of his predecessors a new Œdipus comes forward with a ready answer to the grim riddle. Kelling (*Münchener medizinische Wochenschrift*, June 14, and October 25, 1904) propounds a theory which not only appears plausible, but surpasses all others in that it is not merely of theoretical interest but promises to be possibly of direct service in the fields of diagnosis, treatment, and prophylaxis. He agrees with the adherents of the parasitic theory in believing that the causative factor enters the body from without, and with the followers of Cohnheim in concluding that the heterotopic cells occurring in malignant tumors are embryonal in nature. The combination of these two views leads to the conclusion that embryonal cells from animals other than man gain access to the human body, and lodging there proliferate to form tumors. The normal cells are kept in physiological restraint by certain properties of the body fluids such as the lymph, but these intruders of foreign nature are subject to no such dominance, and their growth is therefore characterized by the lawlessness typical of malignant neoplasms. Such cells are supposed to enter the blood or to be deposited in the wounds of the skin or mucous membranes, by way of the food or through the medium of carnivorous insects.

The embryonal cells most commonly gaining entry to the body are those found in hens' eggs, and the author began his experiments with these. Triturations of chick embryos, such as are found in eggs that are a few days old, were injected into dogs, with the result that tumors having the gross and microscopic characteristics of malignancy were produced. The similar administration of cells from pigs' embryos gave a like result. Every effort was made to exclude sources of error, but of themselves these results, though noteworthy, would not have the significance they do were it not for the next step. A portion of the tumor in a fatal case of gastric carcinoma was macerated and the extract injected into a rabbit. In due course of time this animal yielded a serum which not only gave, as was to be expected, a precipitin reaction with extract of the tumor and with human albumin, but also one with *chicken* albumin, though not with any other sort of albumin, thereby proving that the tumor contained a recognizable amount of albumin having the characteristics of that obtained from the hen. The author has tested in this way twenty-four cases of malignant disease in man and obtained positive results in eleven. Nine of these were new growths of the intestinal tract and gave the reaction for chicken albumin, while a sarcoma and teratoma of the ovary and testicle, respectively, responded to the test for pig albumin. The author ascribes the negative results in the other cases to possible change in the foreign albumin through degeneration of the cells, to inadequate extraction of the albumin, and to the fact that in the cases in question the albumin may have originated from animals other than the hen or pig.

It is possible to go even further than this, however, and we may expect to find that the circulating blood of carcinoma patients contains substances capable of giving a precipitate with the serum of rabbits adapted for the specific albumin. In fact, out of fifteen cases tested in this way by the author, a positive reaction was obtained in ten, using only chicken and pig sera. The inestimable advantage of being able to make an early diagnosis of such conditions as gastric carcinoma, in which operation loses much of its value when performed after the disease is recognizable by the ordinary methods, needs no comment. In one case described by Kelling he operated solely on the strength of the positive serum reaction and found a new growth of the lesser curvature high up under the ribs where it was not accessible to palpation. In three other cases diagnosed as carcinoma on the clinical evidence, but giving a negative reaction, laparotomy revealed non-malignant conditions. A consideration of the facts involved shows that the production of a serum which shall at least prevent or retard recurrences does not seem unlikely, and the author is making attempts in this direction.

A prophylactic crusade carried out on the lines suggested by this theory does not present the difficulties attending the prevention of microbic disorders, and offers much better chances of success. The author says that it is probable that the various other sources of such embryonal transplantations will be discovered, and these must be excluded from our dietary in the uncooked state. Eggs of all sorts, including fish roe, must be well cooked, and great care be taken to prevent contamination of sausage meat, etc., with embryonal tissues from the uteri of the sows or other food-animals used. Insects of all sorts, and also cats and dogs through their habits are likely to be carriers of infection and must be treated accordingly. So sanguine is the author that he expresses the belief that the younger generation of medical men will live to see the day when cancer will be a rarity among people of the educated classes. Whatever merits this theory will ultimately be found to possess, its publication should at least stimulate investigation in what appears to be a promising field of research.

THE TREATMENT OF POST-PARTUM HEMORRHAGE.

IN *The Practitioner* for October are three articles written severally by an English, a Scotch, and an Irish obstetrician on post-partum hemorrhage. The first article is contributed by Dr. D. Berry Hart of Edinburgh. As to the treatment of hemorrhage during the third stage of labor, the writer describes the procedure as follows:—The uterus is firmly grasped

—thumb in front, fingers behind—and squeezed and shaken as it were; usually it becomes firm at once. A hypodermic injection of ergotin is then given. Should this fail, the fingers of the right hand are passed into the vagina, the cervix is grasped all round by the fingers, and the uterus bimanually compressed and anteflexed. In the meantime the nurse has the hot douche ready (115° to 120° F.), and she is instructed to push the tube into the vagina, the practitioner's fingers guiding it up to the roof of the vagina. The hot flow reflexly stimulates the uterus, bringing on retraction and stopping the undue discharge. If, after the placenta is expelled or removed, bleeding begins again, or commences for the first time, it is strict post-partum hemorrhage, and must be treated as described above.

Dr. Hart sums up the main points in treatment as follows: During the labor one must avoid the extremes of undue delay and undue haste. Forceps and turning, when necessary, should be employed whenever possible with dilated parts. The third stage should not be hurried, as meddlesomeness exhausts the uterine muscle. One should let the uterus in a normal case separate the placenta and membranes, but the expulsion may be aided by suprapubic pressure. When hemorrhage occurs from the passive portion of the genital tract, the treatment consists in pressure or suture; when it is from the active position, all that secures uterine retraction, and failing this pressure by tampon, must be considered.

Dr. John Phillips of London considers post-partum hemorrhage under four heads: (1) Visible hemorrhage. (2) Concealed. (3) Traumatic. (4) Secondary. In the treatment of the first condition, Dr. Phillips resorts to the bimanual method and hot water; but if the hemorrhage still continues, he passes a Sims speculum into the vagina and plugs the uterine cavity with sterilized gauze, or applies a solution of adrenalin to the interior, at the same time observing whether from any laceration of the cervix, vagina, or perineum any large amount of blood is being lost. Concealed hemorrhage into the dilated uterus in so-called hour-glass contraction is treated by removing the causative agent, viz., the clot, from the cavity of the uterus. Traumatic hemorrhage, which arises from laceration of a large vessel in the cervix, vaginal wall, or perineum, with an excessive lochial flow still going on after the uterus is well contracted, should be treated by the patient being placed upon her back, the buttocks being well over the edge of the bed and the knees drawn up, and a large Sims speculum then passed. Should the hemorrhage be coming from the cervix, a deep suture passed with a curved needle beneath the bleeding points would be sufficient to prevent it. If the hemorrhage arises from a vessel in the vagina or perineum, its ligature, and complete control of the circulation, is a very simple procedure. If slight rupture of the uterus in its lower segment has occurred, careful packing with sterile gauze will be, as a rule, sufficient. The treatment of secondary post-partum hemorrhage is obviously that of other hemorrhages.

The third paper is by Dr. Henry Jellett of Dublin, who lays down five principles to be followed in the case of post-partum hemorrhage. These principles may be formulated as follows, assuming that a case of hemorrhage is to be dealt with which commenced during the third stage of labor, *i.e.* prior to the expulsion of the placenta: *First principle:* When hemorrhage occurs after the birth of the infant, we should stimulate uterine contractions, in order that the uterus may empty itself. *Second principle:* If the uterus fails to do so, and if hemorrhage continues, the uterus must be emptied artificially. *Third principle:* If the hemorrhage still continues, further measures to stimulate uterine contraction may be adopted, provided that a dangerous amount of blood has not been already lost. *Fourth principle:* If these measures fail, the final cessation of the hemorrhage must be ensured by plugging the uterovaginal canal. *Fifth principle:* During these procedures, and subsequently, the condition of the patient must be watched and the necessary measures adopted to ward off threatened cardiac failure.

Dr. Jellett then proceeds to describe in detail the methods employed by him in carrying out these principles, which are almost identical with those adopted at the Rotunda Hospital, Dublin. As to the fourth principle—that if the hemorrhage is not checked by other measures its final cessation must be effected by plugging the uterovaginal canal—it is, says the writer, not so universally accepted perhaps as the first three. He, however, is firmly of the opinion, borne upon him by personal experience in hundreds of cases, that plugging with iodoform gauze is an absolutely effective means of stopping hemorrhage. Dr. Jellett points out that the results of the treatment outlined by him may be seen from the statistics of the Rotunda Hospital, Dublin, for the past fourteen years. During this period there were slightly over 20,000 patients confined in the hospital, and of this number two died as a result of post-partum hemorrhage, a mortality of .01 per cent.

From a consideration of the three articles in *The Practitioner*, it may be gathered that in order to arrest post-partum hemorrhage, bimanual pressure upon the uterus, injection of hot water into its cavity, or of ergotin into the circulation to assist in the action of contraction, and plugging of the cavity with some kind of tampon, are the main measures indicated.

It is in cases of atony of the muscular substance of the uterus, preventing its contraction, that treatment is most difficult.

Typhoid Fever in the Tropics.

At one time it was believed that typhoid fever was of very rare occurrence in tropical countries, in fact, as Sir Patrick Manson wrote, "the existence of typhoid fever in the tropics was for long not only ignored, but actually denied even by physicians and pathologists of repute." Dr. Thomas C. Biddle, late captain and assistant surgeon in the Kansas Volunteer Infantry, writes on the subject in the *Journal of the Association of Military Surgeons* for August, and puts forward the view that camp life and its influences, even in our Southern States, so changed the clinical history of typhoid fever that the diagnosis was often confusing to the inexperienced in such service. At any rate, there can be no doubt that in the tropics malarial influence in a large proportion of cases of typhoid fever alters the characteristic symptoms of the disease. Typhoid fever now ranks, not only as a common tropical malady, but to the white man there as one of the most deadly.

Referring to tropical typhoid fever, as observed by him in Porto Rico, Dr. Biddle says: "Of the peculiarities of tropical typhoid fever the one that impressed me most strikingly was the presence of

hemorrhagic complications. Intestinal hemorrhages were frequent and alarmingly excessive, although if the hemorrhage was not fatal, the fever usually subsided, and the cases progressed more favorably after the hemorrhage." The writer concludes that these hemorrhagic symptoms are due to blood changes, and that they are the most distinctive characteristic of tropical typhoid fever. He also draws attention to the fact that the temperature and pulse range were not especially different from those observed in temperate latitudes.

With regard to treatment, Dr. Biddle believes that the most desirable place to treat tropical typhoid is in a well-floored and drained tent, and he thinks that fever patients should be allowed to remain where they are located until convalescence is established. He is of the opinion that the practice of carrying typhoid fever patients home in hospital ships during the course of the disease is not good.

Texas Fever in the Philippine Islands.

Bulletin No. 2 of the Entomological Division of the Biological Laboratory, Manila, has been recently issued. The subject is, "Texas Fever in the Philippine Islands and in the Far East," and the authors are Dr. James W. Jobling and Dr. Paul G. Wooley. In November, 1903, American cattle of medium size and of good antecedents were imported into Manila, in order to attempt to improve the grade of native animals. So as not to introduce Texas fever, the cattle exported from the United States had been purchased at places 100 to 150 miles north of the Texas-fever line, in California, all the animals having been raised in the places where they were bought with the exception of one heifer. At the time of disembarkation the animals appeared to be in good condition and not suffering from any acute or chronic disease. The animals were immediately immunized with immune serum, and as soon as virulent blood could be obtained "simultaneous inoculation" was given to all but one animal. The animal from which the virulent blood was taken was received from Shanghai on November 28, developed rinderpest within a few days after arrival without having been inoculated, and was bled to death on December 3, 1903.

The results of treatment in the cases of the American cattle were disastrous, for in a short time, varying in individual cases from four to eight days, the temperature rose abruptly to between 41° and 42° C., and five of the animals died.

Besides these cases, two others occurred in Australian cattle, which were said to have come from a district where neither the ticks nor the disease itself had ever been seen. The animals were temporarily immunized with serum, but shortly after both died with symptoms of Texas fever, and the organisms were found in stained specimens of the blood.

These facts at once brought up the question as to the origin of the disease, and in order to answer this question it was necessary to discover whether the native or Chinese animals were immune to the disease, and whether or not American cattle presumably not immune could be infected by injecting into them the blood from the healthy native or Chinese cattle. The experiments undertaken to elucidate these points showed, first, that native or Chinese animals could not be infected with Texas fever by subcutaneous inoculation with relatively large quantities of blood containing the living parasites; second, that susceptible, nonimmune American animals would acquire the disease following injections of blood taken from apparently healthy Chinese animals which had been immunized to rinderpest in the Philippine Islands; third, that the disease dealt with was true Texas fever, and not the atypical South African, or Rhodesian fever; and fourth, that a tick (*Boophilus australis*), the intermediate host of the parasite of Australian piroplasmosis, is present in the Philippines. The conclusion reached by the investigators was, therefore, that Texas fever is endemic, not only in India, but also in China, Java, Borneo, Cochin China, Singapore, and the Philippine Islands, and that the majority at least of all native and Chinese animals are immune to the disease.

The Evil of Soft Food for Children.

At the Congress of the British Royal Institute of Public Health, held at Folkestone on July 21, Mr. J. G. Turner called attention to the fact that soft food was a fruitful source of caries in young children, starch and sugar, which undergo acid fermentation, being specially harmful and preparing the way for bacterial attacks on the dentine. He advocated hard food as a preventive of caries, insuring mechanical cleansing of some parts and flushing of others by saliva.

At the same meeting Dr. Harry Campbell read a paper on the same subject. He dwelt upon the great importance of giving children their starchy food in a form compelling adequate mastication. He drew attention to the fact that not only were digestive disturbances occasioned by soft food, but the maxillary apparatus not being exercised adequately did not develop properly, neither did the nasal passages nor the nasopharynx. The teeth were apt to be irregular and to decay early, and the child became the victim of adenoids. That the latter was a dietetic disease the speaker had no doubt. Dr. Campbell advised that hard, solid foods should be given at the age of seven months, when the infant should be allowed to gnaw at chop bones and chicken bones and to eat hard, leathery crusts, biscuits, sugar-cane, and certain fruits. In this way the child learned to masticate by instinct, and not till then should a limited quantity of the softer farinaceous foods be permitted. Throughout childhood, concluded the speaker, the bulk of the starchy foods should be in a form which would compel mastication, since that not only favored the development of passages and nasopharynx, but further insured buccal digestion.

Exanthematic Typhoid Fever.

The qualification exanthematic has been applied to a form of typhoid fever characterized by excessive profuseness of the roseolous eruption. The spots often make their appearance early, are of marked size, present in large number, and distributed over the entire cutaneous surface. They may be ecchymotic or papular. It would appear as if an inverse relation existed between the number of the rose-spots and the intensity and extent of the intestinal lesions, as in the exanthematic type the intestinal symptoms are said to be exceedingly slight, although the severity of the constitutional phenomena may be in no way mitigated. The prognosis likewise appears to be the more favorable the larger the number of spots, as the duration of the disease is shorter, while serious complications are rare.

The German Emperor is again reported to be suffering from a return of his throat trouble, and it is said that another operation will be necessary.

News of the Week.

Professor Theobald Smith of Harvard University will deliver an address upon "The Place of Research in the University Medical School" before the Harvard Medical Society of New York City, in Hosack Hall, New York Academy of Medicine, on Saturday, November 26, at 8.30 P. M. Members of the medical profession are cordially invited to attend.

The Fourth Pan-American Medical Congress.—Dr. Rudolph Matas, Secretary of the Section of General Surgery for the United States, asks those who wish to contribute papers in this section to send titles to him at No. 2255 St. Charles avenue, New Orleans. He also announces that the United Fruit Company's agents are offering as a special inducement to American "Congresistas" a reduction of the regular fare for the round trip from New Orleans to the Isthmus to $50—that is, $25 each way. The steamers leave New Orleans every Friday: the last steamer to leave New Orleans in time for the opening of the Congress will sail on December 30, 1904, at eleven A. M. The voyage to Colon takes four and a half days, but the return trip consumes seven days on account of a stop-over at Port Limon, where ample opportunity is given to tourists to visit San José.

University of Pennsylvania Medical Alumni Association.—The following have been elected officers of the Philadelphia Alumni Society of the Medical Department of the University of Pennsylvania for the ensuing year: *President,* Dr. J. F. Schamberg; *Honorary Vice-President,* Provost Harrison; *Vice-Presidents,* Drs. De Forest Willard, Edmund W. Holmes, John Marshall, A. H. Davisson, Joseph Gibb; *Treasurer,* Dr. Herbert B. Carpenter; *Secretary,* Dr. B. F. Stahl.

National Association for the Study of Epilepsy.—The fourth annual meeting of the National Association for the Study of Epilepsy, etc., will be held in the Medical Library, "The Fenway," Boston, on November 22. The Association invites all persons interested in the welfare of epileptics, and in charity work generally, to attend this meeting. A number of papers on the etiology, progress, and treatment of epilepsy will be read. The objects of the Association are: (1) To promote the general welfare of sufferers from epilepsy; (2) To stimulate the study of the causes and the methods of cure of this disease; (3) To advocate the care of epileptics in institutions where they may (*a*) receive a common school education, (*b*) acquire trades, (*c*) be treated by the best medical skill for their malady; (4) To assist the various States in America in making proper provisions for epileptics. The officers of the accociation are: *President,* Dr. William N. Bullard, Boston; *Vice-Presidents,* William P. Letchworth, LL.D., Portage, N. Y.; Dr. William Osler, Baltimore; *Secretary and Treasurer,* Dr. William P. Spratling, Sonyea, N. Y.

An International Congress of Surgery.—Announcement is made that the first congress of the International Surgical Society will be held at Brussels in September, 1905, under the presidency of Prof. Th. Kocher of Berne. The congress, which will be participated in by members only, will be devoted wholly to a discussion of the following six subjects: 1. "Value of Blood Examinations in Surgery," discussion to be opened by Drs. W. W. Keen of Philadelphia, Sonnenburg of Berlin, Oritz de la Torre of Madrid, and Depage of Brussels. 2. "Treatment of Hypertrophy of the Prostate," by Drs. Reginald Harrison of London, Rovsing of Copenhagen, and Von Rydygier of Lemberg. 3. "Surgical Intervention in Non-cancerous Affections of the Stomach," by Drs. Mayo Robson of London; Von Eiselsberg of Vienna, Mattoli of Ascoli Piceno, Monprofit of Angers, Rotgans of Amsterdam, and Jonnesco of Bucharest. 4. "Treatment of Tuberculosis of the Joints," by Drs. Bier of Bonn, Broca of Paris, Bradford of Boston, Codivilla of Bologna, and Willems of Gand. 5. "Treatment of Peritonitis," by Drs. Lennander of Upsala, Friedrich of Leipzig, Lejars of Paris, McCosh of New York, Krogius of Helsingfors, and De Isla of Madrid. 6. "Diagnosis of Surgical Diseases of the Kidney," by Drs. Albarran of Paris, Kümmell of Hamburg, Giordano of Venice, and Lambotte of Brussels. All communications relative to the congress should be addressed to M. le Dr. Ch. Willems, 6 Place St.-Michel, Gand, Belgium.

The Englewood (Ill.) Union Hospital.—This institution is projecting a new building. The institution was established in January, 1893, and was first located on Sixty-ninth street, near Stewart avenue, in a two-flat building. The next fall it was moved into a twelve-room house on Wentworth avenue and remained there until the spring of 1894, when it was moved to 840 West Sixty-fourth street, into a six-flat building containing fifty-four rooms, where the institution now is. The cause of moving each time was the need of more room, and another move must be made because of insufficient room to take care of the patients.

Legacies to Cincinnati Hospitals.—The various charitable institutions remembered in the will of the late Mrs. T. C. Bradford of Cincinnati, who died last September, that have since been led to believe that they would receive nothing because the will was not made prior to the time required by the statute of limitations, are to get their legacies. The decision was rendered November 10 that, inasmuch as Mrs. Bradford left no direct heirs, the statute is not applicable in her case. Mrs. Bradford left $5,000 to the Presbyterian Hospital, $1,000 to the Ohio Hospital for Women and Children, and $1,000 to the Children's Home.

Fire in Children's Hospital.—The two-story frame building of the Staten Island branch, at Castleton Corners, of the Nursery and Child's Hospital on Lexington avenue, was destroyed by fire on November 7. The two hundred children in the hospital escaped uninjured, but the loss to property is estimated at $10,000. The fire started in a defective flue.

New Manhattan Eye and Ear Hospital.—The plans for the new building of the Manhattan Eye and Ear Hospital to be erected in Sixty-fourth street, on a plot of nine lots just east of Third avenue, provide for what will undoubtedly be one of the largest and most complete special hospitals in existence. The five-story building, which is to have a frontage of 118 feet and a depth of 125 feet, will cost between $350,000 and $400,000, and is expected to be ready for occupation in about fourteen months. The first two floors will be devoted to the out-door department, the third floor is for private patients, and the other stories will contain the public wards. Accommodations are planned for 122 indoor patients, and provision is made for ample operating room and laboratory facilities.

French Hospital Opened.—With appropriate formalities the new French Hospital at Nos. 450-458 West Thirty-fourth street was opened last week by the president of the French Benevolent Society, Henri Maillard and M. Jusserand, French ambassador to the United States. The hospital, which has been two years in course of construction, has

cost $400,000, and is designed to accommodate 150 patients. The building is of seven stories. Two floors are occupied by private rooms and small wards. Two other floors are occupied by large medical and surgical wards. The operating rooms, their dependencies, the pathological laboratory, and the quarters of the house doctors are on another floor. The top floor extends over part of the building only, and is absolutely isolated. It contains the wards for consumptives and the solaria.

Women's Hospital Festival.—A fair for the benefit of the New York Medical College and Hospital for Women is to be held at the Waldorf-Astoria, on Friday afternoon and evening, December 2, under the auspices of the Hospital Guild.

Sanitary Reforms in Chicago Schools.—Dr. W. A. Kuflewski, of the Chicago School Board, has presented resolutions to that Board prescribing new methods for sweeping and cleaning public schoolrooms, claiming that the health of every pupil was daily placed in jeopardy by the system now in use. He suggests the following recommendations: That the floors of all public schoolrooms be covered with sawdust wet with a solution of bichloride in the proportion of 1-4,000, and then thoroughly swept. That all windows shall be wide open during the sweeping and cleaning of schoolrooms, provided the weather will permit. That all blackboards be wiped off with wet sponges to prevent the spreading of the chalk dust, which is exceedingly injurious to the lung tissues. That all furniture and woodwork be wiped off at least once a month with a solution of bichloride. That all windows and doors be left open during intermission, except in inclement weather. It is thought that these recommendations will be adopted by the Committee on Buildings and Grounds.

The Bactericidal Activity of Copper Foil.—Dr. Henry Kraemer professor of biology in the Philadelphia College of Pharmacy and editor of the *American Journal of Pharmacy,* has for some time been engaged in conducting experiments for the purpose of determining the usefulness of copper sulphate and metallic copper as bactericidal agents against typhoid bacilli and cholera bacilli in drinking water. He employed copper foil cleansed with pumice-stone, using a strip 3½ inches square to every quart of water, the temperature of the water being raised to between 80° and 100°. The reduction in pathogenic germs was found to be from 75 to 90 per cent. after an exposure of six or seven hours.

Dr. Henry L. Woodward of Cincinnati has been appointed physician to the Widows' and Old Men's Home, in that city, to fill the vacancy left by the death of Dr. John E. Jones.

Dr. Otis L. Cameron was elected Coroner for Hamilton County, Ohio, in the election of November 8. He fills the place of Dr. Weaver, under whom he served as Deputy Coroner.

Chicago Surgical Society.—At the annual meeting of this society, recently held, the following officers were elected for the ensuing year: *President,* Dr. L. L. McArthur; *Secretary,* Dr. William Hessert; *Treasurer,* Dr. F. A. Besley; *Members of the Council,* Drs. Arthur Dean Bevan, A. J. Ochsner, E. Wyllys Andrews, and Jacob Frank.

Mills Training School Registry.—Owing to internal dissensions the associated alumni of the Mills Training School for Male Nurses have decided to remove their registry from the school headquarters on East Twenty-sixth street, and to open a clubhouse, with a registration bureau.

Rumford Medal Awarded.—It is announced that the Royal Society of Great Britain has awarded the Rumford medal to Dr. Rutherford, professor of physics at McGill University, Montreal, in recognition of his researches on radioactivity. The Rumford medal was instituted by Count Rumford in 1796 and is awarded every second year to the author of the most important discovery or useful improvement during the preceding two years on heat or on light, the preference being given to such discoveries as tend most to promote the good of mankind.

Cholera in Russia.—It is reported that this disease is sufficiently prevalent in Russia to cause apprehensions of an epidemic. During the week ending October 24 there were sixty-five cases, with fourteen deaths.

The Pyrheliophor.—At the World's Fair in St. Louis Professor Himalya recently gave the first demonstration of the pyrheliophor, an apparatus for concentration of the sun's rays. Iron melted in less than a minute; fireclay fused in about three minutes, and magnesia, one of the most infusible substances, requiring about 6,400° F. to melt it, was reduced to a molten state in about twenty minutes. In this apparatus the rays of the sun are reflected from more than 6,000 small mirrors arranged in concave form, covering an area of 30 x 42 feet, into a retort 18 inches in diameter and 2 feet deep. The focus of the rays is about 7 inches in diameter and the heat generated is about 7,000° F. The regulation of the mirrors is now done by hand, but a clock for this purpose is being constructed.

The Southern Illinois Medical Association at its recent annual meeting elected the following officers for the ensuing year: *President,* Dr. J. W. Armstrong, Centralia; *Vice-President,* Dr. J. L. Wiggins, East St. Louis; *Secretary,* Dr. E. E. Fyke, Centralia; *Assistant Secretary,* Dr. C. W. Lillie, East St. Louis; *Treasurer,* Dr. A. T. Telford, Olney. The next meeting will be held at Mount Vernon the first Thursday in November, 1905.

The Sanitary Condition of the Subway will be officially investigated under the direction of the Board of Health by Prof. Charles F. Chandler of Columbia.

Vital Statistics of Philadelphia.—For the week ended November 12 there were reported to the Philadelphia Bureau of Health 422 deaths from all causes, as compared with 386 for the preceding week and 376 for the corresponding week of the previous year. Fifty-one deaths were due to pulmonary tuberculosis, 35 to heart-disease (not including 6 due to endocarditis and 2 to angina pectoris), 35 to Bright's disease (not including 3 due to acute nephritis), 34 to pneumonia (not including 12 attributed to congestion of the lungs and 8 to bronchopneumonia), 17 each to apoplexy and to diarrhœa and enteritis in children under the age of two years, 13 to congenital debility, 12 to old age and 11 to premature birth.

St. John's Guild.—The annual report of this society states that during the past summer the floating hospital carried 4,916 babies, 15,443 children, and 7,467 mothers, a total for the season of 27,826. The seaside hospital, at New Dorp, S. I., accommodated 668 infants, 900 children and 688 mothers, a total of 2,256. At the annual meeting the president, Mr. William Sherer, said that the disaster to the steamboat *General Slocum* was the cause of somewhat decreasing the number of persons carried on the daily trips of the floating hospital. The trustees made every effort to overcome the fear of

the public which had arisen through the disaster, but the mothers and their sick babies did not seem to enjoy the sail down the bay as in previous years.

Testing Cold Storage Meats.—The nutritive value of food preserved for a considerable time in cold storage will be made the subject of experiment by Dr. Wiley, chief chemist of the Department of Agriculture, this winter. Among the samples of food to be investigated are partridges, quail, and beef which have been lying in the cold storage warehouse at West Point for two years. This meat appears to be in perfect condition, but the "poison squad," as the food testers are called, will make a practical test of its digestibility and nutritive value. This year's experiments will also include tests of foods preserved with formaldehyde and water disinfected with sulphate of copper. Of the twelve young men who compose this year's squad five are medical students at Georgetown University.

A New Hospital for Newark.—The Essex Private Hospital Association is soon to open its building at the corner of South Eighth street and Thirteenth avenue. It contains eighteen rooms and is to be run by the fifteen physicians comprising the association as a private hospital, to which physicians may send their patients and still continue the treatment themseves.

Montefiore Home.—The annual report of the Montefiore Home shows that 889 patients have been cared for during the past year. The death rate was 11.59 per cent., as compared to 14.34 per cent. for the year previous. The annex to the institution now being built is to be named after the late Louis Gans, in recognition of his services to the home.

An Epidemic of Pink Eye.—Fifteen students of a preparatory school in Trenton are suffering from infectious conjunctivitis.

Obituary Notes.—Dr. John Ely Jones, one of Cincinnati's oldest physicians, died during the first week of November at his home in Walnut Hills. He was born at Newtown, O., in 1834. In early life he taught school at Salem, O., later graduating from Ohio Wesleyan University. He took his degree in medicine in 1861, at the Ohio Medical College. He served in the Civil War as surgeon in the 79th O. V. I. After the war he began practice in Cincinnati.

Dr. George Walton died at his home in St. Louis, on October 8, from an attack of meningitis. He was graduated from the New York University Medical School in 1873. He was 55 years of age and leaves a widow and two children.

Dr. Henry E. Allison, medical superintendent of Matteawan State Hospital since its erection thirteen years ago, died on November 12 of Bright's disease. He was born in Concord, N. H., December 1, 1851. He was a graduate of Dartmouth, where he also received the degree of M.D. in 1878. He served as assistant physician at Willard State Hospital until 1889. He then became medical superintendent of the State Asylum for Insane Criminals at Auburn. He was appointed a member of the commission to found a new asylum for insane criminals at Matteawan, and on its completion in 1892 the inmates of the old Auburn asylum were transferred there. Dr. Allison became medical superintendent and treasurer, and held the place until his death.

Dr. Charles H. Mosely, a dentist practising for half a century in Brooklyn, died on November 7 at the age of seventy-six years. He was said to have been the first dentist to make extensive use of nitrous oxide gas.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DEFECTS IN SURGICAL EDUCATION—CLINICAL SOCIETY—INFANTILE PARALYSIS OF SHOULDER—INFLAMMATION OF LIVER—PROFESSOR WINDLE—ROYAL SANITARY INSTITUTE—THE LATE ANGEL MONEY.

London, October 28, 1904.

Mr. Edmund Owen, consulting surgeon to St. Mary's Hospital, is a man of definite views and is not afraid to express them in very decided terms, though in language always appropriate as well as clear. An address by him is well worth hearing. He went to Leeds and delivered one to the medical students on the 18th, on the lack of practical methods in modern surgical education, and it would be well if students, teachers, and all educational authorities would all take to heart his statements. He began with a reference to Wm. Hey, founder of the Leeds Infirmary, and said if he had been brought under the present system, English surgery would have been robbed of one of its brightest luminaries. Hey could devote his first winter to practical anatomy, spending twelve hours a day at this foundation study of surgery. Nowadays students are brought up to believe that a knowledge of anatomy is best acquired by being taught it. Had Hey been living now, the Dean of his school would be told he was not working at chemistry or histology because he omitted some lectures which failed to interest him, or from which he could learn nothing. If he were now a student he would be strangled with red-tape.

Some months ago, Mr. Tweedy, Pres. R.C.S., called attention to the fact that students were not acquitting themselves as satisfactorily as formerly at their surgical examinations. Now Mr. Owen says they fall lamentably short in clinical work, and like the practical man he is, gives illustrations of the deficiencies in their training, which is not intended to turn out chemists, biologists, or even anatomists, but practical surgeons. To-day, he says, they depend too much on coaching. They listen to demonstrations of clinical lectures, but actual work with patients is every year diminishing, so they fail at the clinical tests. They do not know how to set about investigating a case with a view to diagnosis, *e.g.* to handle a case of hip-disease, to examine one of infantile paralysis, or test for hydrocele. They could see these daily in the out-patient room or the wards where the seniors ought to be, but they trust to a clinical veneer at the college class, and fail. It is disheartening for an examiner to be told by a candidate that he has never seen a common case.

Mr. Owen instanced one result at a little later period, when the student has qualified, but is, perhaps, useless as an assistant. He can prescribe drugs of doubtful value but undoubted expense, but cannot be trusted with the care of a simple case. Then he addressed a word to coaches on a subject that will enlist your sympathy. He said that unless they can write decent English they cannot impart the art to students. Some of their pupils write papers that would not do credit to a Board school boy. If the coaches asked him to what source he referred them for style he would say the "Gospels," the "Pilgrim's Progress," and the "Sentimental Journey." Commending the students to make some attempt at style, even in ward notes, he said the current style of medical literature is tedious to the last degree, and "now that dear old Mitchell Banks' pen is dry forever, there are few to brighten the pages of our journals and to charm the reader."

The student now gets too much teaching. He is lectured to, catechised, and crammed, until a sort of intellectual dyspepsia is produced and he loses all desire to learn. His mental food is given him hot, finely divided, peptonized. His wisdom teeth are of no further use.

Mr. Owen drew from his experience as an examiner at the College of Surgeons some samples of the imperfect way in which many candidates express themselves. Asked what they would do in certain cases, they will reply, you might do this, or you can do that, and then you may, etc. He protested against this use of the second personal pronoun. Once he was asking about the stages of a certain disease, and the candidate said: "When your inguinal glands become enlarged and you break out in secondaries." He requested him to be more impersonal, but without effect, "for he quickly went back to the second person and did not leave me until I was a hopeless physical wreck."

At the opening of the session of the Clinical Society, Dr. Frederick Taylor took the chair as the incoming president, and began his address with an expression of his appreciation of the honor conferred upon him, and passed on to review the progress of the society. The members now number 599, showing growth—nearly 60 per cent. increase in twenty years. The attendance has not been affected by the increase of societies of late years. The most popular

evenings are those on which clinical cases are exhibited, when there are, including visitors, often 100 present. Dr. Taylor said he had been looking into the record of the papers read during the last ten years to see how far treatment, apart from surgery, had occupied attention. While three-fourths of surgical papers dealt with treatment, only one-fourth of the medical papers dealt primarily with therapeutics. Notwithstanding the great advances in the treatment of medical cases by various methods, he thought there was much to be desired by direct therapeutics, apart from surgical or preventive measures. Frequently only indirect treatment is possible. Prevention is all important in relation to degenerative processes and to new growths. The president suggested that papers on direct therapeutics would be valuable material for discussion by the society.

After the address two papers were read, both of them curiously enough surgical. The first was on the treatment of infantile paralysis of the shoulder by nerve grafting. It was by Drs. Wilfred Harris and Warren Low, who have previously contributed on the subject (*Journal of Anatomy and Physiology*). In the case now exhibited progress was slow at first, but lately rapid. It is now fifteen months since the operation, and it is thought the child will completely recover. Mr. Bowlby remarked that the case showed how rapidly motor nerves may recover in early life. Mr. Fugge said the child's arm seemed functionally almost perfect. Would such have been the case if no operation had been done?

Dr. F. Buzzard congratulated the authors on their success, but seemed doubtful how far the return of movement was due to the operation. Certain cases had recovered without any such measures.

The second paper was by Mr. W. G. Spencer, who related four cases of inflammation in and around the liver. In all he thought they could exclude the influence of syphilis or alcohol, and none had suffered from biliary disease, malaria, dysentery, typhoid fever or pyæmia. The first case began with a chill, and rapid enlargement followed. The second was believed to be due to septic absorption from gastric ulceration; the third, to some infection, probably influenzal or at any rate pneumococcal; the fourth followed slight puerperal fever. It was suggested that such cases should not be labeled "cirrhosis or ascites," but the cause sought for. Surgical exploration should be resorted to and venous anastomosis has added to the interest attached to such cases.

Professor Windle, Dean of the Medical Faculty of the University of Birmingham, and its representative on the General Medical Council, has been appointed President of Queen's College, Cork. He has written on antiquarian and literary subjects, as well as on professional matters, *e.g.* "Shakespeare's Country," the "Wessex of Thomas Hardy," "Remains of the Prehistoric Age in England," with illustrations by Mrs. Windle. He will find food for his archæological taste in the collection made by Dr. John Windele (almost a namesake), of the characters of ancient Celtic writing, preserved in Queen's College. The collector was also historian of Cork. He died in 1865.

The King has conferred the title of "Royal" on the Sanitary Institute, so henceforth it will be the Royal Sanitary Institute.

Dr. Angel Money, whose sudden death from heart disease is announced as having occurred at Sydney, N. S. W., on September 2, was settled some time in London, before he emigrated. He was a London University graduate, M.B. and B.S., 1880; M.D., 1881. He joined the R. Coll. of Physicians in 1883, and was advanced to the Fellowship in 1889. He was only forty-eight at his death. A brilliant student and earnest worker, he had been elected on the staff of the Children's Hospital by 1885. Two years later he was on that of University College Hospital and assistant professor of clinical medicine. But health failed, and in 1892 he had to give up his splendid prospects. He went to Sydney, and there was successful.

Cremation in England.—It will be surprising if the remarkable weight and number of names practically subscribed to the cause of cremation within the past few months—names like those of Spencer, Edwin Arnold, Leslie Stephen, Watts, Henley, and Antoinette Sterling—are not some day noted as almost marking an epoch by the historian of what promises to be the method of the future. The Roman Catholic Church, as is well known, still refuses its last rites to those who thus defy one of the dogmas of the Nicene and Athanasian Creeds, and students will be interested to learn the fate of the petition just sent by the Berlin Cremation Society to the Pope, wherein not far short of 10,000 persons pray for the abolition of the Church's official disapproval thus expressed.—*London Chronicle.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 10, 1904.

A Case of Intraperitoneal Rupture of the Bladder.—Daniel Fiske Jones reports the case of a patient who was brought into the hospital four days after the delivery of a healthy child. The morning after the child was born, the attending physician, on making his visit, was shocked to find, as he said, the uterus up to the umbilicus, and the patient very anæmic. He piled some books on to the bed and threw the patient over on to them on her abdomen, and held her down. The uterus was curetted, and contracted well and remained of moderate size. From this time until the patient entered the hospital she had constant pain across the lower abdomen. There was some shifting dullness in the flanks. The urine contained albumin and casts. The patient urinated without difficulty, and blood was never present, except an occasional blood globule microscopically. The patient's general condition became such that a rapid laparotomy was decided upon four days after her entrance to the hospital. The bladder was found to have a vertical gaping wound in the middle of the posterior wall. The patient stood the operation very badly and died in about four hours. On the day before the operation the patient had complained of being unable to sleep on either side without abdominal pain. This symptom is very suggestive of ruptured bladder, but it is also a symptom of any irritating fluid in the peritoneal cavity, and is not pathognomonic of ruptured bladder. The incident of holding the woman down on the books the day after her confinement was not known till after the death of the patient, and the writer believes that it was a dilated bladder that was felt, and not the uterus, and that the bladder was ruptured when the patient was thrown on to the books.

New York Medical Journal, November 12, 1904.

A Case of Hodgkin's Disease.—J. V. Shoemaker reports the case of a physician, aged fifty-two years, who lived but sixteen days after coming under observation. During the last two years of his life he had vaccinated himself, but apparently with a negative result, but six weeks later a rash appeared on his body, causing intense itching, and following this there was a progressive enlargement of lymphatic glands in various parts of the body. Examination of the blood led to the diagnosis of Hodgkin's disease. The author passes to a general description of this malady. Its pathogenesis he believes to be obscure, stating that if we do not accept the theory of a tuberculous origin, we have nothing to fall back on. It is interesting to note that, in spite of the fatal result, the *x*-ray seemed to cause some diminution in the size of the glands, especially in the axillary, inguinal, and retro-peritoneal regions. Shoemaker notes that in the treatment of a case of advanced Hodgkins' disease, or of cancer, for that matter, we are confronted with three distinct dangers: (1) There may not be time enough for the procedure to produce any benefit. (2) The danger of an *x*-ray burn. (3) The danger of a rapid disintegration of the new growths with the production of toxæmia. The patient did, in fact, become toxic during the progress of the treatment, although this may have been but the ordinary termination of the disease.

Observations on a Series of Ten Cases of Disability of the Shoulder Joint.—The series is reported by H. W. Jones and N. Allison, who divide their cases into acute, subacute, and chronic. In acute cases, at the onset the patients suffered with extreme pain, referred almost invariably to the point of the shoulder, and radiating down the arm or across the scapula. Tenderness was very marked at the point of the shoulder and along the bicipital groove. The arm was held close to the trunk and motion was much restricted. There was marked muscular spasm of the shoulder girdle, and any attempts at motion caused exquisite suffering. The pain was apt to be worse at night, and the patient obtained very little rest. The temperature was usually not elevated. In the subacute stage the pain was much less, and was produced only by attempts at motion. Motion was still restricted, and the disability is practically complete. In the chronic stage acute pain disappeared, and the prominent features were atrophy and stiffness, motion in abduction being usually but a fraction of the normal. The patient used the arm chiefly through increased rotation of the scapula, which moved with the humerus as one bone. In conclusion, after giving detailed histories of these cases, the authors conclude: (1) That the affection resulted from traumatism; (2) that the lesion was circum—rather than intra—articular; (3) that permanent disability must be expected if the condition is not treated; (4) that fixation afforded relief from the pain of the acute stage, and generally from subsequent disability, and (5) that in the chronic stage, manipulation under anæsthesia would relieve the disability due to the fibrous ankylosis.

Medical News, November 12, 1904.

Hepatoptosis Complicated by Gastroptosis; a Suggestion as to Treatment.—Ellsworth Eliot states that the object of this paper is to call attention to a new method of operation in those cases in which, with gastroptosis, there is a descent of the liver as well. He describes his method as follows: The operation consists in the exposure of the liver and stomach through a median incision above the umbilicus. The obliterated umbilical vein, forming a thick cord in the free edge of the falciform ligament, is then identified and drawn forward until it comes in contact with the parietal peritoneum. The hepatic extremity of the ligament then rests against the under surface of the right lobe of the liver in front of the transverse fissure. The lower or umbilical extremity is in close contact with the anterior parietal peritoneum, the two parts of the ligament now forming a right angle. In this position the round ligament is sutured to the anterior parietal peritoneum with chromic gut, and the redundant falciform peritoneal reflection is spread out laterally and sutured to the contiguous part of the parietal peritoneum with the same material, in this way forming a species of shelf for the under surface of the liver. The abdominal wound is then closed in layers. The writer does not belittle the importance of medical measures in these cases, but when these fail, it seems wise to resort to surgical treatment. Very marked improvement has been secured in the two cases in which he has used this method suggested, and it seems worthy of early publication.

The Consumption and Elimination of Water in Dry and Moist Climates, with Special Reference to the Cause of Bright's Disease.—William S. Carter has made careful investigations along these lines, and in this paper presents several tables giving the results of his work in various localities. The conclusion seems to be justified that one takes more fluid as drink in a moist climate and passes less urine than in a dry climate. The writer thinks that probably the amount of moisture given off by the skin and the lungs in dry climates is not so great as is often thought. The sensible perspiration resulting from the effort at heat regulation on the part of the animal economy in a hot, moist climate, probably accounts for this difference. Statistics show that there is no relation between the degree of humidity or length of the warm summer season and the mortality from Bright's disease. The writer has made extensive observations in Galveston, Texas, and while there seems to be no doubt that Bright's disease is more prevalent in this city than in most other cities of this country, it seems highly improbable that the climatic conditions have anything to do with this. To the writer there are two causes that seem more plausible than the usual explanations: The excessive use of meats in a climate in which proteids cannot be so readily metabolized as in a colder climate; and the failure to recognize and properly manage acute infections. He emphasizes the fact that too much care cannot be exercised in attending to the after-effects of light attacks of acute infections.

Cicatrization Blood-Vessels in Ulcers of the Bladder.—Gustav Kolischer has noted that in some cases of ulcer of the bladder, disagreeable symptoms, such as irritation in the bladder region, frequency of urination and occasional tenesmus persisted, although the urine was perfectly cleared up and the ulcers had entirely healed. In searching for the cause of this condition, he noticed in most of his cases of traumatic ulcers that when the ulcer began to heal there were quite large blood-vessels in its neighborhood, leading to the circumference of the ulcer. In approaching the circumference of the ulcer these vessels show a meandering course. The loops lie very close to each other. These blood-vessels seemed somewhat similar to the cicatrization loops which appear running to the ulcers in the cornea of the eye. The writer thought that the persistence of these blood-vessels might have something to do with the sensation of irritation of which the patients complained, even after the ulcers had healed. Hebra explained the itching of varicose veins of the legs as due to the sensation produced by the very slow and torpid flow of the blood in dilated and meandering blood-vessels. There is a similar sensation of itching, heaviness, and so on, in cases of so-called bladder hemorrhoids. The writer obliterated these blood-vessels with the pointed galvanocautery of the operative cystoscope, and after the eschar was thrown off, which usually took about a week, the symptoms had entirely disappeared and the patients remained well.

American Medicine, November 12, 1904.

Transudates and Exudates.—Joseph L. Miller gives the results of his careful and detailed study of this subject: The color of the fluid, its reaction, and size of the erythrocytes are of little diagnostic value. Nucleoalbumin is usually much more abundant in exudates than in transudates, although many exudates fail to show more than a faint trace. On account of the constancy of the salts present, the specific gravity and amount of albumin bear an intimate relation. Fluids from different body cavities of the same individual, or fluids of the same origin in different individuals, or successive tappings of the same cavity, may show marked variation in the amount of albumin, probably explained by the permeability of the capillaries, the degree of irritation of the serous surface, the condition of the patient's blood, the tension of the fluid, the amount of absorption taking place, and, possibly, the blood-pressure. Methods of measuring the bulk albumin, as Esbach's or Purdy's, are not applicable to serous fluids. Reuss' formula is the most accurate, simple method for determining the amount of albumin in serous fluids. The diagnostic value of the specific gravity, or amount of albumin, is greatly lessened by the frequent presence, simultaneously, of several processes. A hydræmia, as a result of anæmia or transudation from pressure, may lower the specific gravity of an inflammatory fluid. Secondary inflammation, high tension of the fluid, or resorption taken place, may increase the specific gravity of a transudate. At present there is no absolutely reliable method for determining the tuberculous character of a serous fluid. The specific gravity of a fluid, when taken for successive tappings, may be of prognostic value. Epithelial cells in sheets are not infrequently present in fluids of inflammatory origin. The predominance of lymphocytes may be associated with a long-standing, simple pleuritis, a hydrothorax or a tuberculous pleuritis. The presence of relatively large numbers of neutrophiles in pleuritic fluids may be associated with an acute, simple, or a secondary tuberculous pleurisy. The presence of numerous cells, chiefly neutrophiles, suggests an acute, simple pleuritis. The presence of numerous lymphocytes, with few, if any, neutrophiles, indicates that the process is probably a tuberculous one. In ascitic fluids there is little that is characteristic. Neutrophiles are usually more abundant in fluids, due to portal stasis from cirrhosis than in tuberculous peritonitis. An eosinophilia in one body cavity may occur along with a neutrophilia in another. A study of the cellular elements in fluids, from the pleural or abdominal cavities, is of comparatively little diagnostic value, either in differentiating transudates from exudates, or in determining the character of the latter.

Chronic Prostatitis.—E. G. Ballenger declares that the literature on this subject, except within the last few years, has been both inadequate and misleading, because the pathology of the affection was unknown. The symptoms, until recent years, have been placed under the headings, spermatorrhœa, azoospermatorrhœa, prostatorrhœa, etc., and were claimed to be of neurotic origin. Chronic prostatitis may be the cause of many serious consequences, as sexual neurasthenia, sterility, impotence, and reinfections, it being a favorable nidus for lingering gonorrhœa. Before giving consent for a patient with an apparently cured gonorrhœa to marry, the secretions of the prostate and appendages should be examined. There is no disease in which more information can be obtained from a careful examination of the prostate and secretions. A discharge after urination, defecation, or physical exertions, sexual disorders, no matter how mild, urine passed often with slight pain at the end of the act, should always lead to an examination of the prostate. Treatment must be directed to complications as well as to the establishment of proper hygiene for the patient; the prostate should be treated by massage, and heat or cold variously applied. The brilliant results of prostatic surgery should stimulate increased interest in the rational medical treatment of chronic prostatitis.

The Results of Treatment of Carcinoma by the Röntgen Ray.—J. N. Scott believes that all tumors operated on and found to be malignant, except small epitheliomas of the face, should have a course of Röntgen ray treatment. The cases which best respond to this treatment are those of slow growth, whether the growth is primary or secondary to an operation. The writer's best results in carcinoma have been in recurrent growths involving the breast, next are primary growths of the breast, then the uterus, stomach, and intestines. He has several patients alive to-day who have had no treatment for two years, in whom all the symptoms pointed to carcinoma of the stomach or intestines. Three cases of carcinoma of the rectum have been failures so far as permanent relief was concerned. In fourteen cases of uterine cancer, two patients have been apparently well for two years, one had been operated on with recurrence, the other had not. In eight of the other cases there was a considerable relief from pain, lessened hemorrhage, and, for a time, improvement in the general condition. The other four patients either discontinued treatment or there was no apparent improvement. In eleven cases of primary carcinoma of the breast, diag-

nosed by clinical appearances, four patients are well at the end of two years or longer. In fifteen patients treated immediately following operation, there has been no recurrence after two years in ten. Of thirty-eight patients in whom there was recurrence after operation, eight are well at the end of two years. In about half of the cases in which there was operation, a microscopic examination was made, and in most of the others there was no doubt as to the diagnosis. Life has been prolonged and pain lessened in many cases by this treatment. The treatment of epithelioma of the face, in which the trouble was local and the growth not more than 1½ inches in diameter, with the exception of those cases involving the lip, has been almost uniformly successful, and the cosmetic results excellent. Cases in which the lip is involved seem to be more persistent than others. The writer concludes that he does not believe that this treatment will ever be as efficient in the case of sarcoma as in carcinoma, because the secondary growths are so much more liable to involve distant and internal organs. But the ray often helps those cases in which there are secondary deposits near the surface, where they can be found by palpation when small.

Journal of the American Medical Association, November 12, 1904.

Erythema Nodosum.—A general description of the disease is given by I. A. Abt, who adds the detailed history of three personal cases. He believes that the disease should be classified as one of the exanthematous fevers on account of its clinical course, prodromes, and complications. It may follow one of the infectious diseases, malaria, or rheumatism. Among complications may be named conjunctivitis, pharyngitis, joint lesions, and, more rarely, endocarditis and pericarditis. It commonly occurs between the second and fourteenth year. In some cases it is followed by symptoms of tuberculous infection. The disease usually begins with vague pains, gastrointestinal disturbances, and fever. The fever in some cases is remittent, usually falls by lysis, and lasts, as a rule, from two to seven days. After several days of vague pains about the joints, especially of the lower extremity, and some pain and tenderness over the tibia, the eruption makes its appearance in the form of node-like swellings on the shinbones, and sometimes on the dorsal surfaces of the feet, on the forearms, or on the thighs; it rarely occurs on the tongue or on the face. The lesions are usually distributed symmetrically, and come out in crops of two or three at a time, or a large number may appear at once; they are round or somewhat oval, vary in size from a walnut to a hen's egg, and are not distinctly circumscribed; that is, they have no well-defined border; they are of a bright red color; the skin over the surrounding area is swollen and tense. The nodes disappear in from eight to fourteen days, though the duration of the disease varies according to the intensity of the eruption.

Prophylaxis of Tuberculosis in Children.—L. Fischer discusses this question on the basis of statistics gathered from various sources. In countries in which bovine tuberculosis is common tuberculous disease is very common among children. Autoinfection by the sputa is common. The author analyzes the records of 5,000 children who were examined at random for the presence of tuberculous lesions; of the whole number, 59 showed distinct evidence of pulmonary lesions. Of the 59, no less than 43 had bone and joint lesions in addition. Fischer lays emphasis on the following directions: (1) Insist on each infant being breast-fed; in other words, start the baby right. (2) If the mother cannot nurse her child, secure a wet-nurse. Let the wet-nurse nurse her own child in addition to her foster child, and give both infants alternate bottle-feeding. This mixed form of infant feeding is very successful. (3) In foundling asylums and day nurseries a wet-nurse can be procured who will nurse two infants. In this way we lessen the danger of tuberculosis. He adds that the secret of health and the vitality and endurance of the enormous tenement house population is that they are or have been breast-fed.

The Hot-Water Douche in Treatment of Chronic Catarrhal Deafness.—G. P. Head states with reference to this therapeutic procedure that cases in which the source of deafness lies in the internal ear are not very likely to be benefited. It is particularly adapted to those cases in which there is evident congestion and inflammation of the drum membrane. A drum membrane displaying considerable patches of sclerosis is very likely to show improvement. Tinnitus, when due to introtympanic causes, has been readily relieved by the hot-water douche. When due to conditions in the internal ear, it is not to be expected that treatment directed to the middle ear will relieve it, though it is quite possible that the internal ear may be affected to some degree by application of heat in such close proximity to it. In nearly all cases there is tubal occlusion of greater or less degree; this, of course, will be affected only indirectly by treatment through the external canal. That improvement of the health of the tympanic lining and contents will necessarily cause some response in the Eustachian tube is obvious, although the response may be but slight.

The Lancet, November 5, 1904.

The Red Light Treatment of Smallpox.—The late Niels R. Finsen calls attention in this paper to the article published in the *Lancet* in July by Ricketts and Byles, in which they report thirteen cases treated in red light without favorable results. But these patients were not subjected to this treatment at a sufficiently early period, only one being subjected to it as early as the fourth day. Finsen explains that two conditions are indispensable in order to obtain good results from this treatment: an early treatment of the patient; and an entire exclusion of hurtful rays of light. Smallpox infection puts the skin in a state of great sensitiveness to light, which even under normal circumstances may act on the skin as an irritant. If the patient during the period of the appearance and the growth of the exanthem is protected against daylight, especially against the chemical rays, by means of the red light treatment, the exanthem will be less strong than otherwise, and, as a rule, no suppuration will occur. The exclusion of light will act differently in different cases, according to the extension and force of the exanthem. The writer protests against the statement that this method is ineffective, for to be of any use the treatment must be carried out before the period of suppuration.

A Remarkable Sequel to a Case of Gastroenterostomy.—Arthur E. Baker reports this case. The patient, a woman of twenty-eight years, had been operated on two years ago for severe recurrent hemorrhage from the stomach. A posterior retrocolic gastroenterostomy had been performed in the usual way, followed by perfect recovery. The patient married in March, 1904, and pregnancy soon followed. In July, the patient began to have attacks of pain, most frequent after food, and referred to the region underlying the scar just above the umbilicus. The bowels ceased to act normally, vomiting began, and she was admitted to the hospital. The patient lay on her back with the legs drawn up. The pulse was 99, and of good quality. The respiration was normal. The abdominal muscles were not very rigid. No movement of the intestinal coils could be seen, and there was no evidence of peritonitis. When the writer saw the patient, she was writhing with pain. The case was regarded as probably intestinal obstruction, due to an adhesion about the scar. But at operation not a trace of such adhesion could be found. The whole of the small intestine, with the exception of the last seven inches or so, had passed between the junction of the stomach and jejunum and the root of the mesocolon made two years ago, and over the first part of the jejunum (afferent), and then down into the general cavity of the peritoneum. The whole small intestine formed a huge volvulus, turning on its mesentery in a direction contrary to the movements of a clock. The coils as a whole were lifted up and untwisted one complete turn in the direction of the movements of the hands of a clock. Not until then could the last part of the ileum be withdrawn from under the constriction. But when the volvulus was untwisted all of the small intestine could be easily and rapidly drawn out. The junction with the stomach was placed in the normal position, the coils washed with normal saline solution, and the abdomen closed. Convalescence was uninterrupted, and primary union took place. Just after the operation there was considerable stercoraceous vomiting. The stomach was washed out with the tube. At last report, October 29, the patient looked and felt perfectly well. The pregnancy is now nearing its termination satisfactorily.

Suture of Wound of the Heart.—Edgar Somerville was called to attend a man who had pushed a penknife into his chest in two places. The upper wound was in the fourth intercostal space, and the lower one in a vertical line below it in the fifth intercostal space, both wounds being between the left parasternal and mammary lines. The upper wound was enlarged and the pericardium exposed. This was also wounded. The pericardial sac was full of blood, and on its removal a wound was found in the left ventricle, three-eighths of an inch in length, with its long axis in the long axis of the ventricle. The visceral layer of the pericardium had retracted, making the wound spindle-shaped, and the aperture was plugged with some lacerated myocardium. Blood was oozing from the wound. The lacerated cardiac muscle which was protruding was removed by scissors, and the hemorrhage then became more profuse, but was arrested by the introduction of the little finger tip into the wound. A curved intestinal needle was passed deep into the myocardium. Three interrupted silk sutures were placed. The patient's condition gave rise to considerable anxiety, but after the sutures were tied and a hypodermic injection of strychnine given, the heart's action considerably improved. The pericardial sac was cleansed, a gauze drain introduced,

and the wound in the sac and intercostal muscles was closed. When the lower wound was investigated, it was found that both the pleura and pericardium had been opened, producing pneumohæmothorax and pneumohæmopericardium, but the heart had not been injured here. The wounds were cleansed, a drain introduced and sutures inserted. The patient's condition was very bad at the close of the operation, but as time went on he continued to improve, and now his heart's action is perfectly regular.

Treatment of Hæmophilia.—Lachlan Grant speaks of the well-known fact that females generally escape hæmophilia, and questions whether this female immunity may not be due to some constitutional influence emanating from the reproductive center—probably through an internal secretion of some kind, possibly ovarian—and further, whether the internal administration of extract of ovaries, or other peculiarly female tissues, would have any influence in lessening the tendency to dangerous hemorrhage in cases of hæmophilia. The writer then cites the case of a boy who was a "bleeder," and who was brought to him with a bad hemorrhage from his foot, which he had cut by stepping on a piece of glass. The remedies applied were of no avail, and the boy was growing very anæmic and the prognosis was grave. The writer began to give the patient some extract of ovarian substance procured from a sheep. Local treatment of the wound was continued. On the sixth day, the hemorrhage gradually lessened, the temperature dropped to 99°, and the pain ceased. On the eighth day the wound became healthy looking, and from that time on improvement was steady. Although it cannot be positively asserted that the boy's own system did not of itself naturally overcome the morbid condition, still there is a possibility that the ovarian extract had some effect in bringing about his recovery.

British Medical Journal, November 5, 1904.

A Practical Suggestion for the Prevention of Ankylostomiasis.—P. Manson refers to a plan followed in tropical countries for the prevention of the "coolie itch," so-called, which is a dermatitis of the feet and legs caused by the peneration of the skin by the embryos of ankylostoma contained in contaminated soil. The coolies dip their feet and legs in green Barbadoes tar (a very cheap mineral oil, rich in paraffin) and then walk across and through some fine sand. In this way an impervious sandal and stocking is formed over the ankles and feet, and the men can work in contaminated fields with impunity. Sawdust may be substituted for the sand.

On the Mode of Origin of Nasal Polyps.—E. S. Yonge offers the following provisional conclusions: (1) Mucous polypi of the nose, in the majority of instances, are probably consequent upon, and certainly coincident with, inflammation of the mucous membrane of the nasal cavity. (2) The primary mechanical process is a localized œdema of the inflamed mucous membrane, which œdema, on account of certain structural peculiarities of the lining membrane, does not, in the great majority of cases, develop in any intranasal area but that of a portion of the middle turbinal and of the middle meatal regions. Analogous structural peculiarities are present in the mucous membrane of some of the accessory sinuses. (3) The determining cause of the occurrence of the œdema, in the regions specified, is the degeneration and cystic dilatation of the mucous glands. (4) The particular shape which polypi usually assume, their number, probably the appearance, in some instances, of recurrence, and other special peculiarities of these growths, are due to the œdematous mucous membrane being thrown into folds, and to the normal folds becoming œdematous. Certain of the folds quickly increase in size by the absorption of serous fluid and favored by gravity, and finally present the appearance of ordinary mucous polypi. (5) The "polypoid" outgrowths, which take origin on the interior turbinal, and more rarely on the septum, generally differed markedly in microscopic structure from mucous polypi, and although they claim a common inflammatory origin, these conditions are distinct, principally on account of the dissimilar structure of the nasal regions from which they respectively take origin.

Menière's Disease; A Clinical and Experimental Inquiry.—In a paper with this title, W. Milligan reports the results in three cases of removal of the semicircular canals. All three patients had suffered for years from repeated attacks of vertigo, incessant tinnitus, and progressive loss of hearing power. In all three the usual means of treatment had been tried, but without avail. In two of the cases a satisfactory result was obtained so far as relates to the relief of vertigó and sickness. The persistence of tinnitus in one of the cases suggests, according to the author, either that the terminal filaments of the vestibular nerve were imperfectly destroyed, or that some lesion of the root of the auditory nerve coexisted.

Deutsche medizinische Wochenschrift, October 27, 1904.

Artificial Suppuration in Pyæmia.—Bröse describes a case of puerperal pyæmia in which he made use of Fochier's plan of inducing artificial suppuration. This writer was led to the procedure by observing that in severe cases of pyæmia the general condition improved if local suppuration occurred, *e.g.* pelvic abscess, subcutaneous phlegmon, etc. In cases of systemic infection in which no spontaneous abscess formation took place he therefore induced artificial suppuration by harmless means. For this purpose he injected turpentine subcutaneously and reported on favorable results in six cases. Some other observers have expressed equally favorable opinions, others have found the plan without effect. Bröse's case was one of puerperal septicæmia of four weeks' duration, with septic temperature, a pulse of 140, and great general prostration. Promptly after the injection of 5 c.c. of rectified turpentine into the calf of the leg the temperature began to fall, and the condition to improve, so that on the tenth day there was no fever, the pulse was down to 100, and the appetite had returned. On the fifth day after the injection the leg was incised and a quantity of sterile pus evacuated. The suppuration continued actively, and a second incision was necessary later, and the course of healing was protracted. The author considers that the dose of turpentine used was too large, and produced more of a local reaction than was necessary, but that those who saw the case received the impression that the improvement was due to this measure.

The Treatment of Fractures.—Liermann says that, as a rule the treatment of fractures by practitioners is still far behind the times. The more general employment of the *x*-rays has been of great advantage in many directions, but it has also led to an excess of conservatism in treatment, and of dread lest the photographic plate should reveal some evidence of faulty union. The old-fashioned permanent plaster dressing should be replaced by a more rational combination of immobilization, with massage and active and passive motion. During the first period of treatment immobilization is essential, but even at this time the absorption of the exudate may be hastened and repair accelerated by massage, and even careful passive motion of the neighboring joints. The ambulatory treatment of fractures of the lower extremity requires ingenuity in applying a suitable dressing, but properly used effects a great saving of time. Great stress is to be laid on the conscientious performance of gymnastic exercises intended to exercise the soft parts temporarily incapacitated by the injury. In fractures of the lower extremity, the mistake must not be made of attempting ambulatory treatment too soon, for a period of rest in bed, to be determined for each case, must precede the active motion.

The Quantitative Estimation of Sugar in the Urine by Iodometry.—Citron discusses the advantages and disadvantages of the various procedures for quantitative sugar determination, and comes to the conclusion that the most convenient for clinical purposes is Lehman's iodometric method. In this a measured amount of Fehling's solution is reduced with a measured amount of urine, and the residue of unreduced copper is estimated by adding a known amount of potassium iodide and titrating with sodium bisulphate, using starch paste as indicator. The amount of iodine combining with the unreduced copper is thus readily obtained, and reference to a table gives the amount of sugar present in the urine. The author has devised a specially graduated burette, and various minor improvements in technique, by which the process is greatly simplified and made available for office use.

Berliner klinische Wochenschrift, October 24, 1904.

Attempts to Immunize Against Tuberculosis.—Baumgarten says that all his efforts made during a period of years to immunize rabbits against perlsucht by inoculation with human tubercle bacilli, to which these animals are much less susceptible, have been unsuccessful. Stimulated, however, by v. Behring's positive results in similar experiments on cattle, he has made observations of the same sort, and agrees with this author that through the introduction of human tubercle bacilli cattle may be rendered immune to doses of bovine tubercle bacilli fatal to control animals. This immunity results from a single subcutaneous innoculation, and has so far persisted for two and a half years. It is not necessary to make repeated intravenous injections of the bacilli, as v. Behring and Koch have stated, for simple subcutaneous innoculation is equally effectual. The local lesion produced is not tuberculous in nature, and the immunity caused is probably the result of a stimulation of the antibody forming organs, so that when a fresh dose of poison is introduced, antibodies are at once manufactured in sufficient quantity promptly to overwhelm it. Attempts to obtain in this way a serum protective for rabbits or guinea-pigs have, however, been unsuccessful; experiments on calves are now being carried on. Even in case it should not be feasible to obtain a curative serum, there is still a chance that it may prove possible to immunize man by innoculation with perlsucht bacilli, but the nonidentity of

human and bovine tuberculosis must first be more clearly established.

The Value of the X-rays for the Medical Expert.—Immelmann describes various ways in which the *x*-rays may be advantageously employed by the medicolegal expert, and points out the serviceability of this method for determining the age of premature fœtuses. The epiphyses of the long bones remain permeable for the *x*-rays until after birth, with the exception of that of the distal end of the femur, which is rendered visible at the thirtieth week of fetal life. As this is the period when the fœtus becomes viable in the eyes of the law, the ready means of demonstrating the presence or absence of this epiphyseal center by means of the *x*-ray may be of the greatest service to the medicolegal expert. It may also readily be determined in this way whether the child has breathed or not, for unexpanded lungs give a deep shadow, similar to that of muscle, while lungs that have been filled with air do not. Both of these determinations ordinarily require dissections and microscopical preparations, or the hydrostatic test, whereas the *x*-ray procedure effects a great saving of time.

Münchener medizinische Wochenschrift, October 25, 1904.

Protozoön-like Structures Found in a Syphilitic Fœtus.—Jesionek and Kiolemenoglou describe curious unicellular bodies discovered by chance in both kidneys, the liver and both lungs of a fœtus infected with paternal syphilis. The structures were very numerous in the kidneys, where they frequently occurred in groups of from twenty to forty individuals, while in the other organs they were scattered singly. The bodies have a size of from 20 to 30 microns, and are oval in shape. Their enclosing membrane appears to be double, and the protoplasm consists of granules held in a spongy ground substance. The granules are more tightly packed at the end of the cell opposite to the nucleus. The staining reactions of the structures are given at length, but present no especially striking features. The authors believe that they are justified in excluding either transplanted embryonal cells or degenerative structures. The impression derived from the preparations is that they are parasites of some sort, probably belonging to the gregarines, but whether the case is simply one of gregarine infection of a luetic fœtus, or whether these structures stand in some intimate relationship to the syphilitic process is undetermined. Fixation of the tissues by corrosive sublimate gives much more distinct pictures than does the use of formalin. The authors have examined the organs of a second syphilitic fœtus and also condylomata, but without finding in these anything more definite than a few suspicious looking structures.

A Contribution to the Bacteriology of Noma.—Hofmann and Küster studied the organisms present in the tissues in a case of noma, and were able to isolate what they consider the cause of the infection. Cultures made directly from the diseased surfaces showed a multiplicity of organisms, but pure cultures were obtained by immersing in gelatin small bits of tissue taken from the areas where the infection was just invading healthy parts. In this way an organism could be isolated which corresponded morphologically with the bacteria seen in microscopic sections made through the corresponding areas, and which could not be identified with any previously described germ. The organism is 4-5 μ. long and 0.8 μ. thick, and in fluid media forms chains up to 40 μ. in length. Spores are abundantly found in cultures forty-eight hours old. It grows well on all the ordinary media, is aërobic, and does not form gas. These points serve to differentiate it from *B. hastilis* occurring in Vincent's angina and frequently associated with noma. The authors consider that the causative nature of their organism is attested by the morphological similarity between the bacteria found in the tissues and those obtained by culture, the fact that the technique employed excludes contamination, and the fact that spore formation could be obtained in the original tissues in gelatine just as in the free cultures.

French and Italian Journals.

Treatment of Mucomembranous Colitis.—Mathieu names constipation as the most important symptom of mucomembranous colitis. Constipation in the majority of these cases is due to a spasm of the colon. This spasm occurs most commonly in patients of nervous temperament. The origin of this condition may be a lesion of the appendix, a lesion of the uterus, a lesion of the bile passages, and so on. The coincidence of abdominal ptoses, especially of nephroptosis with mucomembranous colitis is undoubted. The indications for treatment of this form of colitis are to remove the cause of the condition. In order to overcome the constipation, injections of oil are recommended. Electricity applied to the intestines is especially successful. All lesions which may be the origin of the intestinal trouble should be treated. Nervous irritability, both abdominal and general, should be overcome as far as possible. For this purpose hot applications, hot baths, dorsal decubitus in case of visceral ptosis, static electricity, and nervines are all useful. The diet should be carefully looked after, especially with a view to the nervous condition present. Nothing stimulating should be given. Indications for the direct treatment of the intestinal mucosa in acute or subacute attacks of dysenteric colitis, are best met by injections of a weak solution of silver nitrate.—*Le Bulletin Médical.* October 15, 1904.

Repose in Relation to Premature Rupture of the Membranes.—Richard, in order to prove what influence repose exerts on the premature rupture of membranes, has compared two series of cases: The first series shows 1,000 women who rested quietly during the last weeks of pregnancy; the second series includes 1,000 women who worked up to the last minute before confinement. Premature rupture occurred in 13.2 per cent. of the first class, and in 28.1 per cent. of the second class. To draw a distinction between primiparæ and multiparæ, the writer determined that rupture took place in 12.7 per cent. of primiparæ who were quiet, and in 31.5 per cent. of those who worked. Of the multiparæ, rupture occurred in 11.9 per cent. of those who rested, and in 26.1 per cent. of those who worked. It appears from these statistics that primiparæ are more susceptible to premature rupture than multiparæ. As to faulty insertion of the placenta, the proportion was almost the same in both of the series. These observations show that more than one-third of the domestics, and one-third of the laundresses suffered from premature rupture. But the women who worked sitting down did not suffer to nearly this degree—only one-seventh being thus affected. This work will be of great interest to those who are interested in this subject.—*La Tribune Médicale,* August 13, 1904.

Urinary Complications of Appendicitis.—Oddo and Silhol declare that in the course of appendicitis, if hæmaturia appears, one should think of toxæmia, of nephritis, and finally of a vesical or perivesical lesion. The possible diversity of origin explains the difference in prognosis, which may be excellent in some cases, but alarming in others. In view of urinary disturbances appearing in the course of appendicitis, it is most important to make a daily examination of the urine in all cases of appendicitis. The writers cite various cases in point. One child of six years, suffering from attacks of appendicitis, had hæmaturia in the intervals, every time that it partook of bouillon or of potato purée. The slightest intestinal infection showed itself in renal congestion with hæmaturia. A boy of fifteen years, who had an attack of appendicitis, rapidly improved under medical treatment. On the fifth day, when the appendicular symptoms had disappeared, the amount of urine diminished, and albumin, casts, both granular and epithelial, and blood appeared in the urine. This attack of nephritis was undoubtedly associated with the appendicitis. More attention than has heretofore been given should be paid to this phase of appendicular disease.—*Revue Française de Médecine et de Chirurgie,* September 5, 1904.

A New Variety of Nocturnal Incontinence of Urine.—Bazy calls attention to the nocturnal incontinence of urine that often accompanies pyelitis and pyelonephritis. It is distinguished from other varieties of nocturnal incontinence, especially by the nocturnal pollakiuria, which precedes or accompanies it, by its intermittence—for it does not occur every night, but only during very deep sleep—by the fact that it is noted in adolescent or adult patients at the age when incontinence naturally disappears, and finally by the abnormal urine, which varies according to the degree of pyelitis or pyelonephritis present. The diagnosis will be finally clinched by the search for the other signs of pyelitis. Under the influence of renal excitation, the bladder tends to empty itself, and during deep sleep the subject is not conscious of this act.—*La Presse Médicale,* October 8, 1904.

A Clinical and Experimental Contribution to the Study of Actinomycosis in Man.—Salvatore Salinari reports a very interesting case of actinomycosis in a young soldier, who applied for treatment at first for what appeared to be a decayed tooth. The tooth was removed, but the gum did not become normal, and after twenty days he began to complain of pain in the jaw, a small swelling remaining where the tooth had been extracted. This opened and discharged a thin pus, refusing to heal. The submaxillary lymphatics became enlarged, and fever set in. The jaw beneath the swelling became carious and a sequestruum separated and was removed. Yellowish-gray granules now appeared in the discharge. The inflamed cervical lymphatics broke down and were opened, when it was found that the process had burrowed throughout the side of the neck, and the tissues were riddled with tunnels, discharging thin pus and actinomycotic granules. No surgical treatment availed, and the use of iodide of potassium in very large doses alone benefited the patient, finally bringing about a cure. The author believes that actinomycosis is not

so rare as has been thought, and that a careful diagnosis would reveal the process in come cases of chronic inflammation that now go uncured. The appearance of the lesion, in the nature of a new formation rather than inflammatory, the chronicity, the diffuse involvement of the tissues, should suggest actinomycosis before the granules were found. The presence of streptococci caused the liquefaction in this case, which was more rapid in consequence of the mixed infection. The diagnosis from syphilis and tuberculosis is not always easy, except by the microscope. No pure culture could be obtained on account of the presence of the numerous streptococci, but three animals injected with the material died with typical abdominal infection. The patient in question had his trouble shortly after returning from a visit to his mother on a small farm.—*Giornale Medico del Regio Esercito,* September 30, 1904.

The Cure of Cutaneous Tuberculosis by New Methods of Treatment.—Roberto Campana cites ten cases of lupus of the skin cured by curetting and cauterization, without any recurrence. One case, after an apparent cure, recurred following an attack of erysipelas. In three cases there were severe septic complications, followed by recurrence of the original trouble. The author used tuberculin at long intervals and in small doses. The recurrence he believes due, not to the virulence of the tuberculosis, but to the aggravation of the septic complications. The best results from cauterization have been reached when septic complications have been avoided by local protection and asepsis. The use of tuberculin has aided in the resolution of the inflammation, has lessened the tendency to diffusion of the tuberculous process, and has produced a slight grade of immunity in the adjacent parts.—*La Riforma Medica,* October 4, 1904.

A Case of Chorioangioma of the Placenta.—Cesare Finzi has had the opportunity to study a case of chorioangioma of the placenta. Tumors of the placenta are of extreme rarity, only fifty-two cases having been reported up to the present time. The patient was forty-three years of age, in her sixth pregnancy. There was hydramnios, but the delivery was spontaneous after the artificial rupture of the membranes, and the draining away of some of the excess of amniotic fluid. The child was well developed and living, and the placenta came away naturally. On examination of the placenta it was found that nothing abnormal appeared on the maternal surface. On the fetal surface, in the center and 2 cm. from the insertion of the umbilical cord, was a hemispherical mass, elevated above the general surface. It was shining, 10 cm. in diameter, and extended out to the margin of the placenta. It was soft and elastic. Examination showed that its tissues were not continuous with those of the placenta. Large veins and arteries ramified over it, and one of these penetrated its mass. Microscopical examination showed it to be a solitary chorioangioma of the placenta, originating by an extraordinary proliferation of the fundamental tissues of the chorion, developed in a limited space, such as might be occupied by a few choroidal villi, and growing as a parasite in the placenta. The author believes that such tumors arise from a multiplicity of etiological factors, resulting in an atypical proliferation of the elements of the chorion. These causes may be extrinsic to the choroidal villi, referable to genital stasis as the expression of circulatory alterations, to lesions of the endometrium changing the implantation of the villi on the decidua, and other maternal abnormalities; or intrinsic and due to a morbid exaltation of the proliferative powers of the elements of the chorion and alantois. It is noticeable that hydramnios is a frequent complication, occurring in 23 per cent. of cases; albuminuria and eclampsia have occurred in eight cases; in 38 per cent. the pregnancy was interrupted prematurely; and 37 per cent. of the children have died at birth.—*Archivio di Ostetricia e Ginecologia,* September, 1904.

Tuberculous Infection by Way of the Vagina.—Calogero Galbe tells us that tuberculosis of the female genital organs, either primary or secondary, is exceedingly rare. Out of from sixty to eighty phthisical women observed, only two or three had tuberculosis of the genital organs. When there are any lesions, they are of the internal organs, and it is doubtful if infection ever occurs from without. The author's experiments had for their object to show the importance of solutions of continuity in the vagina, and the way in which the genitals act toward injections of tuberculous material, as well as whether pregnancy can occur when there is a tuberculous lesion of the genitals, and how it is affected by it. For this purpose he injected tuberculous material into the vagina of guinea pigs, being careful to produce no solution of continuity; one group was inoculated unimpregnated, one was afterwards impregnated, and a third was inoculated while pregnant. He concludes as follows: 1. Solutions of continuity are of the greatest importance in determining a deposit of tuberculous tissue in the external genitals. 2. The resistant power of the organs probably depends on the epithelium by which they are covered, not on the secretions of the mucous membrane. 3. The organism resists any penetration of the virus, and if it occurs, it is through the interstices between the cells, and spreads by the lymphatics. 4. Conception may take place coincident with a tuberculous lesion; abortion is frequent, and tubercle bacilli may be found in the placenta and organs of the fœtus. 5. The differences of material injected, sputum or culture, make no difference in the effect.—*La Riforma Medica,* September 13 and 20, 1904.

Periphlebitis and Endophlebitis of the Lateral Sinus and Thrombosis of the Superior Longitudinal Sinus.—D. De Carli describes a case of periphlebitis and endophlebitis of the lateral sinus and thrombosis of the superior longitudinal sinus that was apparently either not connected with ear disease, or was occasioned by an ear affection that had given no signs since childhood. At five years of age the patient had acute otitis media, the smyptoms of which cleared up and did not show themselves until the occurrence of the present trouble, a period of eighteen years. At this time he was attacked by fever and chills, ending at night with sweating and reduction of the fever. The attacks were daily, and accompanied by severe pain in the right side of the head at the top, irradiating to the neck. On entering the hospital it was found that the drum membrane was destroyed on the right side, the handle of the malleus hung down behind the opening, the mucosa of the chamber was very hyperæmic, but no pus was to be seen. The mastoid region was not swollen or tender, but percussion over it gave pain. There were no cerebral symptoms, but movements of the neck were limited by pain. Operation at the apophysis set free a large quantity of pus, thin and fetid. The lateral sinus was found thrombosed and the internal jugular was found open. Relief from the operation was only temporary, and the patient died two weeks afterward. At the autopsy the dura was tense, the arachnoid opaque, and the thrombosis of the sinus extended to the torculor and into the longitudinal sinus. There was no caries of the temporal bone.—*Archivio Italiano di Otologia,* September, 1904.

Treatment of Tracheobronchial Adenopathy.—R. Oppenheim and Ch. Laubry, after speaking in some detail of the treatment of this affection in the case of children, discuss it in relation to the adult. Excluding the cases of cancer and of leukæmia, tracheobronchial adenopathy occurs almost always as a complication in the course of confirmed pulmonary tuberculosis. In the cases in which it appears primary, it is exceptional that careful auscultation of the apices does not reveal clear signs of induration. The treatment of this condition is much like that of pulmonary tuberculosis. Besides the hygienic and dietic measures which are commonly instituted, just as in the case of children, preference is given to the arsenical preparations, in the form of Fowler's solution, solution of arseniate of soda, or subcutaneous injections of cacodylate of soda. Care must be taken in the employment of iodine and its derivatives, which may cause congestion or even provoke hemorrhage. Cod-liver oil, the phosphathes, hypophosphites, and glycerophosphates are useful. In the treatment of cough and dyspnœa, the opium preparations will be found most valuable, and their employment for these complications is often necessary.—*La Tribune Médicale,* October 1, 1904.

Contribution to the Morphology of Oxalate of Calcium.—M. Barberio finds that there has been a great deal that is inaccurate written about the shape of the crystals of oxalate of calcium that are found in the urine. He has made careful observations on this subject and publishes the results. The most frequent and best known form is that of octahedral crystals, formed of two pyramids with their bases together. The larger crystals are the most perfect. If two or four crystals are grouped together we get the form of a four-pointed or eight-pointed star. The next in frequency is a quadratic prism terminated at its two extremities by pyramids. They vary much in size, but are smaller than the octahedra. A form so rare that the author has seen it only once consists of quadratic tablets. Aside from the crystalline form is the dumbbell shape, which is not crystalline, and conists of two more or less spherical forms united so as to look like a dumb-bell. These forms may be produced artificially.—*Giornale della Associazione Napolitana di Medici e Naturolisti,* March-April, 1904.

Collodion Dressing for Intranasal Surgery.—C. W. Richardson recommends for a dressing after intranasal operations leaving a raw surface the use of ordinary collodion. The area to be heated is first blanched with adrenalin, then dried, and finally coated with collodion, quickly applied by means of a cotton carrier. Several applications are made, evaporation of the ether and the setting of the collodion being favored by several blasts of air through the meatus.—*The Laryngoscope.*

Book Reviews.

Radiotherapy and Phototherapy, Including Radium and High-Frequency Currents, Their Medical and Surgical Applications in Diagnosis and Treatment. For Students and Practitioners. By Charles Warrenne Allen, M.D., Professor of Dermatology in the New York Post-Graduate Medical School; Consulting Dermatologist to the Randall's Island Hospitals; Consulting Genito-Urinary Surgeon to the City Hospital; Member of the American Medical Association, the American Dermatological Association, the New York Dermatological Society, etc. With the Coöperation of Milton Franklin, M.D., Lecturer on Electroradiotherapy, New York Polyclinic Medical School, and Samuel Stern, M.D., Radiotherapist to Mount Sinai Hospital; Clinical Assistant to the Skin Department of the New York Post-Graduate Medical School. New York and Philadelphia: Lea Brothers & Co., 1904.

A book on x-rays without shadow pictures is a decided novelty—we were going to say a commendable one, and on consideration we will let the qualification stand. Radiographs of bones—normal and broken—are good enough as aids to diagnosis, and shadow pictures of dilated hearts and pulmonary lesions may be studied profitably by those who have had enough experience to interpret them, in the negative, but when reproduced in half-tones they lose all their value, except as subjects for the exercise of the imagination. Dr. Allen has wisely put aside the temptation of ornamenting his book with showy, but worthless, pictures of this sort, and has contented himself with before and after pictures of skin lesions treated by radiotherapy and with drawings of apparatus.

A feature of the book, and one that appeals at once to the reader, is that it is manifestly written from the author's own experience, and is not a mosaic of bits from previous publications, skilfully cemented together by a very thin glue of personal experience. The work is eminently practical in its design and execution, and is one in which the tyro can find all, except the all-essential personal practice, to make him an accomplished radiodiagnostician and radiotherapist.

Examination of the Urine. A Manual for Students and Practitioners. By G. A. de Santos Saxe, M.D., Pathologist to the Columbus Hospital, New York City. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

This is a most complete and satisfactory guide to uranalysis, written by one thoroughly conversant with his subject and practically expert in the methods he describes. The work is divided into three main parts, following the introduction, viz., chemical examination of the urine, microscopical examination of the urine, and the diagnosis of urinary diseases. Special attention is given to the diagnostic significance of the various chemical elements and microscopical structures found in the urine. In addition to a full description of the usual technical methods, Dr. Saxe gives some new procedures which he has evolved in his own laboratory work. Cryoscopy and other means of functional diagnosis have been given their proper places. The text is fully illustrated, including eight colored plates of the various urinary crystals, and the book is provided with an excellent index. At the end of each chapter are questions regarding its contents, by means of which the student may prove the thoroughness of his mastery of the subject.

Beauty Through Hygiene. Common Sense Ways to Health for Girls. By Emma E. Walker, M.D., Member of the New York Academy of Medicine, etc. Illustrated. New York: A. S. Barnes & Company, 1904.

Popular books on medical subjects, sufficiently detailed to be of real value, and yet not so sophisticated as to lead to harmful attempts at lay prescribing, are unfortunately rare. It is therefore a pleasure to encounter so useful and well-balanced a work as is this little volume, and the author is to be congratulated on having successfully accomplished a difficult task. Binding and presswork are dainty enough to appeal to any feminine reader, and the style is equally charming, while there is not a statement or piece of advice in the book that would not be heartily endorsed by any experienced physician. There is hardly a medical man, no matter what his specialty, who has not often wished for some such book to put into the hands of his women patients for the purpose of giving them the necessary information on the hundred and one details of hygienic living that are so often neglected through ignorance, and every page of the present volume is replete with wholesome, common-sense advice. Massage and corrective exercises, the care of the skin, hair, mouth, eyes, nose, and ears, etc., diet in health, and for the purpose of gaining or diminishing weight, bathing, clothing and many others equally practical, are some of the topics discussed. Attractiveness of form and feature is to be attained only through a healthy mind in a normal body, and the author tells young women how to achieve and retain beauty through observance of the principles of healthful living and rational enjoyment.

Text-Book of Human Physiology, including Histology and Microscopic Anatomy, with especial reference to the Practice of Medicine. By Dr. L. Landois, Professor of Physiology and Director of the Physiological Institute in the University of Griefswald. Tenth revised and enlarged edition. Translated by Dr. Augustus A. Eshner, and edited by Dr. Albert P. Brubaker. Philadelphia: P. Blakiston's Sons & Company, 1904.

The fourth edition of Stirling's translation, having been out of print for some years, and three large German editions having meanwhile appeared, the publishers have been led to place a new translation before the profession. In this, as in former editions, the plan has been adhered to of exhibiting the close interdependence of abnormal and normal processes, a brief outline of the pathological variations being appended to each section, heart murmurs, for example, being noticed in connection with the normal sounds, abnormal with the normal respiratory murmurs, etc. To each section is also appended a brief review of the comparative and historical aspects. The student is also introduced to the principal methods of investigation which he will need in his future work. Thus the technique of the blood examination, uranalysis for the principal pathological constituents in connection with that of normal urine, laryngoscopy and rhinoscopy along with the pathology of phonation and articulation, and, in connection with the optics of vision, the subject of astigmatism are discussed. While in general the work appears to be thoroughly up to date and its value is unquestionable, here and there one notes a lack, as the absence of any mention of the islands of Langerhans now emerging into such prominence in connection with pancreatic diabetes. The discussion on the "ductless glands" is a little disappointing, they being relegated as an appendix to the circulation and no mention being made of acromegaly in connection with the pituitary body. Also occasional uncouth teutonisms ("forelying work," for example), are seen. But, after all, these criticisms relate to only minor blemishes in an excellent work.

Les Rayons N et Les Rayons N$_1$. Par le Dr. H. Bordier, Professeur agrégé, à la Faculté de Médecine de Lyon. Paris: J. B. Baillière et fils, 1905.

Though the imprint is that of 1905, the subject matter cannot be so regarded, so rapidly are these subjects added to and apt to change. Indeed, the entire subject of *n*-rays seems but a thing of yesterday, and their very existence has already been denied. The author believes there is no doubt of their existence, and has here collected and condensed for digestion about all that has appeared of importance upon the subject.

In doing this M. Bordier has conferred a benefit upon seekers after truth in these directions. There are less than 100 pages, with 16 figures.

V. Internationaler Dermatologen-Kongress. Verhandlungen und Berichte herausgegeben von Sanitätsrat Dr. O. Rosenthal, General-Secretär. Erster Band. Berlin, 1904.

With commendable promptness the first volume of the transactions and reports of the fifth international congress for skin diseases just held in Berlin, has been given out. Indeed, it was published before the physicians convened, so that they might have before the eye the collected statistical reports upon leprosy from the entire world. Of especial interest to the American reader will be the report of Dr. Dyer, of New Orleans, though it does not reflect an interested activity upon the part of officials or doctors in this country. While it shows that many States are seemingly free, there is enough leprosy to make the present indifference of authorities dangerous. The general secretary is to be congratulated upon getting out this portion of the transactions so early and so well.

Anatomie und physikalische Untersuchungsmethoden (Perkussion, Auskultation, etc.). Anatomisch-klinische Studie von Dr. R. Oestreich, Privatdozent an der Universität, und Dr. O. de la Camp, Privatdozent an der Universität, in Berlin. Berlin: S. Karger, 1905.

This is a treatise of two hundred and sixty-six pages devoted to a consideration of the underlying principles of physical diagnosis. It is divided into a general part in which the laws governing the transmission of sound, the movements of fluids through tubes, the *x*-ray, and the agonal changes produced by death are discussed, and a special part in which the physical signs to be elicited from the thoracic and abdominal viscera are subjected to exhaustive analysis. The book is written with great attention to detail and should prove of service to those interested, but its value would be much enhanced by the addition of suitable diagrammatic or other illustrations.

A System of Practical Surgery. By Profs. E. v. Bergmann, P. v. Bruns, and J. v Mikulicz. Translated and Edited by Dr. Wm. 1. Bull. Vol. V. Philadelphia and New York: Lea Brothers & Company, 1904.

The appearance of the present volume marks the completion of one of the most elaborate treatises on surgery which has been presented to the profession in recent years. The original German edition met with a favorable reception, and the second followed within a brief period. The American edition has been translated from the latter and its character will undoubtedly be a guarantee of an equally favorable attention. The attempt to make the work practical has been sustained through all the volumes, but the more purely theoretical side has not been neglected, as is evidenced by pathological data, details of original research, and statistical facts. The volume under discussion deals with the surgery of the pelvis and genito-urinary organs, and has been translated with the collaboration of Dr. E. M. Foote. Malformation, diseases, and injuries of the pelvis are treated by Steinthal; abnormalities, injuries, and diseases of the kidney and ureter, by Schede; the bladder and prostate, by Nitze and Sonnenburg; the urethra, by Körte and Rammstedt; the scrotum, testicle, etc., by v. Bramman; the anus, rectum, and penis, authors not stated. These topics are quite elaborately discussed and, in most instances, well illustrated, many additions having been made by the American publishers, which add to the attractiveness and value of the work. Being encyclopedic in character, prominence is not given to the views of the individual authors, but each presents the most modern status of the subject. The volume comprises 789 pages, 354 engravings, and 16 plates, mostly colored, is well printed and bound.

Enlargement of the Prostate. Its Treatment and Radical Cure. By C. Mansell Moullin, M.D., Oxon. F.R.C.S. Philadelphia: P. Blakiston's Son & Company, 1904.

The present is the third edition of this book and includes all the recent progress with reference to the condition. The author was among the first to point out the dangers of catheter life and the advances made in treatment have removed most of the doubt that an enlarged prostate is no longer incurable. In addition to prostatectomy, the author also recommends orchidectomy and division of structures contained in the spermatic cord for diminishing the size of the prostate. This often meets with success in cases which are not adapted to the more radical operations, for, as the writer contends, the chronic congestion and inflammation are of as much moment as the overgrowth of the glands itself. There is no doubt that the testes possess a marked influence over the circulatory conditions in the prostate, and orchidectomy is usually followed by a rapid diminution in the size of the organ. The book is well written and forms an exceedingly useful manual on the subject in question.

Regional Minor Surgery. By George Gray Van Schaick, Consulting Surgeon to the French Hospital, N. Y. Second Edition. New York: International Journal of Surgery Company, 1904.

The second edition of this practical little book has been revised and additional chapters added. The author's object has been to furnish the general practitioner with such information as will be of service in daily practice. Subjects of a technical character have been avoided and only the most applicable methods have been presented. The entire body is taken up regionally, and many novel features which have been devised or successfully used by the author are described. The book is illustrated with simple, but clear, sketches, and within its 228 pages contains a large amount of valuable information.

A Text-Book of Histology. By Frederick R. Bailey, A.M., M.D. Adjunct Professor of Normal Histology, College of Physicians and Surgeons, Medical Department, Columbia University, New York City. New York: William Wood & Company, 1904.

Both the teacher and the student of human histology should view the appearance of this volume with gratification, for it will do much to lighten the labor of each. Written by an experienced instructor of this fundamental study, it combines the simplicity and directness of statement desirable for the learner, while at the same time the subject is covered with a thoroughness that leaves nothing to be desired from the standpoint of the teacher.

The selection and most advantageous plan of preparation of the large amount of material necessary for the demonstration of the minute structure of all the tissues of the human body is a most difficult problem, so that the fullness of detail to be found in this volume should make it a very welcome aid to all engaged in teaching the subject. This matter of technique has been made a special feature of the book, for, in addition to three introductory chapters respectively giving all the ordinary methods of fixation, staining, and sectioning; special staining methods, and the technique of neurological methods; there is appended to the description of the histology of each organ a paragraph devoted to the explanation of the exact method of preparation required to yield specimens illustrative of the text. In the choice of the source of material to be utilized great discrimination is shown, and wherever study of organs from one of the lower animals facilitates comprehension of human structures, these are made use of.

The entire text is characterized by clearness and a consistent plan of arrangement, qualities which are particularly noteworthy in the chapter on the nervous system. This is the longest in the book, comprising eighty pages, and is illustrated by an unusually fine series of drawings which should greatly facilitate the comprehension of the intricate structure of this set of tissues. Indeed, the illustrations throughout are admirably chosen and the many original drawings most beautifully executed.

It would be difficult to suggest any improvements in what is undoubtedly the most useful and practical textbook of human histology we have, and the volume needs only to be known to be appreciated.

The Pathology of the Eye. By J. Herbert Parsons, B.S., D.Sc., Lond., F.R.C.S., Eng., Assistant Ophthalmic Surgeon, University College Hospital; Curator and Pathologist, Royal London (Moorfields) Ophthalmic Hospital; Lecturer on Physiological Optics, University College, London. Volume I, Histology, Part 1. New York: G. P. Putnam's Sons; London: Hodder & Stoughton, 1904.

The design of the author of this volume is to produce a complete treatise on the pathology of the eye in four volumes. Volumes I and II will be devoted to the histology of morbid conditions of the eye. Volumes III and IV to a consideration of diseases that affect the eye as a whole, such as glaucoma, sympathetic ophthalmia, congenital malformations, etc.

Volume I is the only volume issued thus far. It includes the pathological histology of the lids, conjunctiva, cornea, sclera, iris, anterior chamber, and ciliary body, together with the bacteriology of the conjunctiva.

The work in its conception is one that has long been wanted by ophthalmologists. If the design is carried to completion, and the volumes to follow are equal in excellence to the present one, the result will be a monument to the writer such as few men in any country have erected to themselves.

The first volume is a book of 388 pages. It contains 267 illustrations. All the new illustrations, of which there are many, are from photographs not retouched. The illustrations are from half-tone plates. All illustrations are in black and white.

The work discloses a thorough knowledge of the subject on the part of the author, familiarity with the literature, and a broad comprehension of the various processes concerned in the production of the tissue-changes. The most advanced views are presented in language that is as brief and concise as possible in conformity with a complete description and discussion of the conditions under consideration. The volume is stored with facts which should be readily accessible to every oculist and pathologist. No medical library can afford to be without it.

Saunders' Question-Compends. Essentials of Chemistry, Organic and Inorganic. Containing also questions on Medical Physics, Chemical Philosophy, Analytical Processes, Toxicology, etc. By Lawrence Wolff, M.D., formerly Demonstrator of Chemistry at the Jefferson Medical College, Philadelphia. Sixth edition, thoroughly revised. By A. Ferree Witmer, Ph.G., formerly Assistant Demonstrator in Physiology at the University of Pennsylvania. Philadelphia, New York, London; W. B. Saunders & Company, 1904.

The new edition of this compend differs but little from its predecessors, by far the greater part of the fifth edition having been reprinted. We still note "formitates" (page 102), atomic weight of silver, 10 (page 134); "proprionic" acid (page 103); the table of elements on page 213 wants bringing up to date; as it stands at present there are several omissions. All of the above, with other small blemishes, have been reproduced in the new edition. The new matter includes three lines on cryoscopy, a couple of pages at the end of the section on electricity, and paragraphs on radium and organotherapy.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., assisted by H. R. M. Landis, M.D. September 1: 1904. Philadelphia and New York: Lea Brothers & Company.

Ewart, Gottheil, Norris, and Spiller are those who present the three months' progress. Each puts considerable of his personality into the work, and Gottheil, as usual, puts in several of his personal good pictures of skin diseases, one striking depiction of a self-produced eruption. The standard of work is being well maintained. In Norris's section on obstetrics there are interesting articles on early signs of pregnancy, diagnosis of conception, twin pregnancy, and procreation of sexes according to will.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, November 3, 1904.

Dr. Andrew H. Smith in the Chair.

The evening was devoted to the Anniversary Discourse by Dr. William H. Thomson.

The Present Statns in the Investigations of the Subject of Internal Secretions.—Dr. Thomson said that there were certain physiological and pathological facts that had been fairly well established, but reports from the laboratories showed how ignorant we have been and how much there was to unlearn. He, therefore, thought that the occasion of an anniversary address should be improved by reviewing some of the new findings. The term itself was an unintelligible one, and meant almost nothing until a short time ago. Little was thought about the important class of glands whose secretions could not be collected or examined, and whose specific properties could only be inferred, until it was discovered that when some of these glands became diseased, often fatal derangements followed. Then followed some animal experiments, the effects of removing the glands being carefully watched. Many facts had been reported from the laboratories which must be taken into account. Instead of the discoveries coming as complete statements, they were more like puzzles, and it was very trying, after receiving what was supposed to be real information, to be told that only partial facts had been presented. True progress in medicine resembled the process of growth, and growth could not be hurried. The mechanism of secretion had always been more or less obscure. For instance, there was no common agreement regarding the urinary secretion, nor one regarding even a single element in the urine. The primary question was, what had the kidney to do with urea? It was a fact that when three-quarters of the kidney had been removed from healthy dogs, the remaining one-quarter would secrete more urea than a sound and whole kidney, until the animal died from a general break-down of the proteid tissues into urea. He asked, what was uræmia? It was not due to the suppression of the functions of the kidneys, because one could have an impacted calculus with complete suppression of urine without uræmia developing . He asked why some forms of kidney disease ran on to death without dropsy appearing, while others developed a general anasarca. No explanation had been given. The function of the thyroid gland had only been guessed when myxœdema developed. In other words, the secretions, no matter in what amounts or how easily procured, had but little to tell of the vital processes to which they owe their origin. If this was so in regard to such secretions as bile and urine, he asked what could be expected from secretions which could not be obtained. There were certain limitations to the study of this subject by the imperfections of our knowledge of the problems in this new department of medicine. He believed the proper course to pursue would be to find out facts so far as had been demonstrated about each of these organs which charge the blood with some internal secretion, and then draw what conclusions he could from the facts presented.

The Spleen.—This was a ductless gland, of large size, with an abundant vascular supply, and always present in vertebrates, which implied that it was an important organ. It had been proven that all animals could get along without the spleen, and extracts of this organ showed no special properties. It was thought that the chief function of the spleen was to fill up a hole under the arch of the diaphragm; this was the old idea.

The Thymus.—The thymus gland was a so-called temporary gland. Physiologically this gland seemed to be associated in some way with the origin of the white corpuscles of the blood. As the lymphatic tissues increased in the body, it appeared that the thymus became superfluous, yet the investigations seemed to show that the true period of functional activity of this body was an important one. He referred to eighteen cases of marasmus that had been reported, in which autopsies had been obtained, in which the only lesion found was an atrophy of the thymus, and in which the average weight of the thymus was 2.2 grammes. This writer had concluded that an atrophy of the thymus was always found in cases of infantile atrophy; that the condition of the thymus was an index to the general nutrition of the infant; and that the state of nutrition in an infant might be determined by an examination of the thymus at autopsy by the microscope. Unexpected death might occur in children as well as adults when there was a persistent thymus; this, in some cases, might be due to pressure upon important structures in its neighborhood; in others from interference with the action of the heart, the heart stopping before respiration. The general increase of lymphatic tissue throughout the body, the so-called *status lymphaticus*, accompanied by enlargement of the thymus, was best treated by cod-liver oil, the children taking it with relish.

Thyroid Gland.—The diseased condition, myxœdema, had been artificially induced in man, and was an unmistakable result of atrophy of the thyroid gland. The administration of the thyroid extract held myxœdema in abeyance. Whatever the gland added to the blood in the way of secretion was very important. One writer had shown that myxœdema never occurred in old people; other writers had shown that as age advanced the thyroid elements lessened, and in old people the gland structures could not be recognized. In time the function of the thyroid ceased to be associated with life. No organ of the body had been the subject of so much investigation as the thyroid gland. In carnivora its removal seemed to be fatal, but in omnivora less so. The question whether this gland was necessary to life had been considered by many, and with different answers, but more recently it had been held that there were certain small bodies, called parathyroids, which were found closely associated with the thyroid; in some animals they were found to be imbedded in the thyroid gland itself, and in others they were found to be quite separable. Parathyroid bodies could not be converted into thyroid tissue, the organs being of a different nature; the parathyroid bodies could not compensate for the thyroid if the later was removed. It had been demonstrated that if the parathyroids were dissected out from the thyroid in carnivora, the animals would appear with tremors, convulsions, etc.; but if the thyroid was removed and the parathyroids left, no such conditions resulted. The speaker believed that some internal secretions might have an antitoxic function, by which poisons in the body were neutralized. There were poisons which acted upon the nervous system, and whose accumulation in the blood did not act in health because of the presence of certain antidotes. Much confusion existed at present regarding the functions of the thyroid gland. In Graves' disease it had been claimed that this was accompanied by hypertrophy of the thyroid, and this charged the blood with its own secretion in excess. He referred to one case of Graves' disease in which no parathyroid bodies could be found. In all cases of Graves' disease it had been found that the parathyroids were smaller than normal. The thyroid was susceptible to certain toxic agents which circulated in the blood in somewhat the same way that exophthalmic goitre seemed to have some connection with drinking water, and which was found to be epidemic as well as endemic. This was proven by certain people who, in order to avoid going to war, partook of a certain drinking water, thus inducing exophthalmic goitre. Dr. Thomson here referred to an article published some time ago on forty-eight cases of Graves' disease. Here it was concluded that the thyroid was not primarily the seat of the malady, but was only a secondary involvement, in much the same way that the spleen was involved in ague. There seemed to be produced a certain toxin which caused the symptoms of Graves' disease, and these toxins were, in all probability, gastrointestinal in origin. He maintained that the treat-

ment of this disease by diet and gastrointestinal attention was speedier in results and far better than any symptomatic or surgical procedures. What were the derangements that could be charged to the thyroid and parathyroids? When the parathyroids were excised and the thyroid left, very severe symptoms developed; but this was not true if the thyroid was removed and the parathyroids left. Dr. Thomson was inclined to the belief that the internal secretion of the thyroid was intimately related to the nutrition of connective tissue. The mucoid infiltration occurring in myxœdema was due, in his opinion, to some degenerative change in connective tissue fibers. In gliomata the question arose whether an extract of the thyroid gland could not be made use of in treatment; given a history of intracranial growth, the administration of thyroid extract, after other measures had been tried without success, might result favorably. He was aware of such a case in which relief was obtained in a very short time by the giving of thyroid extract. This agent had been prescribed in almost everything from skin diseases to insanity, but the final verdict must be waited for.

Pituitary Gland.—This was a small, reddish-gray vascular body, weighing from five to ten grains, with only one lobe of really glandular character, and which was situated in the sella turcica. The fact that massive nutritive changes, as in acromegaly, should occur when the function of so small a gland was interfered with, was very strange. In three out of seven cases of acromegaly reported, the pituitary body was diseased, and one could not but concur with the opinion that disease of this body was a common accompaniment of acromegaly, possibly secondary to the bony changes. In acromegaly there was disordered body growth. When the testicle of a young animal was removed the subsequent development of that animal was modified. Various theories had been propounded to explain these facts. He believed that the normal growth of the body generally represented the sum of the interaction of the growth of different organs of the body. In acromegaly one might find a general derangement of the processes of nutrition, and this might include the functions of one or more of the ductless glands.

The Panereas.—Attempts at study of the pathology of diabetes were most tantalizing. The pancreas, no doubt, had much to do with the origin of the disease; if the whole gland was excised, diabetes would develop in its most severe form. The islands of Langerhans exerted some influence upon the development of diabetes, but the extent of this influence was not clearly known. It was a remarkable fact that diabetes was not dependent upon the quantity of secretion, for if one-quarter or one-fifth of the pancreas were left in the body no diabetes would occur. Even if only a small piece was grafted in the skin it would suffice to prevent diabetes occurring. Glycogen was really the fuel for combustion, and Dr. Thomson referred to the action of the adrenals and their influence upon the excretion of sugar in the urine, showing that it was very unlikely that certain physiological functions depended upon one organ or single process. There had been instances of total destruction of the pancreas by cancerous disease, and yet no diabetes developed.

Suprarenal Glands.—Addison's disease was caused by disease of the adrenals. The active principle could be obtained, whose properties could be demonstrated as definitely as those of quinine. The chief property of adrenalin seemed to be in its ability to cause arterial contraction. As small a dose as 1-800 of a grain of suprarenal extract in an adult man would do this. The active principle acted upon the vessels through an influence upon the muscular coats directly, and not through the nervous influence. Even the skeletal muscles did not escape its action. Its action upon the heart was very marked. This agent should be used with great caution in cases of obstruction in arteries. It might be of value in hæmatemesis, but its value in hæmoptysis was doubtful. An effect of adrenalin described by Oliver and confirmed by others was upon the volume of the kidney, a shrinkage occurring of one-half its bulk when this agent was administered. It had been stated that the high-tension pulse of kidney disease was the result of the kidney changes themselves; but high pressure could be assigned as the leading factor in producing changes in the arterial walls, and this factor, he said, was present in the beginning of the kidney disorder, and was not a late consequence. The high tension caused an endarteritis; an endarteritis did not cause the high tension. The primary cause of high-tension pulse must be found in the fact that the blood was charged with some agent which had the property of producing universal arterial contraction. The arteries of the kidney were those first affected. A not improbable surmise was that the high tension of the pulse in many forms of kidney disease was due to the action and excess of adrenal secretion in the blood. If this was true, its importance in this pathological condition was very great. The inference was that a high tension pulse went with contracted kidney; if the kidney was functionally contracted, wholly or only partially, by the action upon it of some agent in the blood, then the administration of some vasodilator should be followed by an increased urinary excretion. Dr. Thomson here referred to a paper published by him in which were recorded the effects upon the excretion of urea of full doses of aconite in patients with chronic kidney disease with marked high arterial tension. In such conditions he thought that aconite was indicated. The relation of adrenalin to high-tension pulse was demonstrated experimentally by administering this agent to rabbits; there followed atheromatous changes and an arteriosclerosis. He thought it was greatly to be desired that the condition of the adrenals should be examined carefully in all cases of kidney disease.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

Stated Meeting, Held October 7, 1904.

Dr. Robert T. Morris in the Chair.

Resection of Greater Part of Stomach and Transverse Colon for Carcinoma.—Dr. A. A. Berg presented a patient who had been admitted to Dr. Gerster's service at the Mt. Sinai Hospital during the middle of last June. He came from Texas, where a diagnosis had been made of malignant growth of the stomach. This diagnosis was easily confirmed. There was a freely movable mass, about the size of the closed fist, in the epigastric region, which was connected with the stomach. An examination of the gastric contents revealed an absence of free hydrochloric acid. The patient had lost a great deal of weight and was very cachectic. A median incision was made after the customary preliminary treatment, and revealed a cancerous mass of the stomach, about one and a half inches from the pylorus. It was an annular malignant growth with considerable glandular involvement, especially in the gastrocolic omentum, and some in the transverse meso-colon. Bleeding was very free, and numerous little vessels, branches of the cœliac axis, were separately ligated. The preliminary removal of the glands occupied at least one-half an hour. He ligated the pyloric branch, and then a large branch of the gastro-hepatic artery. The stomach was removed, with the exception of about one and a half to two inches at its cardiac end, just enough being left to make an anastomosis with the Murphy button. A gastro-jejunostomy posterior was then performed. When he ligated the colica media artery and removed what fat was necessary, he thought it best to make a resection of the transverse colon. A gauze strip was then introduced down to the stump of the duodenum, and the wound was closed throughout its greater part. Twenty-four hours after the operation the patient was fed by mouth, and he never vomited during the entire course of his convalescence. He made a steady recovery, although there was some leakage from the duodenal end, and caused probably by the irrita-

tion of the gauze drainage. The patient was out of bed on the fourth week and had gained steadily in weight. There were no evidences of any recurrence of the growth. This patient represented the most complete extirpation of the stomach, there being left only one and a half inches of its cardiac end. The patient gained over 30 pounds in a little more than three months. The peculiar part of his present condition was that the patient was able to eat one meal and take considerable more than the average man would. The test meal, taken one hour after ingestion of his food, showed 30 c.c. to be contained therein. Dr. Berg expected to distend the stomach in the near future, after administering bismuth and taking an *x*-ray photograph, which he will present the Section.

Dr. Charles H. Peck referred to his experience with a case of intestinal resection, where the gauze drainage was carried out, leakage occurring on the seventh day; this leakage lasted three days, and then the opening closed spontaneously. The future course of the case was uneventful.

Dr. Robert T. Morris asked Dr. Wiggin if, in cases of sepsis, he favored the use of salt solution in the peritoneal cavity, and if he did not think that it interfered with the coagulation of the lymph?

Dr. F. H. Wiggin replied that he had not found it so.

Dr. Morris asked Dr. Berg if he had known how extensively the glands were involved would he have operated?

Dr. Berg replied that in malignant disease of this type that there was nothing else to do.

Dr. Morris said that the three months of comfort afforded the patient was worthy of mention. He had never removed the stomach but once, and thought it was easy of accomplishment. The results in Dr. Berg's case were certainly satisfactory.

Dr. Berg stated that in intestinal anastomosis, unless there was some soiling, he had never been prompted to drain. Where drainage was indicated, he introduced it down to the line of sutures.

Experiments Demonstrating the Value of Oxygen in Connection with All Anæsthetization.—Dr. James T. Gwathmey read this paper. (See page 816.)

A New Surgical Chisel.—Dr. Frederick Griffith showed some chisels. (See page 839.)

Granulation Wound Adhesions with a Prelimimary Report on a New Application in Preventive Treatment.—Dr. Frederic Griffith said that in an article two years ago he brought forward the theory that the healing of granulation wounds was dependent upon mechanical principle of friction, and his present contribution had in view the presentation of an application for preventive treatment, and some thoughts upon another method of treating these wounds. After considering the pathology of granulating wounds, he stated that the value of a given application to a granulating wound depended upon the amount of fluid it caused to be produced, and, according to this principle, dusting powders were without exception irritating. Watery solutions failed of their purpose by the amount of relaxation and maceration which they produced. If an outer covering of sheet rubber tissue, or oiled silk, protective be applied, the condition was made worse by the direct bid for pus development being made. An approach to an ideal application to an external granulating wound was the membranous quality of rubber tissue when applied shingle fashion. This, however, was not an animal membrane, and, therefore, could not react to the progressive changes of regeneration in the wounded tissues. The employment of the peritoneum of an ox, known by the name of Cargyle membrane, marked an epoch in the treatment of granulating wounds. The specimen of tissue which he wished to present consisted of the gastrointestinal mesenteric attachment of the gray or sand shark (*Carcharias littoralis*), so common to the American coasts. Two or three square feet of this gossamer, but tough, membrane were obtainable from an ordinary sized fish. The material was readily secured and cheap.

Dr. Robert T. Morris said that it was often difficult to separate the peritoneum from the abdominal walls, especially in some sharks, mackerel and dog-fish. If the material mentioned could be cleaned without much difficulty, he thought it would prove to be an admirable preparation. Cargyle membrane absorbed too rapidly unless it was chromicized. There was more fat in the peritoneum of the ox than in that of fish. Cold-blooded vertebrates, like the seal, had no fat in the peritoneum. He believed this preparation might be more easily prepared than the peritoneum of the ox.

Southern California Dental Society.

Several papers of more than ordinary interest to the medical profession were presented at the annual meeting of this society, which took place at San Diego on October 24-26. These were read at the evening sessions and many of the local physicians attended by invitation; several of them participated in the discussions. The papers were illustrated with numerous stereopticon pictures, some of them projected directly from the microscope. E. S. Leonard, M.D., of Los Angeles, read a paper on "Tumors of the Mouth and Face, with Especial Reference to Early Diagnosis;" William Bebb, D.D.S., one upon "Comparative Odontology," and Ray D. Robinson, D.D.S., one on "Mouth-Breathing in Its Relation to Orthodontia." The paper of Dr. Robinson was of especial value to physicians. The essayist was emphatic in his statements that the elevation and narrowing of the palatine arch with deviation of the nasal septum and faulty occlusion of the teeth are invariably due to mouth-breathing, and that all efforts of the orthodontist to rectify the deformity must prove unsuccessful until this habit has been overcome. He insisted, therefore, that it is the duty of dentists to urge upon parents the importance of having the adenoids or enlarged tonsils removed without unnecessary delay, both as a preparatory measure to other treatment and as a means of preventing an increase of the existing disturbances. Both dentists and physicians, he said, should exercise greater vigilance toward the early recognition of mouth-breathing, since the removal of adenoids in early childhood would prevent the formation of the habit of breathing through the mouth, and thus render subsequent treatment unnecessary. By one of his illustrations he demonstrated the ultimate failure of orthodontal treatment, with return of the deformity, in a case in which the habit had not been overcome prior to the operation. The most phenomenal results in other cases were clearly shown; cases in which the palatine arch had been widened from a half to seven-eighths of an inch, with corresponding lowering of the apex and straightening of the nasal septum; other cases in which the molar teeth had been moved bodily a distance nearly equal to their width; others again in which the entire row of teeth on one side had been carried backward without disturbing the position of those in the opposite side. Equally striking results had been obtained in the straightening of distorted and protruding incisors. Several of the photographs beautifully illustrated the improvement of facial expression, every evidence of the dullness so characteristic of the mouth-breather having been removed. In speaking of the methods employed the essayist expressed decided preference for the Angle arch and the Baker anchorage. Another interesting feature of the meeting was the exhibition by Dr. William Bebb, of a large collection of skulls illustrative of comparative odontology. These were the property of the museum of the Dental Department of the University of Southern California, at Los Angeles.

Philadelphia Neurological Society.

At a stated meeting held October 25, Dr. L. C. Peter exhibited "A Case of Hysteria." The patient was a woman, about twenty-seven years old, employed as a shipping clerk, who several years previously had been seized with difficulty in walking, to which subsequently motor incoordination and difficulty in speech became added. The gait presented the features of ataxia, spasticity, and asthenia.

The knee-jerks were exaggerated, ankle-clonus could be elicited, and the Babinski phenomenon was present. There had at one time been difficulty in the expulsion of urine, and in parts of the body, especially below the thorax, there was impairment of painful and tactile sensibility. The pupils were of normal size and they reacted properly. The fundus of each eye was normal. There was no nystagmus. The power of accommodation was almost entirely lost. The visual color fields were greatly reduced in size and reversed. Coordination in the upper extremities was at times more marked with the eyes open than when they were closed. There was no wasting. There was some difference of opinion as to whether the case was one of hysteria pure and simple, or a combination of hysteria and organic disease, most likely multiple sclerosis. Dr. J. H. W. Rhein presented "A Case of Trauma of the Cervical Spine Exhibiting Syringomyelic Symptoms." The patient was a middle-aged man, who had been struck by a heavy roll of carpet, falling from a considerable height. He was at once rendered unconscious, and subsequently presented the features of a left hemiplegia, with impairment, especially of thermal sensibility on the right side of the body. Skiagraphic examination failed to disclose evidence of fracture or dislocation of the cervical spine. Dr. Charles K. Mills presented a communication entitled, "A Case of Myokimia, with Remarks Upon the Different Forms of Tonic and Clonic Myospasm." He exhibited a man, twenty years old, with neurasthenic symptoms, who had grown rapidly and was more than six feet in height, and in whom there appeared from time to time twitchings in small portions of muscles in different parts of the body. Dr. Alfred Gordon demonstrated "A New Reflex, Paradoxical Flexor Reflex." He had observed in cases presenting spastic phenomena that with the observer standing on the outer side of the patient and the ulnar margins of the hands resting on the internal border of the tibia, extension of the great toe, and sometimes also of the other toes, and sometimes also flexion of the foot, took place when the deep flexors of the leg were firmly grasped between the fingers. The phenomenon was often observed in association with exaggeration of the knee-jerks, ankle-clonus and the Babinski reflex, but at times independently, and it is believed to be of considerable importance in the differentiation of cases of organic from those of functional disturbance. Dr. S. D. Ludlum made "A Preliminary Report on Neurofibrillar Changes," reporting the results of observations on rats subjected to inanition and physical exhaustion, and in one case of insanity of manic-depressive type. In each instance degenerative changes were found in neurofibrils related to cells of the cerebral cortex. Dr. Charles K. Mills and Dr. T. H. Weisenburg reported "A Case of Mixed Aphasia, with Hypesthesia and Partial Hemianopsia in a Left Hemiplegic." The patient was a man, fifty-nine years old, who during childhood had suffered a fracture of the right radius, and in consequence had learned to use the left hand for many purposes, though not for writing. He was seized with left hemiplegia, associated with aphasia, being word-blind and letter-blind, and unable to write spontaneously, on dictation, or by transcript.

Philadelphia County Medical Society.

At a stated meeting held October 27, Dr. Moses Behrend reported a case of typhoid fever with many complications. A man, 33 years old, presented at first in the course of an attack of typhoid fever severe muscular twitching, with general agitation and insomnia, followed later by profound sopor. During the fourth week symptoms suggestive of perforation of the bowels developed, namely, collapse, chill, abdominal distention, tenderness, and rigidity, with slight effacement of the liver-dullness. Immediate operation was advised, but was declined, on account of the debilitated state of the patient. Later, however, operation was assented to. No perforation of the bowel was found, but the appendix was inflamed and adherent, and it was removed. The mental condition improved in a short while, but signs of effusion into the left pleural cavity developed and a pint of serous fluid was removed by aspiration. Subsequently, symptoms of pneumothorax appeared. Considerable relief was afforded by aspiration of some of the gas. Polyuria was a feature of the attack, being especially marked when the temperature was highest. Recovery eventually ensued, in the course of ten weeks.

Dr. M. C. Thrush read a paper entitled "The Trend of Modern Prescription-Writing," based upon a careful examination of five hundred prescriptions received and filed in each of two of Philadelphia's best prescription-stores, so located as to receive prescriptions from the leading physicians of the city, including teachers in the medical schools and members of hospital staffs, as well as a number of physicians in general practice. Of the entire one thousand, 13 contained chemical incompatibilities, the same number pharmaceutical incompatibilities, one a therapeutic incompatibility, 50, six or more ingredients; 718, from two to five ingredients; 232, one drug or preparation; 484, only official preparations; 359, proprietary preparations in whole or in part; 2, patient medicines, and 155 non-official preparations. In 5 the metric system was employed in whole or in part, and 621 were written correctly.

Dr. S. W. Newmayer read a paper entitled "The Relation of the Physician to the Bureau of Health." He maintained that the treatment of disease is secondary to its prevention. The diseases that affect the masses are principally the infectious. Authoritative guidance in sanitation and forensic legislation is vested in specialists in public health, constituting bureaus of health, but the practical application of the principles of sanitation by these lacks completeness without the constant co-operation of the entire medical profession. It is necessary for practitioners to report cases of contagious disease, and the diagnosis has been simplified by the maintenance of public, modern, efficiently equipped laboratories for bacteriological and chemical investigation examination.

Medical Jurisprudence Society of Philadelphia.

At a stated meeting, held October 17, Dr. T. Luther Coley read a paper entitled, "The Influence of Certain Food-Preservatives on Digestion; Based on Experiments." He had found that the presence of benzoic acid in food had an accelerating effect on digestion when present in a proportion of 1-10 per cent., and even up to 10 per cent. it has no retarding effect. It exerts no deleterious influence on the organs of animals, as experimental observations have demonstrated. It is a normal constituent of some foods, and it is eliminated from the body without irritation. It has been used as a preservative of food in a proportion of 1 to 1,000. Dr. Henry Leffmann presented a communication entitled, "Suggestions for Food-Laws." He pointed out that the adoption of a food-law is the beginning of the work of suppressing adulteration. It is necessary to institute investigations, obtain and analyze specimens, make results public, and bring prosecutions. The usual method is that inspectors make purchases, mark packages so as to identify them, and deliver these to the chemist, who makes a return of the result of his tests. In most cases the seller is not warned at the time of the purchase that the article is to be analyzed, and may never know the result if the article is found to be satisfactory. If it be unsatisfactory, the first knowledge the seller may have is when a warrant is served on him. The course followed in England is to be commended. The sample purchased by the inspector should be divided into three parts—one given to the seller, one to the chemist for examination, and one kept by some central body for reference in case of a dispute. The portions should be sealed and marked. The results of the analysis should be transmitted to the seller in any event, that is, whether adulteration is found or not. Analytical results should be obtained and reported quickly. With proper arrangements not more than a week need elapse from the time of the purchase of a

sample and the receipt of a report on it. All prosecutions should be brought not more than a month after the purchase of the sample, and the formal trial of the case should not be more than six months after. In the bringing of a series of suits on a long line of samples from one dealer, there is an opportunity for oppression and extortion. The principle of "warranty" might also be given some play in the matter of food control. This is substantially that a guarantee of purity transfers any responsibility from the dealer in whose hands the goods may be to the manufacturer or intermediate dealer. There should also be a system of warning. The first offense should be met by a written notice to the offender that a second offense will be prosecuted. Many instances of food adulteration are due to inadvertence.

Chicago Medical Society.

At a meeting held October 5, Dr. Hugh T. Patrick presented several cases, and Dr. Charles L. Mix reported a case of "Traumatic Neurosis Associated with Tubes."

Dr. Norman Bridge read a paper entitled, "Some Common Errors in the Treatment of Pulmonary Tuberculosis." He said the mortality of tuberculosis had been reduced in less than three decades by probably 29 per cent. of the former figures, or from 14.25 to 10 per cent. of all deaths. These results were not accidental, but were clearly due more to the better management of the pulmonary form than to any other influence. The great first purpose of all treatment was to increase the physiological power of the patient to resist the disease and destroy or circumscribe its course within his own body. To give creosote to the extent of lowering the digestive power, or to give serum injections to the production of phlegmons and higher temperature, or to give coal-tar drugs for fever, while the patient was allowed to go on in his usually unhygienic course of life without advice or correction, was an error so awful in its results that not even confession and penance were sufficient atonement. And all practitioners had sinned in some of these directions, and some of them grievously. Every patient should be constantly supplied with outdoor atmosphere in such abundance that every successive inspiration brought a fresh dose of air to the lungs, and none from previous expirations. Every one should have long hours of rest; if feverish, the rest recumbent should be almost or quite constant, for exercise increased the fever. The digestive powers should be made to do their best under the most careful supervision and direction toward improving the nutrition and possibly also the resisting power of the patient. A tuberculous patient was never helped to resist the disease by muscular development above his normal standard. A consumptive's body should always be well and equably clothed, and never be hampered or restricted by garments. Snug corsets and conventional gowns were an abomination for the tuberculous woman. Worn as they were by most such women, they frequently tipped the scales in favor of death rather than recovery. Climatic treatment of tuberculosis had rightly become popular the world over; yet he was compelled to the belief from abundant observation that of all the remedies prescribed for the tuberculosis, one of the most unfortunate and unsatisfactory was climate as it was usually employed. Going away for climate was one of the most abused and misused of all the great measures for the sick; and so what ought to be a blessing unspeakable often became a pitiful deception and a vision of death. This misfortune was largely an error of the people, but the profession was greatly at fault about it also. In more than half of the instances in which it was advised it was for the wrong kind of cases, or at the wrong time, or for the wrong people; that is, with poor regard for all the circumstances of the situation.

At a meeting, held October 22, Dr. E. Fletcher Ingals read a paper entitled "Bronchoscopy for Foreign Bodies in the Bronchial Tubes." The author reported two cases in addition to those reported by him to the American Laryngological Association, in June, 1904. Case I. Lower bronchoscopy. Infant, fourteen months old; two days previously had inhaled a coffee bean. Usual symptoms of cough, and labored respiration followed. At the time of examination, pulse was 126, temperature 102.2°, and respiration 62. As to physical signs, respiratory murmur was much diminished over the right lung; vesicular sounds were hardly audible. There was no dullness on percussion. Owing to the small size of the child, and the consequent difficulty of pasing a tube through the glottis, lower bronchoscopy was decided upon. Dr. Arthur Dean Bevan did the tracheotomy; the coffee bean was found at the lower end of the right bronchus, and removed without difficulty. The child did not rally satisfactorily, and in spite of reopening of the wound, stimulation and administration of oxygen, died about sixteen hours after. Case II. Upper bronchoscopy. Patient was a boy, two years of age; aspirated a large kernel of corn. Upper bronchoscopy was done under chloroform, and the kernel was found in the right bronchus and removed. Recovery prompt and uneventful. The cases were presented on account of their similarity. Question of cause of death of Case I. not certain. Post-mortem could not be obtained. Death may have been due to bronchopneumonia or to the shock following the operation. The latter theory seemed to be borne out by the fact that very young children do not stand tracheotomy well. Dr. Norval H. Pierce had seen Killian use his method in the case of a South American girl, six years of age, who had the whistle of a toy in her right bronchial tube, low down, for two months. Two attempts were made to remove it. The first attempt lasted an hour and ten minutes, the second three-quarters of an hour, and, although Killian could see the foreign body distinctly, he was unable to extract it on account of the swelling that occurred in the bronchial mucous membrane above the foreign body. As he pushed his bronchoscope downward, the mucous membrane, which was very edematous, welled up in front of it, so that when he reached for it with the forceps the mucous membrane got directly in the way of vision. The third attempt was made through an opening in the trachea, and this was successful. The patient later succumbed to bronchopneumonia, which, the speaker believed, was the usual cause of death in these cases.

At a meeting held November 2, 1904, Dr. B. W. Sippy showed a man who had "Stenosis of the Lower Portion of the Œsophagus." Great discomfort was experienced in swallowing, the discomfort being located by the patient below the lower portion of the sternum. An œsophageal bougie of large size was introduced, and the obstruction located at forty centimeters from the incisor teeth, near the cardia. Dr. Sippy introduced the œsophagoscope, after having preceded it with thorough cocainization of the œsophagus, so that any member could see the point of constriction. In treating this patient a bougie would be passed day by day; the patient would be given food that was non-irritating; also between thirty and forty grains of bromide of sodium every four hours. Furthermore, the patient's body would be given as much rest as possible. With this treatment the speaker hoped to succeed finally in overcoming the spasm, as in this case there was no ulceration, no erosion, and no sacculation. Dr. Norman Bridge urged great caution in passing œsophageal bougies, as he had known of some instances in which injury was done by exerting too much force in introducing these instruments into and against the spasm of the cardiac end of the œsophagus. A case was narrated by him of a woman who had a spasm of the œsophagus, which was extremely unyielding at times, rendering swallowing of food difficult, yet at other times the spasm would relax so that she could swallow without much difficulty. Dr. Norval H. Pierce had used the œsophagoscope in the diagnosis of tumors and in extracting foreign bodies. In diagnosis it was

an extremely important instrument, and for the purpose of removing foreign bodies it was a valuable instrument. Dr. Sippy said that probably not more than seventy-five or eighty cases of spasm of the œsophagus, producing dilatation of this viscus, had been reported in the literature up to this time. The condition was relatively common, but was simply overlooked. Within the last eight months he had seen several cases of idiopathic dilatation of the œsophagus and cardiospasm. Dr. Mortimer Frank read a paper on "Myasthenia Gravis," in which he reported the case of a female child, ten years of age. In this case ptosis was first ovserved in November, 1902. The present condition was one of bilateral ptosis and external ophthalmoplegia. The prognosis as regards recovery was practically hopeless.

New Instruments.

A NEW SURGICAL CHISEL.*

By FREDERIC GRIFFITH, M.D.,
NEW YORK.
SURGEON, FELLOW OF THE ACADEMY OF MEDICINE.

The illustrious French surgeon Faure, who has lately visited our country, in commenting upon American surgery in an article published in the *Presse Médicale,* observed that American surgical instruments were upon the whole clumsily made and fell far behind the graceful and artistic products of the artist instrument makers of France. Having visited M. Faure in his own surgical clinic at the Hospital Laennec in Paris, I can say of a truth that some of the Frenchmen's instruments at least partake of the sprightly cavorting characteristics of the French people themselves, and my own observation regarding them was that ingenuity was oftentimes wasted upon complicated mechanism.

Simplicity in construction must ever be the standard of a surgical instrument, and while there are no joints to a chisel, there is a vast difference between a stone-cutter's pitching tool and the surgeon's delicate osteotome.

The chisels presented are intended to preserve the grace of the dainty little instrument commonly called a chisel by the surgeons. The simple and evident fault of this instrument as it exists lies in the shortness of the handle. It is only necessary to observe an operator using one of these miniature chisels to be made aware of its disadvantages, for he either completely covers his field of labor with his grasping fist, or when by endeavoring to hold the implement between two or three fingers to allow himself a view of the bone he is cutting thereby loses a proper control. Instrument makers in seeking to remedy these difficulties, lengthen the chisel, it is true, but they seem to have the idea that the instrument is to be most often used as the shoemaker employs his awl. The handles are therefore made too bulky, with the result of an illy-balanced implement. The claims made for the models shown are: a free view of the cutting edge is obtainable to the extent allowed by retraction of the soft tissues and a proper balancing between the handle, shaft, and cutting edge.

40 East Sixty-Fourth Street.

*Presented at a meeting of the Surgical Section of the New York Academy of Medicine, October 7, 1904.

Beiträge zur wissenschaftlichen Medicin und Chemie. Festschrift zu Ehren des sechszigsten Geburtstages von Ernst Salkowski. 8vo, 480 pages, illustrated, paper. August Hirschwald, Berlin, Germany.

Hand-Book of the Anatomy and Diseases of the Eye and Ear. By D. B. St. John Roosa, M.D., LL.D., and A. Edward Davis, A.M., M.D. 12mo, 297 pages, muslin. F. A. Davis Company, Philadelphia. Price $1.00 net.

Diseases of the Nose, Throat and Ear and Their Accessory Cavities. By Seth Scott Bishop, M.D., D.C.L., LL.D. Third Edition. 8vo, 564 pages, muslin. Illustrated. F. A. Davis Company, Philadelphia. Price $4.00 net.

The Art of Compounding. A Text-Book for Students and a Reference Book for Pharmacists at the Prescription Counter. By Wilbur L. Scoville, Ph.G. Third Edition. 8vo, 337 pages, muslin. P. Blakiston's Son & Co., Philadelphia. Price $2.50 net.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and Their Employment Upon a Rational Basis. By Hobart Amory Hare, M.D., B.Sc. Tenth Edition. 8vo, 908 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price $4.00 net.

Surgical Emergencies. The Surgery of the Abdomen. Part I. Appendicitis and Other Diseases About the Appendix. By Bayard Holmes, B.S., M.D. 12mo, 350 pages, illustrated, paper. D. Appleton & Company, New York.

Outlines of Physiological Chemistry. By S. P. Beebe, Ph.D., and B. H. Buxton, M.D. 12mo, 195 pages, illustrated, muslin. The Macmillan Company, New York. Price $1.50.

Multiple Personality. An Experimental Investigation Into the Nature of Human Individuality. By Boris Sidis, M.A., Ph.D., and Simon P. Goodhart, Ph.B., M.D. 8vo, 462 pages, muslin. D. Appleton & Company, New York. Price $2.50 net.

Syphilis and Gonorrhœa. By C. F. Marshall, M.D., Ch.B., B.Sc.Vict., F.R.C.S. 8vo, 267 pages, muslin. Rebman Company, New York.

La Chirurgie du Médiastin Anterieur (Cœur et Péricarde Exceptés). Par Le Dr. Maurice Auvray. 8vo. 224 pages, illustrated, paper. J. B. Ballière et Fils, Paris.

The Principles of Relief. By Edward T. Devine, Ph. D., LL.D. 8vo, 495 pages, muslin. The Macmillan Co., New York. Price $2.00 net.

Qualitative Analysis Brief. By Allard Memminger, M.D. Second Edition. 12mo, 118 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price $1.00 net.

Clinical Diagnostic Bacteriology, Including Serum Diagnosis and Cytodiagnosis. By Alfred C. Coles, M.D., D.Sc., F.R.S. 8vo, 237 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

Antagonism of Certain Infusoria and Pathogenic Bacteria.—Guiseppe Pacinotti reports the results of some experiments made to determine the action of an infusorian called paramœcium upon virulent bacteria, such as those of tuberculosis, anthrax, and typhoid fever, streptococcus pyogenes, etc. He placed the infusoria and the bacteria in the same solutions and observed the results. The infusoria eat blood corpuscles, decaying animal matter, etc., and these materials can be seen in the vacuoles of the cell bodies of the infusoria. In the same manner, he found that the paramœcia not only were not hurt by the virulent bacteria, but that they even devoured the latter, which could be seen in the process of digestion in the bodies of the infusoria, just as the blood corpuscles had been seen. The author also found that substances like chloroform stopped the action of the infusoria. The cultures of bacteria lost materially their virulence by contact with the infusoria.—*Rivista Critica di Clinica Medica.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 12, 1904:

	Cases.	Deaths
Measles	59	3
Diphtheria and Croup	362	27
Scarlet Fever	201	8
Small Pox	1	.....
Chicken Pox	77	.....
Tuberculosis	299	154
Typhoid Fever	100	21
Cerebro-Spinal Meningitis	.....	11
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	1,099	224

Mental Phenomena and Visceral Disease.—Cary B. Gamble declares that the mental changes that at times take place in different pathological conditions may be due: 1. To changes in the blood in cardiac disease, or to vascular degeneration. 2. To poisoning, resulting from disease of certain organs, as for example, the kidney or liver. 3. To the effects of alcohol and like poisons, either in acute or chronic form, by themselves, or in conjunction with diseases of the viscera. 4. To a change in some gland whose secretion is necessary to the normal metabolism of the body, for example, to atrophy of the thyroid with its resultant hebetude as seen in myxœdema. The writer believes that if we could get away from the names that are appended to different mental conditions and remember that many cases of mental illness start with different conditions of physical disease, it would be a long step toward solving the condition of mental abnormality. The writer presents two series of cases, in the first of which are the following: Mitral stenosis, hallucination of sight. Asthma, and hallucination of smell. Adherent pericardium, hallucination of hearing, alternating depression and exaltation. Mitral stenosis, adherent pericardium, alternating depression and physical exaltation. Mitral stenosis, failing compensation, suspicion. Asthma, emphysema, loss of attention and memory, and unreasoning fear. In this class the patients can be easily persuaded that their moods have simply a physical basis. The writer briefly refers to Head's explanation of these phenomena, some of which are as follows: Liability to hallucinations is increased by the presence of pain over the trunk of the body. The only necessary concomitant of an hallucination is headache of the reflected type. Depression is characterized by its lack of projection. It is not an intellectual condition at all. It is an alternation of feeling tone in the direction of ill-being. To produce this condition, the pain must be of considerable intensity, or last for a long time, and at the same time a considerable area must be involved. The higher the area of pain the less liable is the patient to attacks of depression. Exaltation may be due to organic heart disease. Reflected pain is not always necessary to loss of attention and memory. The individual is unconsciously engrossed by his visceral existence, and his entire attention is not given to any one object, consequently there is afterwards no memory of what he has done. In the second class of cases, the patients cannot be persuaded that they are subject to hallucinations. This is easily explained by the well-known fact that an idea by continually being present can become fixed in an individual's mind. The writer states that the existence of the symptoms can be easily learned by questioning. But this should be done tactfully, and the confidence of the patient should be secured. It must be remembered, also, that these individuals come first into the hands of the general medical man, and not under the alienist's care. By the study of causes of disease the proper solution of many causes of insanity may be achieved. Many symptoms which do not belong to hysteria have been wrongly placed under that head. The writer finally emphasizes that mental illness and physical illness are closely allied to each other.—*Bulletin of the Johns Hopkins Hospital.*

Disadvantages of Peroxide Solutions in Otological Practice.—Bruder calls attention to unpleasant results which have followed the careless use of peroxide solutions in otological practice, such as diffuse external otitis, cerebral symptoms, suppurative phlebitis in the lateral sinus (fatal result from cerebellar meningitis), etc. He insists on care in the choice of a solution. Solutions made for industrial purposes are too irritant for medical or surgical practice. The meatus should be smeared with vaselin before the peroxide is introduced, in order to avoid maceration of epithelia. If unpleasant results follow the use of the remedy, it must be at once discontinued and sterilized vaselin substituted. In cases of cholesteatoma, and especially in operations on the mastoid, with sinus phlebitis and extradural abscess, the remedy should be used with great caution. Under the above restrictions the remedy can be profitably employed.—*Revue Hebdomadaire de Laryngologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended November 11, 1904.

DISEASES OF THE SKIN CONNECTED WITH ERRORS OF METABOLISM.*

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

THAT normal and abnormal metabolic processes play an important part in health and disease cannot be denied, but we are yet far from an accurate knowledge of the exact manner in which their effect is produced, or indeed of the definite changes in the tissues produced thereby. While experimental physiology and laboratory studies have done much to demonstrate some of the facts of assimilation and disassimilation, it is to clinical observations that we must mainly turn for our knowledge of the effects of metabolism on the skin or other organs.

It must be premised that thus far there have been relatively few recorded observations showing these effects with anything like the positiveness which is often demanded in modern medicine. It can further be stated that many of the facts which must be accepted clinically, as to the relationship under consideration, can probably never be demonstrated experimentally or by laboratory methods, with the precision we are accustomed to look for in regard to some of the medical and surgical matters in the realm of bacteriology.

But, on the other hand, there is much in medicine which is incapable of exact demonstration, and we rightly accept many facts and conclusions on the basis of accurate clinical observation by those qualified to judge. In this way much of the evidence in regard to the relation of errors of metabolism to certain diseases of the skin has been accumulated, and with advancing science they are being more and more put to the tests of laboratory work.

It is interesting to note that while older observers recognized and believed that certain diseases of the skin were dependent upon what were then called disordered blood states, or "bad blood," more recent scientific inquiry has confirmed the real truth of the observations, only under the different names of "autointoxications," "errors of metabolism," etc. It is also instructive to remember that the more recent study of Haemotology has conclusively demonstrated that the elements of the blood itself are subject at times to great changes, which are more and more recognized as resulting from or indicative of disorders or diseases of various organs. This is the more important because not many years ago only ridicule was given to those who subscribed to the older and more popular views regarding any forms of dyacrasia, diathesis, or blood-states in connection with diseases of the skin or other organs.

Time and space would fail in any attempt to treat fully of the views of older authors in regard to these matters; but in justice to the prescience and clinical acumen of those who had few if any of the methods of proof now available, some mention should be made of the wise judgment which experience led many to make in regard to the true nature and cause of certain affections of the skin.

Not to go back to the humoral pathology of what might be called the dark and middle ages of medicine, reference must be made to the many English and French writers of the last half century who advocated so strongly the dependence of certain skin lesions upon what was called the gouty, lithæmic, or arthritic state, or diathesis. The work of Garrod, Bence-Jones, Murchison, Bazin, Hardy, Tilbury-Fox, and many others, testify that, although ignorant of the exact manner in which the results were produced, they were convinced from clinical observation that systemic changes, now included under the general term of metabolism, faulty in character, had much to do with alterations of tissue, to which the names of various diseases were given.

The subject for our consideration, "Hautkrankheiten bei Stoffwechselanomalieen," or "Diseases of the skin connected with errors of metabolism," is by no means an easy one, for it involves the deepest and most secret processes of the economy, and seeks to penetrate the mysteries of nutrition in health and disease.

We can investigate the food and drink taken, and understand their chemical constituents, and know of the oxygen absorbed through the lungs; we can study some of the processes of digestion and comprehend the integral elements of the salivary, gastric, hepatic, pancreatic, and intestinal secretions which have to do with them; we can examine the blood chemically and microscopically, and recognize certain changes in health and disease; we can analyze the excreta and discover in them certain changes indicative of abnormal states.

But, after all this, how much do we know of the processes of life which intervene between the ingestion of aliments and oxygen, and the formation and regeneration of tissues and their activity? We can trace, to a certain point, the manner in which organic and inorganic materials combine and split up again into other substances: we can follow, to a certain degree, the chemico-vital processes which take place in the body, and account largely for the oxygen and food consumed; we know the condition of metabolism in health and under various conditions of diet and starvation; we understand also the difference in the metabolic processes belonging to conditions of labor, rest, mental activity, sleep, etc.

But still, after all this, we can know very little of the actual methods in which metabolic changes take place in the various tissues of the system, and still less of the mysterious power by means of which the living cells of the organism appropriate for their use the elements required, and cast off effete matters, which has given up its "potential energy" to be expended as "living force" in the economy.

It is thus seen that while we can go to a certain distance with our physiological laboratory knowledge, when it comes to the actual relations of

*Read before the Fifth International Dermatological Congress, Berlin, September 14, 1904.

errors of metabolism to diseases of the skin or other organs, we are entering quite a different field of study. We have now only to rely on the careful clinical observations of repeated occurrences of certain morbid changes in an organ, in connection with evidence of deranged metabolism, as manifested in the excretions; and from this we infer an association or even a causal connection between the two.

The four great emunctories of the body, the lungs, skin, intestines, and kidneys, between them eliminate the waste products of metabolism, including water, the total of which, under normal conditions, very nearly corresponds to the amount of the ingesta and oxygen taken; in sickness and in conditions of starvation, or over-feeding, the proportions may vary considerably.

It is rather a difficult process to ascertain and analyze the amounts yielded by the lungs, skin, and intestines, and the urine has always been the excretion most depended upon to reflect the normal or abnormal state of the system. And this rightly remains a most valuable indication of the state of metabolic changes; for, coming so directly from the blood, when repeatedly and properly studied it portrays the state of that vital fluid with an accuracy and reliability leaving little to be desired. The results of the destruction of the carbonaceous elements are largely given off as carbon dioxide by the lungs, and to a very slight extent by the skin. Little is known as to the part played by the excretion of the skin, other than as to its water, except that under some circumstances considerable urea, uric acid, and even sugar may be found; and it is not ordinarily feasible to utilize this excretion in the study of metabolism. The intestinal excretion, while it undoubtedly contains some of the products of metabolism, is so largely composed of refuse from the food, varying so greatly with the variety of the ingesta, that relatively little is known as to the part it plays in removing the waste products of catabolism; and the difficulties in the way of accurate analysis of its components are so great that practically it is excluded in the ordinary study of metabolic changes.

But the urine yields itself with peculiar advantage to the investigation of the results of metabolism, both by the readiness of its collection and relative ease of its chemical analysis; its revelations are also peculiarly valuable from the fact that it represents nearly one-half of the total excreta, and practically all of the nitrogenous and soluble mineral substances, together with about one-half of the water expelled from the system. Complete and minute urinary analysis, therefore, affords a very fair indication of the manner in which anabolism and catabolism are performed. It is understood, of course, that this urinary analysis does not refer simply to the detection of albumen or sugar; indeed, these morbid elements seldom play an important part in the studies under consideration; for in the class of cases to be considered these conditions are relatively rare.

The urine, however, on close analysis, often shows derangements in its many constituents which are of the greatest significance in connection with metabolism, which clinical experience teaches are of the highest importance in their relations to many diseases of the skin. And, as a corollary to this, we find that in many cutaneous diseases the favorable results of a therapeusis which corrects evident errors of metabolism warrants the belief that the errors which have been thus corrected have exercised an influence on the causation and the continuance of the skin lesions.

We find, therefore, the proper study of the urine an invaluable aid in the practical management of this class of cases, without which much of the treatment would be experimental and empirical.

This proper study of the urine involves often a knowledge of the total daily output, and an estimate of the entire quantity of solid ingredients, as well as a quantative analysis of the same, in respects to urea and its various salts, indican, etc. The determination of the amount of solids excreted daily is not a difficult matter, as I have elsewhere shown[7], and the other matters are well treated of in the text books, and relatively simple methods can be employed.

For many years I have given very special attention to the condition of the urine in connection with various diseases of the skin, and have had some thousands of complete urinary analyses made in my laboratory, and have repeatedly written upon the subject.[8] But, while the experience reported has demonstrated undoubtedly that errors of metabolism are of very frequent occurrence in many diseases of the skin, and has continually assisted very materially in the treatment of the cases referred to, I am not yet at all prepared to speak with positiveness in regard to the exact changes which belong to special skin lesions.

Bouchard[3] has well shown the toxicity of the urine and also the toxicity of the blood which supplies the urinary ingredients, and the necessity of full and proper elimination from the tissues. In view of the varied errors in the urine, in the direction of its quantity, density, acidity, and the relative proportion of its ingredients, which I have constantly found in analyzing specimens from patients with various diseases of the skin, there is no doubt in my mind as to the relation between certain cutaneous affections and the faulty metabolic changes indicated thereby.

Hardouin[21] has made a remarkable contribution in regard to the elimination of urea in polymorphous dermatitis, which may have a very important bearing on our knowledge of metabolism in this disease. Making a daily analysis of the urine of 24 hours, over a period of nearly six months, he found that in one case on eight occasions, at pretty regular intervals, there was a fresh eruption after a period of diminished excretion of urea; the outbreak began a few days after the lowest point of urea elimination was reached, and when the quantity of urea was rising. In the second case the onset of the attack repeatedly coincided with the lowest point of urea excretion. He believes that "there is a constant relation between the variations of urea and the outbreaks of the eruption."

Tenneson and Lyon[43] have strikingly confirmed these observations, and Gaucher and Claude,[17] Thieberge,[45] Julien,[24] Wickham,[48] Hallopeau and Fournier,[19] and Dekeyser,[11] have reported cases with urinary analyses, bearing in the same direction.

Tommasoli[46] has written at length to show the alloxuric origin of eczema, and believes firmly that the purim bodies furnish the pathological condition whereby the eruption develops from various other causes, external or internal.

While it is difficult to establish exactly the mode or method in which metabolic processes, which may be erroneous to a greater or less degree, operate in regard to the causation of diseases of the skin, there is no question scientifically or clinically that such is the fact. Even in the microbic and vegetable parasitic diseases we must look for some factor other than infection, for it must be acknowledged that we are all so constantly surrounded by microorganisms that otherwise none would escape.

Undoubtedly, disturbances in nutrition, produced by erroneous metabolic changes, due to functional disorders of many organs, render the soil suitable for the development of organisms, which would otherwise be quite harmless. It is also easy to see how disordered metabolism can lead to changes in structure of the skin, as in other tissues in gout, to which we give the names of various diseases, modified unquestionably by different extraneous influences.

In all this study of the relationship of diseases of the skin to errors of metabolism, it is to be remembered that the latter does not represent a distinct disease process, but is only a modern term to express briefly, and perhaps more scientifically, that which was formerly spoken of as nutrition in health and disease.

Metabolism represents the series of chemical changes occurring within the system, whereby, first, nutritive material is converted into an integral part of living tissues, *anabolism;* second, *catabolism*, whereby its potential energy is expended in living force and heat, and the products of physiological disintegration of tissue are rejected, in altered form, and appear in the various excreta.

It is also to be remembered that the well-recognized relation between many diseases of the skin and certain errors of diet, disorders of the digestive apparatus, and the changes in the system belonging to the menstrual cycle, all find their ultimate explanation largely in the errors of metabolism, belonging thereto or occasioned thereby. All processes of health and disease must be and are intimately dependent upon or affected by metabolic action, rightly or wrongly carried out.

Recent writers on metabolism, von Leyden,[28] von Noorden,[35] and others, recognize four principal diseased conditions as dependent upon errors of metabolism, namely, gout, chronic deforming rheumatism, diabetes, and obesity, to which I would add a fifth, namely, the scrofulous or strumous state, as exhibiting a metabolic condition favoring the growth of microorganisms. Some have added oxaluria and phosphaturia, which, however, can hardly be regarded as more than symptoms, often associated with one of the other states mentioned. These metabolic diseases will now be briefly considered in succession, so far as relates to cutaneous phenomena, more or less definitely observed to be connected with them.

1. Gout. It is understood now that the term gout is no longer applied solely to an inflammation of the joints, notably that of the great toe, but refers rather to a gouty state of the system, which may manifest itself in a great variety of manners. It is not necessary to enter here into a discussion of its nature and cause, but only to state that in the present connection the word gout is used to express all that is understood thereby, according to the best modern writers. It may be described as a disease of faulty metabolism, largely relating to nitrogenous metamorphosis, with hereditary tendncies; of unknown origin, but acknowledging a dietetic, digestive, or nervous causation, and exhibiting various functional and structural disorders of many organs and tissues.

There is no doubt but that the circulation in the blood of the results of faulty metabolism induces inflammatory changes in the structures of the joints, also alterations in the blood vessels, disturbances in the nerves, and, indeed, modifications in very many of the tissues and structures of the body. There can, therefore, be no doubt but that the skin suffers with the other organs, and this may occur in two ways: (1) In common with the rest of the body its tissues can take on inflammatory or hyperplastic action (idiopathically, or from external causes), excited by the presence of the results of erroneous metabolism; or (2) That as an excretory organ its elements may suffer in endeavoring to remove imperfectly formed waste products.

It would lead far beyond the proper limits of this paper to attempt to discuss the nature of the metabolic alterations connected with the gouty state, or the part which uric acid plays in the results observed, which have by no means reached their final solution. At present we have rather to do with the clinical observations of competent men who have noted the connection between certain skin lesions and the gouty habit with such frequency, or with such therapeutical results, that we are forced to accept a relationship of cause and effect.

(*a*) *Eczema.*—Foremost among the diseases of the skin which very many trained observers have recorded as often of gouty origin, comes that protean eruption to which the name of eczema has long been given. While all cases of eczema are by no means of a gouty nature, it appears that the eruption is at least favored by the conditions of metabolism belonging to gout.

Garrod,[16] in a study of nearly 2,000 cases of gout, seen in private practice, found that in his last group of 212 cases no less than 47 per cent. had eczema, and he estimates that probably over 30 per cent. of patients whose gout has been of long duration have eczema. He states that eczema, in its acute form, will occasionally occur in place of an ordinary attack of gout, of which he had seen many illustrative cases. He further says, "Eczema is often present at the same time as the articular disease, and sometimes the intensity of the two alternates, one increasing and the other decreasing; at other times they run a simultaneous course. Not infrequently eczema is present many years before the joint disease manifests itself; and I have numerous records of patients suffering from skin disease, whose whole history points to its gouty character, but who have not yet suffered from joint complication. On the other hand, eczema often occurs late in a gouty life, and even in extreme old age, when the fits of ordinary gout have become much less frequent and severe."

My own experience, viewed from a different standpoint, confirms fully the statements of Garrod. Among over 4,000 recorded histories of patients with eczema, in private practice, I should place fully 30 per cent. of them in the gouty category; not that acute or active gout was observed in any proportion of them, for I believe this to be relatively rare in this country, it becoming less frequent as we advance in our knowledge of the conditions which lead up to it. But fully 30 per cent. of the cases exhibited phenomena recognized as belonging to the gouty state, or gave a strongly gouty family history.

Many writers on gout confirm the tendency to eczema in these subjects, and many authorities on disease of the skin also recognize the close relationship, and lack of space only prevents our presenting much corroborative evidence.

A number of other skin diseases have been pretty definitely associated with gout, but the connection is not always as clear as in eczema.

(*b*) *Psoriasis.*—This eruption is far more commonly associated with rheumatism or chronic arthritis, as will be mentioned later, but unquestionably it is often found connected with the gouty state. Duckworth[12] quotes Greenhow as reporting several examples where there were alternations of articular gout, psoriasis, and bronchitis, and men-

tions two personal cases of psoriasis associated with tophi.

(*c*) *Dermatoneuroses.*—Gout is constantly seen to be associated with eruptions of a neurotic or angioneurotic character, for, as Minkowski[32] says, "gout is accompanied by manifold nervous affections."

Prominent among these is *chronic uricaria,* and its allied condition *angioneurotic œdema,* which are extremely common in the gouty, as has long been known. *Pruritus,* both general, and localized in the anal and genital regions, is a well recognized gouty symptom. Duckworth[12] gives a colored plate of uratic tophi, much resembling patches of *xanthoma,* in the eyelids of a gouty man; there were also extensive deposits of the same in the integument, of all parts of the body. He also states that "true gout figures in the etiology of *dermatitis exfoliativa,* perhaps in one-fifth of the cases, and it may alternate with attacks of it." He mentions likewise the *flushing of the face* in gouty subjects, and the concurrence of indolent inflammatory *follicular inflammation* in the ala of the nose, both of which I have repeatedly observed.

2. Chronic Deforming Rheumatism.—Although resembling gout in some features, it is pretty generally agreed that this condition, known also as arthritis deformans, or rheumatoid arthritis, is quite distinct from both gout and rheumatism, with different metabolic changes; although, as is well recognized, the faulty metabolism of all the states under consideration are closely allied, and may appear interchangeably.

Certain skin lesions have been observed so often in connection with rheumatoid arthritis that some writers recognize the former as dependent upon or related to the latter. But the various forms of arthritic disease, gout, rheumatism, arthritis deformans, etc., have been so confounded, and so little is clear as to the differential metabolic processes in them, that we are not yet in a position to assign any skin diseases definitely to the class of arthritic deformans.

While acute rheumatism is now generally recognized as an infective disease, due to ordinary cocci (especially streptococci), Menzer[30] holds that they have become pathogenic only owing to a special reaction of the body, and that rheumatism is a clinical entity, not because it owns a specific microbe, but on account of the special susceptibility of the organism, which enables a general infection to occur. The same is more or less held in regard to chronic rheumatism and arthritis deformans, in which much the same organisms have been found. So that we are again led back to the metabolic changes which, as Theilberg[44] holds, result in a diminished alkalinity of the blood (due to increase in lactic acid), which lessens the resisting power to micro-organisms. And, in the same manner as in gout, these faulty metabolic processes can favor or produce lesions in the skin, or render it susceptible to parasitism.

Psoriasis is the main disease which has been connected with all the forms of arthritic disease, and my experience certainly associates it strongly therewith, both clinically and therapeutically.

Bourdillon,[5] in a study based on 36 cases of psoriasis and anthropathy, argues strongly for the common origin of the psoriasis and joint trouble, in an alteration of the trophic (nervous) centers of the cutaneous and articular surfaces. But the cases are of such varied character as to their arthritic symptoms that little can be judged as to any relationship; some of them with generalized stiffening of most of the joints were probably of nervous origin.

Pribram[39] considers at some length the subject of cutaneous alterations in connection with rheumatoid arthritis, referring freely to the views of others, and while he does not consider that psoriasis is a very frequent accompaniment he does recognize that changes in the skin are not unusual in this class of subjects, as are also alterations in the nails and hair.

Lipman-Wulf[29] reports a case of arthritis deformans with psoriasis, and after reference to the work of others he concludes that there is no necessary connection between the two; but whether both the joint disease and the psoriasis arise from a common but unknown cause, he is not prepared to say. Menzen[31] has made a very complete study of the subject, with many references to the observations of others, and an analysis of 1,000 cases of psoriasis, and arrives at about the same conclusion.

Forrestier[14] records a curious tubercular-crustaceous eruption in a man aged 50, who developed multiple arthritis, tending to ankylosis; some of the skin lesions seemed to be determined by iodized dressings, but others appeared in the scalp and forehead. Bosanquet[2] reports a case of rheumatic *urticaria,* where the eruption was observed to appear with an exacerbation of the rheumatic pain, and to recede under the administration of sodium salicylate. Much clinical and pathological work is yet to be done before the real connection between arthritic disease and lesions on the skin can be clearly established, and the metabolic processes in both need to be observed and recorded.

3. Diabetes.—The pathology and true metabolism of diabetes are still in such a chaotic state that as yet any observations in regard to its connection with certain diseases of the skin must be only provisional. Moreover, observers are by no means agreed as to just what urinary conditions should be classed as diabetes, and the distinction between true diabetes and non-diabetic glycosuria is steadily gaining ground. Some would exclude from diabetes those cases where sugar is found in the urine accidentally, as in connection with boils, etc.

However, as far as relates to certain changes in the skin, it seems to be simply a matter of hyperglycæmia, indicated by the presence of saccharine urine, for many of those reporting in regard to skin lesions do not directly specify if the condition was true diabetes or only one presenting a glycosuric urine.

A very considerable number of quite different affections or conditions of the skin have been noted by different good observers as connected with the diabetic state, and dependent upon it, so much so that the conclusion is irresistible that there must be some pathogenetic connection. We may briefly mention them, grouped mainly in accordance with Naunyn's[34] arrangement, as (1) Glycæmic; (2) Cachectic; (3) Neurotic; (4) Suppurative and neurotic.

1. *Glycæmic.*—First is placed *xanthoma diabeticorum,* which von Noorden[36] states is the only dermatosis peculiar to diabetes. This, though rare, is now a well established entity, of which Stellwagon[42] gives a bibliography relating to 38 cases. The other cutaneous disorders placed here are *saccharine sweat,* said by Naunyn to have been often demonstrated, *pruritus,* which occurred in 21.5 per cent. of von Noorden's cases, *urticaria, eczema, bronzed skin, parasitism.*

2. *Cachectic.*—*Acne cachecticorum, impetigo, rupia,* Kaposi's *bullous serpiginous diabetic gangrene,* and *dermatitis diabetica papillomatosa* (Saalfeld[41]), also *purpura.*

3. *Neurotic.—Zoster, angioneurotic erythema* and *œdema, cyanosis of fingers and toes, shedding of the nails, anæsthesia,* and *perforating ulcer.*

4. *Suppurative and Necrotic.—Furuncle, carbuncle, diabetic gangrene.*

We are, of course, in no position to establish the direct relations of any of these conditions with the faulty metabolism pertaining to diabetes, but mention them because reliable observers have connected them with errors of metabolism.

Barthelmy,[1] in treating of the relations of skin lesions to diabetes, dwells largely on the fertile soil afforded for microorganisms, by the diminution of the resisting power of the tissues; and also on the circulatory disturbances, inducing miliary embolisms, leading to infarctions in the skin, in connection with gangrene.

4. Obesity. The last of the four disorders of metabolism generally recognized is obesity, the true nature of which, and the metabolic changes producing it, are still in much doubt. There is, however, little question but that there is a metabolic error, especially in respect to the carbohydrates and hydrocarbons, even as gout exhibits a faulty metabolism, especially of the nitrogenous elements.

But there is thus far very little direct evidence accumulated that any skin lesions are directly dependent upon this state, although some writers have claimed such relationship.

Von Noorden[35] claims that *intertrigo* and *eczema* occur especially in the obese, and are characterized by great obstinacy and tendency to relapse. He also mentions *dermatitis seborrhœica* and marked *hyperidrosis.* Bouchard[4] records 13 instances of eczema in 108 cases of obesity.

While these conditions, which I have also noted, may possibly be influenced by the faulty metabolism belonging to such subjects, their occurrence can be better explained on other grounds, such as circulatory disturbances of the capillaries and lymphatics, etc.

5. Scrofulosis.—While this is not ordinarily included among the diseases due to errors of metabolism, there is abundant clinical evidence that, in both the hereditary and acquired condition, the processes of waste and repair are far from normal. All are familiar with the type of individual to whom this term is applied, and with the class of diseases, and their course, belonging to this state.

As far as relates to the skin they exhibit a laxity of tissue which favors the growth of microorganisms. Hence in them we see the tendency to suppurative processes, *boils* and *cutaneous abscesses,* and *eczema* in them tends to take on an *impetiginous* form. In them also the tubercle bacillus finds easy lodgment and growth, and *lupus* and the various forms of *scrofuloderma* flourish. Thus far, to my knowledge, there have been few if any researches in regard to the metabolic changes belonging to scrofulosis, but that faulty anabolism and cataboism play an important part in the poor nourishment of this class of individuals there can be no doubt.

We have thus passed in review some of the abnormal states of the system, including the skin, more or less clearly associated with errors of metabolism; we should, however, fail greatly in our study if we stopped here.

As already pointed out, we recognize perversions of metabolism largely by the conditions of the excreta, of which, as has been seen, the urine affords by far the best indication. But it is to be remembered that the blood furnishes to the urine these results of normal or abnormal metabolism, and much more study of the blood is necessary before we understand the true relations of assimilation and disassimilation. Studies in regard to the changes in the blood have been largely confined to its solid constituents, and relatively little is known in regard to changes in the plasma, which forms fully one-half of the volume of the blood, and is recognized as the chief carrier of the products of metabolism, through the agency of the lymph: as Hammarsten[20] puts it, "The bodies necessary for the nutrition of the tissues pass from the blood into the lymph, and the tissues deliver water, salts and products of metabolism into the lymph."

But much has been done in studying the changes in the blood cells in various diseases of the skin, and as these observations are extended and properly interpreted we shall learn more of the metabolic relations of certain diseases of the skin. Especially in regard to the eosinophiles there have been many investigations made, of which Ewing[13] and Coe[10] have collected many observations. Leredde,[26] Okamura,[37] Radaeli,[40] Wende[47] and others have also contributed one or more studies in this direction.

Leredde[27] especially has emphasized the importance of eosinophilia in connection with certain eruptions of the bullous type. He insists that amongst the large number of bullous dermatoses formerly classed as *"pemphigus"* and *"erythema multiforme"* there is an eosinophila and an elimination of eosinophiles by the skin. These conditions bring into relationship certain types, which clinicians have in turn united and separated. He believes that there is a grand "hæmatodermite," which has manifold cutaneous symptoms, and reveals itself now as a *dermatitis herpetiformis,* again as a *pemphigus foliaceus,* or as a *pemphigus vegetans.* He questions if eosinophilia is ever lacking in dermatitis herpetiformis.

Chlenoff[9] has made some researches on the alkalinity of the blood in thirty patients with various skin diseases, the blood being taken, when possible, two hours before dinner. In a number of general eruptions, *lichen ruber, erythema multiforme, eczema* (acute and chronic), *psoriasis,* and some others, the alkalinity of the blood was lowered.

Haig[18] still adheres to the theory that colloid uric acid produces changes in the skin, through defective capillary action, and also by the local irritation induced by precipitation of uric acid in fibrous tissue. When the deposit is in the vessels the circulation is sluggish, the skin becomes dry and harsh, and slow to heal, the culmination of such a condition producing *Raynaud's disease.* When the uric acid is deposited in the tissues, there is increased circulation, resulting in such eruptions as *eczema, psoriasis* and other forms and conditions of skin irritation.

Thus far, however, no definite statements can be made in regard to the exact blood conditions, belonging to any particular disease of the skin, but abundant evidence has been adduced that goes to prove that many of them are connected with blood changes which probably indicate metabolic derangements.

The subject of the metabolic relations of certain skin diseases is undoubtedly a most complicated one, and still very far from satisfactory solution: but advances have certainly been made along some lines, which can often be taken advantage of therapeutically.

But in all studies as to the etiological relationship of diseases of the skin there are many elements to be taken into consideration. External agencies certainly play an important part in regard to many of them, and parasitism is always to be reckoned with. The agency of the nervous system, direct or reflex, is often very influential, and internal toxic

agents, medicinal or alimentary, may be effective in inducing skin lesions, to which may be added toxins from intestinal fermentation.

But autointoxication, as ordinarily spoken of, must be included under errors of metabolism, for, except when caused by special putrefactive processes in the intestines, it arises largely from faulty action of the chylopœtic vesiera, together with derangement of the ductless glands.

We are thus led, by our studies on metabolism, back to errors of digestion and excretion, in their largest sense, which have long been recognized as of the utmost importance in connection with the etiology and treatment of many diseases of the skin. For when we speak of metabolism we only go one step farther in the great study of nutrition, which necessarily depends on the former.

It would lead far beyond the proper limits of this paper to enter at all fully upon the disorders of digestion and liver derangement, which, through faulty metabolism, may have an effect upon the skin, as they have been dwelt upon by many writers, both in monographs and text books. Jessner[23] has collected together much material bearing on this subject, and Herz[22] and Mrazek[33] have also elaborated the matter very fully; and Brocq,[6] in a masterly essay, shows how the idiosyncrasy of the patient has everything to do with the manner in which external, neurotic, or metabolic agencies may affect the skin.

Although not wholly connected with our subject some of the cases of the erythema group reported by Osler[38] and Galloway[15] are of value, as indicating the connection between lesions of the skin and disorders of the blood and internal organs.

In attempting to show the metabolic relations of certain eruptions on the skin we may be met with two objections. First: That the special state of faulty metabolism does not always produce the eruption in question; and, second: That the same eruption often exists without the apparent occurrence of metabolic causes. It may be answered that the same is true in regard to many other etiological matters, of which we are reasonably certain. In gout the errors of metabolism may proceed indefinitely and the acute gouty explosion occur only when some definite point or climax is reached, while in the meantime many minor symptoms may arise equally indicative of the gouty state.

In regard also to lesions of the skin, so many elements may enter into etiology that, although we may attribute an eruption to one cause at one time, at another it may have quite another etiological basis. Take urticaria as an example: all recognize that it frequently arises from acute indigestion after almost any food, while in different persons clams, lobsters, mushrooms, or various sorts of berries, etc., will invariably evoke it, even without special digestive disturbances. But, on the other hand, exactly the identical eruption may also occur, and recur with perfect regularity from malaria alone, and again certain drugs can produce the same lesion.

We recognize, then, that the same or similar metabolic disturbance may cause different skin lesions, to which are given special names, each according to the idiosyncrasy of the patient, as Brocq[6] has pointed out. Furthermore, this excitation of skin changes by perverted metabolism can occur in three ways: (1) by direct irritation of skin tissues by faulty blood supply; (2) through nervous influences, direct or reflex, and (3) by the agency of the glands of the skin, endeavoring to furnish an excretion from improperly prepared blood and lymph. In a large share of instances, local agencies of various kinds, atmospheric, mechanical, chemical and parasitic, play an important part as secondary or exciting causes, faulty metabolism having prepared the ground for their action; even as the acute attack of gout in the toe can often be traced to direct exposure of the part to cold or mechanical injury.

We have by no means fathomed the depths of metabolism, but we know enough of its processes to understand that, as in health perfect anabolism and catabolism produce and maintain healthy tissues, so when their action is perverted the same tissues take on unhealthy action, which we call disease, whether it be in the skin or in other organs.

In conclusion, we may, perhaps, sum up our knowledge in regard to diseases of the skin dependent upon errors of metabolism, as follows:

1. Metabolism represents the changes occurring in the system, whereby nutritive materials and oxygen are transformed into living tissue, and re-transformed into waste products, while, during these processes, their potential energy is being given off in living force and heat.

2. As healthy cell action and transformation is produced and maintained by perfect metabolism, so when there is perverted metabolism the structures in various parts of the body must suffer, and this we call disease.

3. As every cell in the body constantly takes up and gives off material, so the results of metabolism can be affected by the normal or abnormal action of every living cell in the organism.

4. Metabolism is, however, principally affected by (1) the kind of nutriment taken; (2) the action of the digestive organs and ductless glands, and (3) the action of the nervous system.

5. Certain skin lesions, or eruptions, have been credibly reported as connected with or dependent upon the generally recognized metabolic conditions of (1) gout; (2) rheumatoid arthritis; (3) diabetes; (4) obesity; (5) scrofulosis.

6. As yet no absolute statements can be made as to the necessary connection of the two, for the same eruptions occur in several of the metabolic affections.

7. The idiosyncrasy of the patient, and many causative elements, external or internal, nervous, etc., often determine which form of skin disturbance or alteration shall take place.

8. Errors of diet, disorders of digestion, faulty excretion and nervous derangement, which have all along been recognized as causative elements in many diseases of the skin, often find their ultimate expression or mode of action through the faulty metabolism induced thereby.

9. Metabolic errors are exhibited in the excreta from the lungs, skin, intestines and kidneys; and of these, the urine best affords a satisfactory indication, as it represents nearly one-half of the total excreta, and practically all of the nitrogenous and soluble mineral substances, together with about one-half of the water expelled from the system.

10. Complete and minute urinary analysis is a very great aid in discovering metabolic errors, and in establishing proper therapeutic measures for the cure of many diseases of the skin.

The Emblem of Respectability.—According to the *Medical Press*, whether for use or ornament, it may be unhesitatingly affirmed that nothing could be less well adapted to its purpose than the top-hat, which is ugly, unhygienic, and embarrassing. Its sole claim to support is the appearance of respectability it gives. If only a few medical baronets would drive to their consultations in Panamas and caps they would break the tyranny of habit over health and comeliness, and at the same time earn the undying gratitude of their humbler confreres.

A CASE OF CONGLOMERATE TUBERCLE OF THE CHOROID.*

By THOMAS R. POOLEY, M.D.,
NEW YORK.

From a clinical standpoint the tumors of the choroid of most practical importance are sarcoma and tubercle. At the last meeting of this Society I reported one of non-pigmented sarcoma, by far the rarest form of sarcoma. I now beg to present one of conglomerate tubercle, which from several points of view is very interesting.

On July 6, 1903, I was consulted by a young man, aged 26. There was nothing in his general appearance to suggest a grave constitutional disorder, although he was somewhat emaciated and of a sallow complexion, and he declared that besides the eye disease, about which he came, he had not suffered, except from the usual infantile diseases, but had always been healthy. He denies syphilis, and there were no physical signs of tuberculosis present. His mother died of diabetes in her fifty-third year. His father, aged 65, is still alive, and has never been sick a day in his life, but all of his brothers and sisters died of consumption. For the past year he had suffered from pain and redness of the right eye, which had been alternately better and worse. For a long time (several months) he was under the care of a member of this Society, who treated him with antisyphilitic remedies, but at the end of six months advised enucleation. He then consulted Dr. Knapp, who also gave the same advice.

When I saw the patient, the eye presented the usual symptoms of absolute glaucoma: Wide, immovable pupil, circumcorneal injection, anæsthesia of the cornea, slight opacity of lens, + T^2, no pain on pressure over the ciliary region, V = O, no ophthalmoscopic reflex. Left eye normal. The same day he was admitted to the hospital, and the eye enucleated under ether anaesthesia. The healing was without any incident, and he was discharged on the 13th, with a good conjunctival stump.

The globe was examined by the pathologist of the New Amsterdam Eye and Ear Hospital, Dr. Edward B. Coburn, whose report is as follows:

"*Macroscopical.*—The globe is somewhat irregular in shape, appearing somewhat enlarged in a plane slightly oblique to the antero-posterior axis of the eye, being larger from above and to the temporal side than to the lower and nasal side. This axis measures 30 mm., the one at right angles to this measuring 22 mm. The antero-posterior diameter measures 26 mm. This enlargement is to the outer, upper and temporal side, just behind the equator. Transillumination of the globe shows the pupillary area least illuminated when the light shines through this thick part, which appears more dense and more resistant to the touch. The lower half of the cornea appears somewhat opaque. The pupil is dilated and irregular. On section, the anterior chamber is shallow and is partly filled with an albuminous exudate. The iris is pressed forward by the lens, which is surrounded by what looks like condensed vitreous or exudate. The retina is almost entirely detached, only a small portion being adherent over the site of the above-mentioned thickening. Elsewhere it extends from the *ora serrata* to the head of the optic nerve. The enlargement of the eyeball seems to be due to thickened sclera, which measures about 4 mm. in thickness. Measurement of this thickened sclera shows that it extends from the equator about 15 mm. toward the optic nerve. The choroid under this enlargement is also thickened and solid and of a different color from that of the rest of the choroid.

*Read before the American Ophthalmological Society, July, 1904.

This thickened choroid is about 1 mm. thick at its densest part, is flat, and extends in every direction, covering an area about 12 mm. in extent, tapering off toward the ends.

"*Microscopical.*—The circumcorneal vessels are dilated and filled with blood. These appear to merge with vessels from the scleral and episcleral tissue, and extend into the *substantia propria* of the cornea. This corneal infiltration and new vascular formation appears separable into two distinct regions, the anterior one having its origin in the conjunctival and episcleral vessels and extending to and beneath the anterior limiting membrane (Bowman's). From the scleral vessels are continuations extending into the middle and posterior lamellæ of the cornea. These extend so far into the *substantia propria,* that only the central portion is free from them. One vessel appears to lie on Descemet's membrane. The anterior chamber is shallow and contains some albuminous exudate. The angles are closed and the root of the iris is adherent to the cornea.

"The iris is infiltrated and thickened. The anterior surface is covered with an exudate membrane, which extends to the pupillary margin and is continuous with an exudate in the pupillary area lying on the lens capsule, and extending backward to a mass of exudate behind the lens and in the ciliary region. There are several aggregations of round cells in the iris, and the cells here and elsewhere in the eye show marked mitosis.

"The lens is normal except in one part just outside of the pupillary area and beneath the capsule where the lens fibers are broken, and there is a small area of infiltration with round cells. At this place, the intracapsular epithelium is absent, being replaced by round cells. Continuous with and from this infiltrated area is a layer of flat cells, three or four in thickness, but gradually diminishing to a layer of a single cell, extending for some distance to either side of the infiltrated part, between the capsular epithelium and the lens substance. At either side of the lens, and continuous with the iris exudate and the condensed vitreous behind, is a mass of hyperplastic tissue. This appears to come largely from the proliferated retina at or behind the *ora serrata* and extending forward. The ciliary body and processes are only moderately infiltrated and but slightly involved in the inflammatory action. The ciliary processes are somewhat entangled in the circumlenticular mass, but not apparently active in its production.

"A satisfactory description of the sclera, choroid and retina is difficult, as the changes are so numerous and the characteristic features of each are so altered in many places that it is quite impossible to distinguish one tissue from another. The thickened part of the eyeball consists of tissue eminently tubercular in character, and here the landmarks are in large measure destroyed. The sclera is infiltrated in different parts, and many of the nerves and vessels are surrounded by areas of round cells. The linear infiltrations in the cornea extend into the sclera in a similar form (or more properly speaking, from the sclera into the cornea). Many infiltrated parts consist chiefly of round cells, but numerous ones contain nests of epitheloid and giant cells. The thickened part of the sclera which occupies about the position of exit of one of the perforating vorticose veins, is composed most of caseous material, surrounded by a zone infiltrated with round, epitheloid and giant cells. At one point the diseased tissue does not appear to have been entirely removed when the eyeball was enucleated.

"The choroid is everywhere infiltrated, in many places is increased in thickness, especially where the sclera is thickened and near the entrance of the optic nerve. In some places it appears to merge into the retina and sclera in an indistinguishable union. Epitheloid cells are particularly numerous in this structure and numerous giant cells are visible.

"The retina is generally detached except for a limited extent over the thickened choroid and sclera. It is generally hyperplastic and where not so changed, is infiltrated with round epitheloid and giant cells in a structureless mass. This hyperplasia of the detached retina seems to form the material surrounding the lens. The optic nerve shows round cell infiltration, but the nerve was cut behind this affected portion.

"The result of the staining for tubercle bacilli was positive.

"*Pathological Diagnosis.*—Conglomerate tubercle of choroid, with extension into the sclera and retina and secondary glaucoma."

The pathological examination of this conglomerate mass therefore gives positive evidence of the tuberculous nature of the growth, the result of the staining for tubercle bacilli being positive. In view of the statement made by the pathologist, "at one point the diseased tissue does not appear to have been entirely removed when the eyeball was enucleated," I think it proper to say that the operation was done in the usual way, that no rupture of the globe occurred, the conjunctiva was circumcised to the corneal margin, and, as it is stated, the optic nerve was divided far back in the orbit behind the affected portion, and therefore, it is difficult to see how the operation could have been more thorough without the removal of all the orbital contents, a procedure which did not seem to me to be warranted.

It is well established that tubercular growths in the choroid are met with in the subject of chronic tubercule whose general condition is not such as to be of greater importance than the local affection, and that although the choroidal disease is probably always secondary to tubercle elsewhere, the existence of the latter is often difficult to establish. Such seems to be the fact in the case here reported. That the diagnosis, in some instances, too, may be made by ophthalmoscopic examination, is well known, and cases have been reported by Brailey, Horner, Manz, Carpenter, Schöbl, Hirschberg, and others, (*vide* Griffith's Chapter on Diseases of the Choroid Vitreous in Norris and Oliver's "System of Diseases of the Eye." These growths sometimes spring from the disk, as shown by Michel, Brailey and others, and quite recently Dr. Arnold Knapp has reported one of Localized Tuberculosis of the Head of the Optic Nerve (*Archives of Ophthalmology,* Vol. XXXII, No. 1, 1903) in which the eye was removed on the probable diagnosis of glioma. It is obvious enough, however, that in my case no positive diagnosis other than the one of a probable tumor and the supervention of glaucoma, could have been made. As would be expected from the fact that tubercle usually causes softening of the tissues in which it originates, the globe generally assumes the form of a general inflammation with rapid formation of a staphyloma, when it has to be distinguished from panophthalmitis or specific disease, for which this was mistaken, or it may, as shown, occur as an ophthalmoscopic picture, or, as in my case, which is the rarest, under general glaucomatous symptom.

In regard to the prognosis of my case, I will state that I have seen the patient while writing this paper, one year after the operation. He has married since, looks perfectly well, has gained in flesh, and there is no evidence in the appearance of the stump, of any return of the disease. In order, however, to be

better advised as to his physical condition, I referred him for examination to Dr. J. F. Russell, whose long experience in the diagnosis, observation and treatment of tuberculosis, makes his report of much value and importance.

His report is as follows:

"My dear Doctor Pooley:

"Thank you for the opportunity of examining Chas. Hedde. I find no physical signs of disease. Should he develop any symptoms later I shall be happy to examine him again any time.

"Very truly yours,

"John F. Russell."

In considering in a general way, prognosis and treatment, I agree with Griffith (*loc. cit.*), that we are not justified in removing every eye affected by tuberculosis, in the hope of preventing general infection. This should only be done when the eye is either lost or the course of the disease is of a markedly rapid and progressive character. But the eye should be carefully observed, and the disease treated with the usual remedies. Death may occur—whether or not enucleation has been performed—from tuberculosis of any organ, but not with the same frequency that it does in miliary tubercle of the choroid. Thus, as pointed out by Griffith, in the summing up of the whole matter, it is more than probable that the dissemination takes place not from the affected eye, but from the lighting up of activity of some latent focus in the interior of the body.

107 Madison Avenue.

THE TREATMENT OF PNEUMONIA.*

By FRANK DEWITT REESE, M.D.,
CORTLAND, N. Y.

I have practically no apology to offer for presenting a paper upon the treatment of pneumonia at this time. When the meeting of the American Medical Association was held at Saratoga I listened with others to a very interesting paper which was read before the section on medicine, by Dr. E. Fletcher Ingalls (*Journal of the American Medical Association,* November 22, 1902). His subject was "The Prognosis and Treatment of Croupous Pneumonia." He also gave an analysis of the cases of pneumonia that had been treated in the Cook County Hospital for the fifteen months preceding April 1, 1902, which showed an appalling mortality of 36 per cent.

The discussion which followed this paper was as interesting as the paper itself, and the climax was reached in my mind when Dr. Osler, of Baltimore, stepped out and said, "When we think that other infectious diseases we treat have their mortality reduced, some 10 or 15 per cent. it is terrible to realize that we, as physicians, must listen with mute, impassioned faces to the announcement of a 36 per cent. mortality in pneumonia. What I deeply feel is that something should be done, in a systematic and energetic way, to study this problem of pneumonia, and to see if we cannot reduce this death rate of 36 per cent."

My desire to do what I could towards solving this problem came when I began to realize the great variety of drugs that were used in the treatment of Dr. Ingalls' cases, and to reflect upon the statement that in some cases from 16 to 36 ounces of whiskey was given within the twenty-four hours.

I immediately asked myself these questions: (1) Were not the patients overdrugged, and some of them overstimulated (if alcohol is a stimulant?). (2) Can we not let the pendulum swing the other way and dose less, both with whiskey and drugs? Since that time I have treated a limited number of cases of pneumonia, without the use of alcohol, with a greatly simplified medication. As a result the mortality is practically nothing, and my confidence is greatly strengthened in the belief that a physician can somewhat modify the course or intensity of lobar pneumonia, and so favor a successful termination of the same.

It goes without saying that we should understand the pathology of a disease before we undertake to treat it. This we do know of pneumonia, because the pathology is studied and can be at the autopsy. There are many changes going on in the metabolism for days, before the initial chill announces the beginning of pneumonia. With these changes we should acquaint ourselves.

After consulting a number of authorities, I was impressed with the way in which they did or did not record the premonitory symptoms of pneumonia, some ignoring them altogether, and beginning the description with the initial chill, while others mention as a prodrome a slight indisposition. The writer is convinced that pneumonia is not as acute a disease as at first appears. The system is preparing for days and perhaps weeks, I might say months, for the initial chill.

What takes place previous to the chill? Metabolism is disturbed and its products are retained, the urine is reduced in quantity; the bowels are sluggish; appetite is not as good as formerly, and the routine of work is accomplished with great fatigue.

In treating pneumonia these factors must be taken into account. I am beginning to believe that the disturbed metabolism which comes from overwork, exposures, and errors of diet, is the primary cause of pneumonia, rather than the pneumococcus. Other observers confirm this statement, and if this is true it gives us a principle upon which to base or formulate a satisfactory treatment.

What conditions have we to meet and overcome in the treatment of lobar pneumonia? We have (1) toxæmia which is due to retained products of a defective metabolism, and to the introduction of the pneumococcus; (2) impaired function of the kidneys in nearly all cases and upon examination of the urine, which is scanty, albumin is found; (3) an overtaxed right heart, weakened by the toxæmia, and extra work put upon it, because of the solidification of the lung; (4) cough, which is usually constant and annoying and is aggravated by the viscosity of sputum; (5) an impaired nervous system, which disturbs the function of all the organs and glands of the body; (6) pyrexia; (7) a disturbed digestion, accompanied, usually, with constipation.

There are many drugs, called specifics, put forth to overcome these conditions. For example, A. H. Kerr advocates creosote and says that it is the nearest approach to a specific that has yet been reached. Creosote renders the *Micrococcus lanceolatus* (of Welch) less active and virulent. A. H. Smith thinks

* Read at a meeting of the Third District Branch of the New York State Medical Association, June 23, 1904.

that carbolic acid and chloroform are specifics, having seen good results from their administration.

Robert Liegel reports a series of 72 cases of pneumonia treated with salicylates, without a death Large doses are required, two drachms daily. I am persuaded that salicylate of sodium judiciously used at the onset of the disease is of the greatest value. It seems to retard the activity of the pneumococcus and neutralizes or eliminates the toxins. This is really the one drug that I give most commonly when the premonitory symptoms are those of influenza. I have practically no experience with the antipneumotoxin serum in the treatment of pneumonia. However, the authorities which I have been able to read question its utility, as yet. Large doses of digitalis have been advocated by those who believe this drug would abort the disease.

Of all the specific treatments that have been advocated, the one advanced by Dr. H. Altshul, of New York (Medical Record, March 26, 1904), impresses me as having been founded upon the most reasonable scientific premises of any. It is that of giving an initial dose of 10 or 15 grains of iodide of potassium, and increasing the dose by 5 or 10 grains every two or three hours, according to the severity of the disease, day and night until defervescence is established. He says that the effects of the drug are: (1) antiseptic and antizymosis; (2) markedly increased activity of the lymphatic system, and hence increased absorption of products of inflammation; (3) increase of the alkalinity, and lowering of the specific gravity of the blood; (4) very decided vasodilator action, and thus cardiac stimulation; (5) direct cardiac stimulation through its base, and through increasing circulation in the arteries supplying the heart; (6) diuresis; (7) diaphoresis; (8) antipyresis; (9) respirator sedation. This drug, if it works as Dr. Atlshul claims, meets all of the cardinal indications for the successful treatment of pneumonia. He claims to have treated a series of sixty-two cases, extending over twelve years, without a death.

Surely we ought to be liberal enough to give this very sensible method of treatment a trial. In nearly all the special treatments for pneumonia which have come to my notice, the dosage has been large.

I think we should refrain from putting anything into the system in such large doses as taxes the vital powers to eliminate it. We should not overdose, but should aid nature. We should ask ourselves, what would the system do to cure itself of pneumonia if it was able to do it, and then try to do that thing.

I have intimated that the products of metabolism are retained, these products affect the function of the mucous lining of the bronchial tubes and air cells which throw out the exudate. This exudate is a natural medium in which the pneumococcus is propagated, and it is from this splendid means of propagation of the pneumococcus that the system is overwhelmed with toxins, and the pneumococcus finds entrance into the blood. It is said by Thompson that the cause of the dyspnœa is the action of the toxic material in the blood, acting on the respiratory centers, rather than the mechanical action of the exudate in the lungs. It is also claimed that in one mouth out of every five the pneumococcus can be found in health.

In my own practice I have had twenty-one successive cases of lobar pneumonia, which have been treated in what I call a very simple way, with few drugs and without alcohol. In this series of cases I had two deaths. One was a man 28 years of age, who was doing well until it was discovered that he had a stricture, by which we could not pass a catheter, and he died, practically from uræmia. The other was a traumatic case, that of an old lady of 83 years who fell and broke two or three ribs, and developed pneumonia; she lived only a few days. This case should be eliminated from the series, making a mortality of 5 per cent., and in that case the death was due to a cause that was foreign to the disease.

I will outline the treatment employed in the twenty-one cases. The treatment of pneumonia should always be eliminative. There are three ways by which the toxins can be eliminated, viz., the kidneys, the bowels, and the skin.

When called to a case of suspected lobar pneumonia I at once order a foot-bath, which should be given according to Dr. Rochester's method. The foot-bath should be given in bed with the patient on his back and well protected from drafts; the water should be at a temperature of 110° or 115° F. By this, I wish to accomplish two things, namely, to equalize the circulation and to quiet the nervous system. At this time I give 5 grains of calomel, followed by a saline, to empty and disinfect the alimentary canal, and stimulate the action of the kidneys. I also give salicylate of sodium in small doses, every hour, until the diagnosis is fully established. Then the patient is put upon acetate of potassium, 10 grains every four hours, with half a glassful of water, for I believe if we can stimulate the kidneys (which are nearly always now elminating albumin) by making the blood more alkaline, the system will be relieved of the ever-accumulating toxins, which depress the nervous system and poison the heart muscle. I have a belief, confirmed by experience, that the potassium salts have some specific action in the treatment of pneumonia, and that they should be administered in some form to every case. Associated with the acetate of potassium, there is given one dessert-spoonful of liquor ammoniæ acetatis, with fluid extract of licorice, diluted with water, every two hours.

It is expected with this to relieve continually the burdened right heart, by bleeding the patient into his capillary vessels and eliminating the toxins by diaphoresis. With this also, pyrexia and cough are controlled to a great extent. If the temperature rises to 105° I usually order cold sponging or the cold pack to the chest, changed every two hours. I look for this to soothe the nervous system, even if the temperature is not materially lowered. Patients are usually grateful for this.

The method of applying the pack is the following: Fold a cotton cloth of desired width (smoothly) to four thicknesses, wring out of icewater, then place it in a flannel cloth which encircles the chest, and fasten. If the patient is excitable, use a flannel cloth instead of a cotton one. If the temperature does not reach 105°, turpentine and lard is applied. I have used some of the putty mixtures which give a degree of comfort.

The diet is of very great importance. The patient should not be fed too often, nor too much, and the food should consist of the most digestible substances, such as milk, beef-tea, broths, beaten egg, etc. If the patient rebels against food, or is nauseated, with-

hold food for a time, and if necessary use nutrient enemas.

Abdominal distention must be overcome, for it interferes with the action of the diaphragm, impeding respiration. The distention is relieved by the use of the rectal tube, or a daily enema, and turpentine stupes to the abdomen.

The pulse should be closely studied, for it is the keynote to impending troubles. A slow pulse is not always a safe pulse, neither is a rapid pulse always one that denotes danger. It is the quality of the pulse that points either to safety or to danger, and this should be carefully watched and the indications met. A hard pulse is softened with Dover's powder and nitroglycerin, and a soft pulse is strengthened with strychnine, digitalis, ergot, and *rest*.

I wish to lay great emphasis on the latter. How many patients have taken their departure because the family, nurse, and doctor have disturbed their rest with kindnesses, baths, and by frequently administered medicine! Plan to give the patient two-hour intervals of rest during the day, and never waken him in the night if he will sleep. Rest and fresh air are the very best of remedies in the treatment of pneumonia.

The patient should never turn himself without assistance. He should not be allowed to sit up to attend to nature's calls. The attendant should be instructed to anticipate the wants of the patient, thereby saving him thought and effort.

Pneumonia must soon be permanently classified with the infectious diseases. The utensils and clothing used around the patient and the bedding should be disinfected, as in typhoid fever. The sputum should never be allowed to dry, and should always be burned. The sick-room should receive the pure sunlight, and should be well ventilated.

Why not give alcohol in pneumonia? Because experience has taught me that the mortality is less, in my practice, when I do not give alcohol during the treatment of this disease. Alcohol is nearly always prescribed when we do not know what else to do. It is called a food by some investigators, and we must admit that, in small quantities, it is oxidized in the system. Some one has said that the human system is a crematory, in which substances are burned or oxidized, as urea is, to protect the system from harm. Because strychnine, phosphorus, morphine, ptomains, some leucomains, and toxins are oxidized in the system, should they be classified as foods? Who would think of making a meal of these or of substituting a small quantity of them for food? Grant that alcohol is a food, I want to ask, did one ever know a patient with pneumonia to die of starvation? Usually the trouble is that patients are overfed. Alcohol really does just what we try to undo with our treatment.

Listen to one of our greatest teachers on dietetics: "One of the most injurious effects of the enormous quantity of alcohol used and prescribed in this country and Europe is its influence in lessening the efficiency of respiratory movements, and the capacity of the blood to receive and distribute oxygen to the tissues of the body. Experimental therapeutics have fully established the fact that alcohol by its anæsthetic or paralyzing influences on the respiratory nerve centers diminishes the depth of respiratory movements, thereby lessening the amount of air used, in direct proportion to the quantity of alcohol taken. At the same time by its action on the hæmoglobic and corpuscular elements of the blood it lessens the capacity of that fluid to receive oxygen from the pulmonary air cells, and to carry it to the various tissues of the body. It is by this duplicate interference with the reception and internal distribution of oxygen that alcohol retards tissue metabolism, encourages the retention of effete products and lessens the vital resistance to all toxic agents, including pathologic bacteria."

I do not believe that any one can give a good scientific reason why alcohol should be used in the treatment of pneumonia, nor an indication for its use that has not been met by some other drug or remedy. In Europe and America it must be noted that the medical profession is discarding to a great extent the use of alcohol in the treatment of this disease. During the symposium on the treatment of pneumonia before the section of medicine at the American Medical Association held at Atlantic City, in June, 1904, one could not help observing that of the twenty-six physicians who took part, not one advocated the use of alcohol in the treatment of this disease.

To show how thoughtless and bound by routine those physicians are, who depend on alcohol and its compounds, as a remedy in pneumonia, permit me to give a brief history of a case that occurred in my practice in the winter of 1902-03. On December 5, 1902, I was called to see Mr. W. in a neighboring village, and found him ill with typhoid fever. The fever pursued the normal course without complications until December 25, when the patient was taken with a severe chill. The temperature rose from normal to 102° and pulse from 86 to 100. Physical signs and symptoms revealed the fact that the patient had lobar pneumonia in the right lung. The lower lobe first took on the process, but later the whole right lung was solidified. The disease pursued its usual course for a few days when the family demanded that the patient be given whiskey or brandy, as a tonic, they said, but I refused to give it, because I saw no indications for its use. The friends requested counsel and I assented, with their choice of a physician.

On December 28, the patient's symptoms were these: the lung was in the stage of red hepatization, sputum rusty and characteristic; pulse 120, full soft, and regular; respiration 30; temperature 103. The patient was somewhat restless and anxious, but was easily controlled with sponge baths. He was taking nourishment nicely. The bowels were moved with an enema, the urine very scanty. The counsel ordered half an ounce of whiskey every hour. At the end of the next twenty-four hours, when I saw him again, his condition had changed somewhat. He was delirious with a pulse of 130, soft and compressible, respiration 36, temperature 102°. The same treatment was faithfully followed for another twenty-four hours, when the family saw that the patient was failing. On December 30 the pulse was 140, very soft and thready; temperature 101°; respiration 46 and labored. There was cyanotis and the mind was wandering. There were involuntary bowel movements and the patient expectorated a bloody mucus with difficulty. I suggested that the whiskey was partly the cause of the symptoms, and if the

family would consent I should withdraw the alcohol. I then gave tincture of nux vomica in ten-minim doses every two hours. The effect was pleasing. The next morning the patient was more quiet and his mind less wandering; he expectorated with less difficulty, but the character of the sputum was the same; pulse 120, temperature 102°, respiration 36. This treatment was pursued, lengthening the interval to four hours until January 6, when the change for the better came. The patient made a slow but sure recovery. I told the family then, and I believe now, that if we had persisted in administering the alcohol the patient would have died, and of course contributed to the usual 20 to 40 per cent. mortality in pneumonia. This case shows the effect of whiskey and brandy on the pulse, respiration, and temperature. It reduces temperature and quickens the pulse and respiration by attacking and paralyzing the nerve centers that govern these functions.

In concluding my paper I wish to call attention to these points:

1. More attention should be given to the prodromes of pneumonia; for the toxæmia may be cellular or due to the *Diplococcus lanccolatus*.
2. The treatment should be eliminative and some form of potassium should be used.
3. Rest is of the greatest importance.
4. There is no indication in the treatment of pneumonia that cannot be met by other remedies than alcohol.

THREE CASES OF PRIMARY MALIGNANT TUMOR OF THE LUNG.

By SIEGFRIED WACHSMANN, M.D.,
RESIDENT PHYSICIAN MONTEFIORE HOME,
AND
ALFRED W. POLLAK, M.D.,
ASSISTANT PHYSICIAN MONTEFIORE HOME.

THE comparative rarity and certain peculiar clinical and pathological features may justify the report of the following three cases that were seen at the Montefiore Home in the past eighteen months.

CASE I.—L. P., male, fifty-five years of age, German, bookkeeper by occupation, contracted bronchitis in January, 1903. The pains in his chest became so severe and his expectoration so persistent that he went to a hospital on July 1, 1902, and on August 7th sought admission to the Home. On examination, his pulse was 96, his temperature 98° F., and his respiration 24. His fingers were clubbed. There was no glandular enlargement. His tongue was protruded straight. His chest was barrel-shaped, and his respiration labored and wheezing. Percussion gave an emphysematous note. There was a small area of slight dullness over the left upper lobe in front (over the third rib), and one more marked posteriorly at the same level. The lower borders of the lungs were freely movable. Auscultation gave some sibilant and a few moist subcrepitant râles over the upper part of the right lung posteriorly. The heart, liver, spleen, and kidneys were normal. The urine was negative. In the sputum were seen many cells resembling mouth cells, but smaller, with a large nucleus. In some of these nuclei there were two or three nucleoli. The chromatin threads were arranged as in beginning karyokinesis. There was segmentation of the nuclei. There were no elastic fibers, but numerous fatty globules in emulsion.

During September, 1902, the patient's condition became gradually worse. On percussion, an area of dulness was found over the right upper lobe, extending downwards on the side. Soft grating râles were heard in the axillary line at the level of the sixth and seventh ribs. These were directly under the ear, and sounded as if two adherent surfaces were forced apart; they were heard at the end of inspiration. The pains were so severe that the patient could not sleep at night. A slight tumefaction was noticed over the right supraspinous fossa, which was exceedingly painful. There was no abnormal temperature. Examination with the *x*-ray revealed a mass to the left of the spinal column, adherent to the vertebræ; also a mass to the right, but here there was a light space between the column and the dark area. A loud thump was heard over the mass on the left; also a systolic blow. Percussion dulness corresponded to these areas. The patient constantly became weaker. He complained of great pain, unrelieved by large doses of anodynes. The pains spread to the left side and leg. The sputum was profuse and bloody. October 16, 1902, patient died from exhaustion. He had lost 11 lbs. while at the Home.

The post-mortem examination was made by Dr. Harlow Brooks on October 18, 1902. Body of an aged male showing very marked emaciation. There were no adhesions to the anterior thoracic wall. The lymph nodes along the internal mammary arteries were enlarged, their tissues firm and white, apparently infiltrated with new growth. The left pleural cavity was free. The right pleura was intimately adherent over the upper lobe posteriorly. The epicardium showed old patches of thickening. There was slight atheroma of the aorta, and all the valves were thickened. The heart muscle showed brown atrophy. The isthmus of the thyroid gland was entirely absent, but the lobes were of normal size. The tissue was markedly œdematous, and contained frequent, firm, whitish nodules. The right lobe was, however, permeated by new growth. The tissue was firm and, in the central portions, fibrotic. The lymph nodes of the neck contained pearly-white nodules, clearly neoplastic in nature. The tracheal lymph nodes were greatly enlarged and infiltrated. The mucous membrane of the trachea was anæmic and covered by a thin purulent exudate. The right upper bronchus led into the right upper lobe, which was entirely infiltrated by new growth, which communicated directly through the ulcerated walls of the enlarged bronchus. This growth infiltrated a considerable portion of the upper lobe, but in no area was atelectasis complete. The infiltration extended downward through the inferior and posterior portions of the lobe, where it mingled with and could not be distinguished from, a general œdema, complicated by pneumonia and thrombus of the pulmonary arteries. The growth further infiltrated the posterior portion of the middle and upper lobes, the anterior borders being largely uninvolved. The growth was evidently extended by infiltration. The pleura over the upper portion of this lung was thickened, and intimately adherent to the parietal layer. The new growth infiltrated the lung from the pleura. The pleura itself was free from growth, but, however, showed inflammatory thickening. The lymphatics on the upper left lobe were outlined by new growth, but the growth apparently had not infiltrated beyond the immediate neighborhood of the lymphatics. The intervening portions of the pleura were apparently uninvolved.

The upper left lobe was apparently free from growth, markedly anthracotic and largely airless, but the inferior portion was infiltrated by new growth, while the pleura covering this new growth was apparently uninvolved. The liver was small, mottled by spherical areas varying from 1 to 2 cm. in diameter, and composed of pearly-white tissue of a very firm consistency. The mesenteric lymph nodes were infiltrated with new growth. The pancreas was small and normal, but the lymph vessels were infiltrated with new growth. The adrenal capsules were large, and showed extensive post-mortem changes and nodules of new growth.

Causes of death: (*a*) Pulmonary carcinoma, probably primary in the lung, with general lymphatic metastases; (*b*) hepatic carcinoma; (*c*) carcinoma of the thyroid gland.

Case II.—F. B., female, an Austrian nurse, sixty years of age, was exposed to rain six months before entering the home, and a few days later intense pains in the left shoulder appeared, and she began to cough. There was no swelling or redness of the shoulder joint, but the pains were worse on movement. The cough stopped after two or three weeks, but the pains persisted, and gradually extended downward in the axillary line, and also in the vertebral column. The pain was intense and "twisting-like." She never had any fever or hæmoptysis; she became hoarse just before entering the Home, on April 1, 1903. On examination, we found an emaciated cachetic woman, with a dry and parchment-like skin. Her pulse was 96, temperature 99° F., and respiration 25. A periosteal growth was present over the right temporal bone of about two inches diameter. There was wasting of the temporal and masseter muscles. The tumor on the head was tender, firm, not cystic, yet elastic. The veins over the left mamma were dilated. The percussion note showed flatness over the upper left lobe and also at the base in the posterior axillary line. A marked dulness over the base posteriorly. Anteriorly there was a boardy note in the axillary line. There was also a marked dulness over the right upper lobe, chiefly the apex. The rest of the lung gave a boardy note. There was marked dulness over the upper end of the sternum. The breathing in the left lung was markedly diminished throughout, especially over the upper lobe, and almost absent over the base in the posterior axillary line. The left side of the thorax was bulging. There was exaggerated vesicular breathing over the right upper lobe. Pleuritic friction râles were heard over the base of the left lung in the posterior axillary line. Whisper voice and vocal fremitus were diminished over the greater part of the left lung. Exaggerated vesicular breathing was present over the right base. The heart was found to be within normal boundaries. The sounds were somewhat muffled. The second pulmonary sound was accentuated. The pulse was of increased tension with moderate arterio-sclerosis. Her fingers were clubbed. There were many stigmata of degeneration. Attempts to move the left shoulder, passively, elicited violent pain. The patient herself was able to do so, with the assistance of the other hand, and with less pain. There was marked wasting of the left pectoral and deltoid muscles. Grating was present in the left shoulder joint. Percussion of the left upper chest caused pain. There was a bulging of the ribs (seventh, and chiefly eighth) in the axillary line. The left lobe of the liver was enlarged. The inguinal glands were greatly enlarged but no enlargement of the axillary glands. The urine showed no pathological constituents. The sputum never showed tubercle bacilli, but there were found clumps of cells which resembled cancer cells.

The post-mortem examination was made by Dr. Wachsmann on August 27, 1903. Body of an extremely emaciated female. The following tumors were visible: a flat nodular tumor over the right parieto-occipital region, over which the hair is atrophic; a small, hard tumor over the second left chondrocostal junction; and another hard nodular tumor to the left of the first lumbar spinous process. The superficial femoral glands were enlarged on both sides. Both lungs were adherent. About 60 cm. of serosanguinous fluid were found in the pericardial sac. The heart was of normal size. The pericardium showed patches of fibrous thickening. At the apex was a hard, nodular, intramural, projecting node the size of a hazelnut; in the auriculo-ventricular groove there were a series of nodules varying in size from that of a hazelnut to that of a bean. A similar nodule in the region of the pulmonary artery. On section the nodules were hard, fibrous, resembling the medullary swelling of glands, the center being yellowish and softer. The color of the heart muscle was normal. Both pleural sacs were obliterated, less on the base. The left lung was very friable and adherent to the thoracic wall. At the base of the left lung were a series of hard nodules, varying from the size of a cherry to that of an apple. At one place, corresponding to the left second rib, the tumor was infiltratory and projected through the chest wall. The tumor mass was firmly adherent to the lower cervical vertebræ, to the upper three left ribs, and also infiltrated the sternal end of the left clavicle. The entire left lung was infiltrated by tumor mass, with large lumps in the upper lobe and base. There were similar infiltrations in the right lung, though smaller in size. The liver was small, smooth, glistening surface, and showed several whitish-yellow protuberances, some showing central depression, and which, upon cutting, prove to be tumor masses varying in size from a pea to that of an apple. The substance of the liver was friable, brown, and congested. The right kidney was small, adipose, the capsule showed a small amount of fat, the fibrous capsule was not adherent. The markings were indistinct; a few tumor masses projected on the surface, the size of a large pea. The left kidney was about normal size and consistency; very small tumor masses were found in the pyramids, and also in the periphery. There were tumors in the left adrenal, making it about three times its normal volume. The right also had a few small tumors. The retro-peritoneal glands were replaced by tumor tissue. The stomach was vertical in position and contracted. The mucous membrane was normal. The mesenteric glands were slightly enlarged, hard, not resembling the other tumors.

Cause of death: Carcinoma of the lungs, with metastases in the heart, liver, ribs, kidneys, clavicles, skull, mesenteric glands, and suprarenal capsules.

Case III.—L. H., female, Hungarian, Hebrew, thirty-eight years of age, who worked in a very dusty fur shop, had been ill for a year and a half before her admission to the Montefiore Home on August 31, 1903. Her illness began with a tickling sensation in her throat, followed by a cough, accompanied by a profuse, greenish-yellow, tenaceous, mucoid sputum, which would sink to the bottom of the vessel. At times she noticed blood in the sputum. Her skin became a little darker, and this gradually increased until it was of a bronzy-brownish color. By that time she was very weak and had lost about 50 lbs. Her voice became hoarse, but she never had any pains in the larynx. Pain in the left side of the chest began about one year ago, and gradually increased in severity. On examination

her temperature was 100.2° F., pulse 120, and respiration 26. She was poorly nourished. Her skin was of a brownish color all over the body, darker on the face and forehead, where freckles were present. The larynx was prominent. The base of the tongue was very much congested. The arytenoid cartilages were congested and infiltrated. The right vocal cord was thickened; the left was paralyzed. The voice was husky. On the left side of the neck a few small glands could be felt, along the posterior border of the sternomastoid muscle. The thyroid gland was rather full. The platysma reflex was delayed on the left side. With respiration the intercostal spaces retracted. The right side was more movable, and the right scapula stood higher than the left. In the left axilla a small gland could be felt. During inspiration the left infraclavicular space was not as filled out as the right. A tremor in the upper portion of the pectoralis major was at times seen, especially during inspiration. The intercostal muscles retracted during inspiration, but more on the right than the left side. The mammillæ were normal. The apex-beat was distinctly visible, but more so during expiration; it was felt in the fifth intercostal space, at a distance from the mid-sternal line of 11 cm. During expiration the systole and diastole could be noticed in the impulse. During inspiration these were broken up into a number of small throbs. The impulse was not very forcible. The right relative dulness began at about one centimetre to the left of the right sternal border; above at the fourth intercostal space in the mid-clavicular line; the left border was marked by the apical impulse. The cardiac dulness did not extend beyond the apex. Auscultation at the mitral area gave the first sound forcible, the second much weaker. No murmur. The first aortic sound was practically absent. A short diastolic murmur was heard, rather rough and blowing in character, and followed by the second sound, which was very weak. The murmur was transmitted upward and into the vessels of the neck, as well as into the right axilla, where it was plainly heard. The first pulmonic sound was weak; the second distinctly accentuated. No murmurs. The pulse showed increased tension and greater volume on the right side. The rhythm was equal on both sides. The respiration was more marked on the right side, and was laboring in character. The vocal fremitus was absent on the left side, present on the right. The percussion note over the right apex was somewhat increased anteriorly. At times a note was obtained resembling somewhat a cracked pot. This extended down to the upper border of the fourth rib. From there down the note was dull. In the axilla the note was normal. Increased pulmonary resonance was found on the right posteriorly down to the spine of the scapula. Lower down it was normal. On the left side there was a dulness over the apex to the first rib, and from there flatness down to the base. Breathing was rough over the apex. A few small distant râles were heard after coughing. At the first interspace the breathing was nearly cavernous, accompanied by small dry râles, especially during inspiration. Exaggerated breathing in right axillary line. No râles on coughing. Rough breathing, with a few distant râles down to the spine of the scapula over the right side posteriorly, and from there down the breathing was slightly exaggerated, but no râles were heard. On the left side anteriorly there was no respiratory murmur over the apex, that which was heard was transmitted from the trachea. Practically no respiratory murmur down to the third interspace. From there a very slight murmur could be heard, but no râles. Respiratory sounds were absent in the left axillary line, and in the back. The cough was metallic and whistling, occurring at short intervals, followed by expectoration of thick globular masses of a greenish-gray color. Cough did not stop until one of these masses was brought up. The pain in the chest varied as to the location, but mainly on the left side and axilla. This pain was pressing in character and not influenced by respiration. When patient lay on left side the pain would disappear entirely, and as soon as she turned over to the right side the pain returned. The pain was not affected by the cough. The pains in the right side were less severe and less frequent. The pains in the left side would at times start in the back and radiate to the front as far as the sternum. The abdomen was normal. Liver dulness began at the fifth rib and extended three finger-breadths beyond the free border. The inguinal glands were somewhat enlarged on both sides. The right scapula moved with greater excursion than the left. The urine always had a very heavy sediment—no albumin but much triple phosphates urates, and hyaline and granular casts. Renal and vesical epithelium were present. The sputum was bloody and malignant-looking (somewhat like raw chopped meat). In thirty examinations it was negative for tubercle bacilli and cancer cells were found at times. The blood count made September 12 gave the following results: Hb. 80 per cent. R. B. C. 4,200,000. W. B. C. 8,000. Differential—Baso. 0.02. Neutro 0.82. Eosino. 0.03. Small Lympho. 0.02. Large Lympho. 0.08. Large Mono. 0.03. On September 24,—Hb. 65 per cent. R. B. C. 3,950,000. W. B. C. 21,200.

There was a (Head's line) of pain extending from below upwards, beginning at a level corresponding to the sixth dorsal segment. There was also pain upon percussion of the spine of the fifth dorsal vertebra. On October 11, 1903, the patient developed œdema of the lungs of the right side during the night, was too weak to expectorate, and died the following day.

The post-mortem examination was made by Dr. Harlow Brooks on October 13, 1903. Body of an emaciated woman. The skin was generally dark, especially over the face, where the pigmentation was almost melasmic. The thyroid region was prominent. The thorax was unusually long, slightly pigeon-breasted. The lower border of the liver lay 2 cm. below the umbilicus (corset liver). Old adhesions to the anterior thoracic wall, particularly on the left side; marked adhesion of an acute and ulcerative character to the parietal pleura at the level of the second intercostal one inch to the chondro-osseus junction. A few strands of adhesion at the right upper lobe. The pericardial space was pretty well enlarged and extended 5 cm. to the right of the medium line. The left pleural cavity was completely obliterated by very dense old adhesions. Complete adhesion to the diaphragmatic pleura. The pericardial lymph nodes were considerably enlarged, anthracotic and partially involved by some new growth infiltration. The pericardial sac was found distended and its surface covered by a recent fibrino-hemorrhagic exudate. The posterior wall of the pericardial sac on the left side was found completely involved by a white nodular growth, for the greater part subendothelial. Near the base the growth had ruptured through the endothelium, producing nodular excrescences, extending in one place into the left auricle; passing backward, it involved the bronchial lymph nodes and so caused laryngeal prominence. The epicardium showed recent pericarditis apparently caused by friction against the roughened pericardium, thus accounting for the hemorrhagic effusion. The ventricles were contracted. The left

ventricle was distended with mixed clot, was of normal size, and the superior portion of the wall was completely invaded by new growth. The aortic murmur was accounted for by the fact that the tumor involving the bronchial lymph glands had forced the aorta to make an acute angle in its descending portion. The heart showed a moderate brown atrophy. The arotic arch extended upward and backward, being displaced to the left by the involvement of the lymph nodes, particularly to the right of the arch. This all tended to compress the right subclavian artery to a lesser extent than the vessels on the left. Those on the left were compressed by separate nodules of new growth. The vessels showed moderate degree of atheroma. The thyroid was about double volume. The blood vessels were greatly enlarged in the gland, and the tissue appeared adenomatous. The growth was apparently due to a true adenomatous struma. The involvement of the bronchial and tracheal lymph nodes was almost universal, and these compressed the laryngeal nerve to a marked degree. The lumen of the œsophagus was compressed and deviated first to the left, then to the right. The mucous membrane of the œsophagus was congested. A marked compression of the bifurcation was present, and the trachea and both bronchi contained large quantities of pus. The right lung showed general emphysema, especially the anterior border, with marked œdema. There was a general fibrotic infiltration of the upper lobe with minute areas of bronchopneumonia. A few isolated healed tubercles were found, together with a beginning pneumonia of the lower lobe. The left lung was completely involved by new growth, most extensive in the base of the lower lobe, where the growth was white in color, soft, giving rise to a milk-like exudation upon scraping. Functionating tissue was entirely absent on the left side. The tumor growth in the lung united with the growth in the pleura in the sixth and seventh intercostal spaces, compressing the fifth, sixth and seventh intercostal nerves on the left side. The growth had extended into the diaphragm, and also involved the pleura at the junction of the first and second left ribs with the spinal column. There was one small nodule of new growth in the upper portion of the right lobe of the liver. Otherwise it showed a general fatty degeneration, with congestion. The spleen was enlarged about two volumes, and its tissue deep purple in color, showing small areas of amyloid degeneration. The stomach and kidneys were normal, but were forced down by the liver. The mesenteric lymph nodes were enlarged, but not involved by new growth. The left adrenal body was separated from the kidney by a distance of 4-5 cm., being itself attached in its normal position to the left lateral aspect of the lower dorsal column. The right adrenal body was completely isolated from its kidney, being found attached in its normal position, and some 10 cm. from the corresponding kidney. The bodies were large, their tissues firm and deeply congested, and the distinction between the cortex and medulla was indefinite, as though there was some inflammatory infiltration. The kidneys on section showed marked fatty degeneration, with general congestion. A section through the mid-dorsal segment showed no apparent gross lesion. It was possible that the symptoms noted were partly due to pressure upon the intercostal nerves.

Causes of death: (*a*) Acute hemorrhagic, neoplastic pericarditis with lobar pneumonia terminating a tumor of the lung with lymphatic metastases; (*b*) chronic parenchymatous nephritis with fatty degeneration; (*c*) septic bronchitis; (*d*) thryoid struma.

From the gross appearance of the tumor, it appears that it was probably primary in the lung or pleura, and from its general characteristics most likely endothelioma, or small round-celled sarcoma. Microscopical examination of the specimens proved it to be an endothelioma, probably originating in the pleura and then spreading to the lung. At the region of the cord, where the section was made, there were signs of a very early myelitis.

From the histories of these cases, it will be seen that pain, of great intensity and persistence, is one of the early and characteristic symptoms of carcinoma of the lung. Quite often it is, at first, localized by the patient in the shoulder and spine, and is independent of the cough. As to the localization of the lesion, in one of the cases, we ascertained Head's lines of hyperæsthesia and found them to correspond to the fifth and sixth dorsal segments of the spinal cord. There was no gross communication nor any involvement by contiguity of the spinal cord, yet microscopically a beginning myelitis was found in the fifth and sixth dorsal segments of the cord. The clinical history of carcinoma of the lung resembles, mostly, a tuberculous affection, but runs a more rapid course, and is not accompanied by fever. In the beginning expectoration resembles the frothy sputum of a bronchitis, but soon it assumes the mucopurulent, tenacious, globular nature of tuberculous sputum, and quite often shows streaks of blood, or even at times larger quantities. In the later stages copious hemorrhages may occur. In one case the sputum showed a very peculiar appearance:—in a serous, flesh-water-like fluid were firm masses with ragged outlines, of a beefy color, sometimes mixed with yellowish-white, tenacious mucopus. No elastic fibers were present. The microscopical examination, naturally, is of more decisive importance than the macroscopical aspect. Aside from the absence of the tubercle bacillus, there is very often a positive result obtainable, *i. e.*, the presence of certain cells may be detected. These cells resemble mostly epithelial cells of the mouth, but are smaller, more the size of pus cells. They are not granular, have one or more small nuclei, sharp, angular outlines, and occur singly, or in nests or pearl-like arrangements, and, what is most important, sometimes intimately mingling with pus cells, thus giving evidence that the mixing took place in regions remote from the mouth. At the post-mortem examination we were surprised to find metastic tumors of considerable size in the heart muscle. They must have taken some time to grow to that size, and it is remarkable how little they interfered with the heart's action. No murmurs or irregularity had been demonstrable. There was an inequality of the pulse, due to depression of one subclavian artery.

The Population of the World.—In a paper entitled "Die Bevölkerung der Erde," by Dr. Supan, quoted in the *Bulletin* of the American Geographical Society, the author gives the results of the latest censuses and sums up his estimates of the population of the world in the following table:

	Total Population.	Per Square Mile.
Europe	392,264,000	104
Asia	819,556,000	46.6
Africa	140,700,000	13
Australia and Polynesia	6,483,000	2
North America	105,714,000	13
South America	38,482,000	5
Polar lands	91,000	...
Total	1,503,290,000	30.6

REPORT OF A CASE OF CHRONIC CYSTIC DILATATION OF THE VERMIFORM APPENDIX.

By J. C. LANDENBERGER, M.D.,
SALT LAKE CITY, UTAH.

Through the courtesy of Dr. S. H. Pinkerton, of Salt Lake City, I report the following interesting case of cystic dilatation of the appendix, which occurred in his practice and was operated upon by him, the writer assisting:

C. S. H., male, age 32 years, single, white, born in Illinois; occupation, farmer, stationary engineer, and as laborer in packing house. His work has always been heavy and laborious. Habits good. The father died at the age of 45 of "dropsy;" the mother of Bright's disease. He had mumps at the age of ten, typhoid pneumonia at fifteen (in bed nine weeks, good recovery), and chicken pox at twenty-three.

He seemed perfectly well until April, 1903, at which time he was assisting twelve men in unloading piles from a freight car, each weighing one thousand pounds. He was in a stooping position with shoulder under a pile when the other men let go, allowing the pile to crush him against the car. At this moment he felt a sudden sharp pain in the left side of the back running around the front to the left testicle, thence to the region of the appendix, where it remained. Thirty days after this injury he fell off a scaffold, twelve feet high, striking with the left hip on the end of a pile.

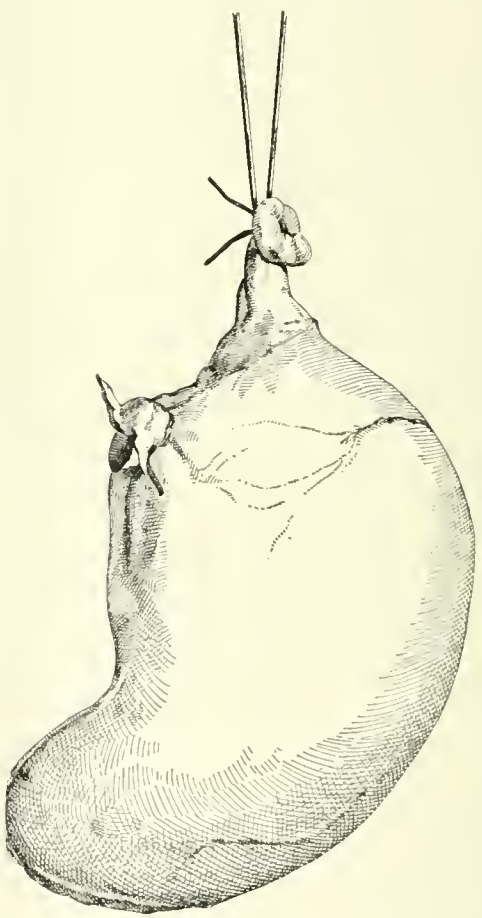
Following the first injury he complained of constant pain in right iliac region; following the second injury vomiting developed, occasional and irregular, but always after a meal, and there was a peculiar dragging sensation in the abdomen, at times relieved by a reclining position. When vomiting he would always make pressure on the right side of the abdomen for relief, as "there seemed to be something there that wanted to push out." He was admitted to the hospital March 13, 1904, complaining of a "heavy bearing-down pain in the bowels and a sharp pain in the right side below the navel." This sharp pain would at times last only a moment, at others four to five hours, and would always occur at least once daily. All of his complaints were increased by work, but ceased when he was confined to bed.

The patient is of medium height, well nourished, and very muscular. A complete examination with especial attention to the abdomen, made upon admission, elicited nothing. He was retained in bed, and put upon liquid diet, the temperature, pulse and respiration being recorded every four hours.

The abdomen having been palpated on several occasions with negative results, there was finally detected a mass in the right iliac fossa about the size and shape of a small goose-egg which could be easily grasped between all the fingers, slightly tender on squeezing and so freely movable that without great care, when one thought it was held firmly, it would slide away much in the same manner as a cake of soap in the bath-tub, and when it had escaped the grasp, usually it would disappear until the next day, despite immediate and continued efforts to again locate it. When the tumor was palpable, in every instance it was found between McBurney's point and Poupart's ligament of the same side, usually hugging closely to the outer end of the ligament and the anterior part of the crest of the ilium. So difficult was this tumor to palpate, that if with three or four abdominal examinations one succeeded in finding it once the occurrence was fortunate.

Close observation on several days revealed nothing further to advance a probable diagnosis, and it is only fair to say that a cystic appendix was not considered. There was no abnormality of temperature, pulse, or respiration, and so long as the patient remained in bed he admitted feeling very well; only when he was up and about, working, did he vomit and complain of abdominal pains and a "dragging sensation in the bowels."

Following proper preparation and under ether anæsthesia, an exploratory incision was made in the right semilunar line and the tumor brought out by the hand on to the abdomen. It was now seen to be an extremely dilated vermiform appendix. There were no adhesions whatever, the appendix and cæcum being freely movable, with no semblance of inflammation present in either the appendix or



the peri-appendicular tissues, so that the cyst could sink deep in the pelvis or lodge under a mass of intestines almost anywhere in the abdominal cavity, which readily accounts for the extreme difficulty in locating it during an abdominal examination. The dilatation was throughout the distal four-fifths of the organ, the proximal end for about three-fourths of an inch being apparently normal, excepting that the lumen at one point was obliterated, as no fluid from the cystic end could be squeezed out. The condition accurately resembled an ordinary cyst with pedicle. This pedicle allowed a very easy and simple excision as well as opportunity to ligate and save the specimen, a picture of which (exact size) is here furnished.

The patient's recovery was complete.

The appendix, closely examined after removal, showed nothing peculiar pathologically. It was not dissected, but appeared to contain within its lumen a quantity of serous, watery fluid which distended all the coats regularly and evenly to the size of a

small goose-egg. It was translucent. The pathology of this case, as well as of other appendical cystic dilatations, is first that of an obliterative appendicitis occurring at one or more points, after which, the secretion continuously increasing, there is a gradual distention distal to the occlusion from mere accumulation.

Just when the obliteration occurred in this particular instance is conjectural as no definite history of an acute attack could be elicited. However, it will be remembered that pain was a constant symptom. The history of trauma seems very significant etiologically. The patient was perfectly well until the first injury, immediately following which there was pain in the right iliac region, and vomiting and a dragging sensation in the bowels at once succeeding the second injury.

The occurrence of cystic dilatation of the appendix is manifestly rare, considering the vast numbers of appendicectomies yearly, with the few reports of such an occurrence. Of the many surgical textbooks treating on appendicitis, only a few devote any space to this condition.

John B. Deaver in his "Treatise on Appendicitis," second edition, mentions a cystic dilatation of the appendix the size of an orange, which was "adherent to the neighboring coils of small intestines and to the right broad ligament," and speaks of similar conditions having been observed by Coats, Weir, Kelynack, Fenwick, and Guttman, the latter's specimen being 14 cm. in length and 21 cm. in its greatest circumference.

"The Twentieth Century Practice of Medicine," Volume VIII, merely mentions the possibility and states that "Wolfler found one of these cysts in an appendix contained in a hernia."

Hemmeter mentions retention cysts having been described by Mayland, Sonnenburg, Ribbert, Gruber, Hawkins, Shoemaker, and Coats.

The pathology of this condition is considered in detail in the new American edition of Nothnagel's Practice, where it is also mentioned that Latham found a dilated appendix filled with small, round, white bodies which did not give the reactions for mucin or for fibrin.

The contents of these cysts may be tough and gelatinous, or white and mucous, or serous and watery.

NATURAL VS. SCIENTIFIC FEEDING OF INFANTS.

By D. E. ENGLISH, M.D.,
MILLBURN, N. J.

The prevention of sickness is more important than its cure. How shall we feed a baby in order to keep it well? This is a more important question than, How should a sick baby be fed? The mother finding herself unable to nurse her new-born babe asks the attending physician how she shall feed it; on the wisdom or folly of his answer depends the future happiness of a human being, and probably the length of its life. First let us consider the manner of feeding, rather than the matter fed.

My first advice is to give the baby nothing but water for the first three days, and to give as much water at a time as the baby will swallow. At the end of the third or beginning of the fourth day suitable food is begun, and my instructions then are to give the baby all it will take of this food at each feeding. Not to let it fall asleep too soon, but to keep it awake and feeding as long as possible, in fact, until it "runs over." After that the baby is not to be fed again until absolutely necessary. In the intervals between feedings give it water, and so try to keep it contented for a time, and make the interval as long as possible. The baby should always be allowed to cry and fret some before the next feeding; not long enough to get it into a state of hysterical nervousness, but long enough to prepare the stomach and nervous system for the next meal, to give them warning, as it were. The intervals will not, and should not, be of equal length. Some may be as short as two hours, others may be eight hours in length. A baby will not always digest the same amount of the same kind of food in the same number of minutes, any more than an adult will, and it should not be fed again so long as any remnant of the last meal is still in its stomach. When the right time comes fill the baby full again, as before, and so on. This is what I mean by natural feeding, and differs from scientific feeding in the length and irregularity of the intervals, and in the amounts given at each feeding. This is the way in which a puppy or a kitten is fed, either of these animals eating enough at each feeding to make the abdomen round and tense, and both being forced to cry and worry for a time before being allowed to feed again. This complete filling of the stomach develops it and makes it strong. The long interval allows time for complete emptying of the stomach, for the firm contraction that prevents dilatation, and for the creating of an appetite that prepares the stomach for the next meal and draws out the digestive juices. Under scientific feeding the stomach never gets properly stretched, never becomes entirely empty, never is firmly contracted, and never has a normal, irresistible craving for more food. As a result the stomach becomes weak and flabby, the digestive juices scanty and poor, and the innervation of the digestive organs sluggish, and the baby is not so well able to resist disease. The natural method of feeding applies as well to breast-nursing as to bottle-feeding. It simplifies very much the question of the quality of the baby's food, for under this plan of feeding a stomach is developed that will digest food that would cause indigestion in a baby that has been scientifically fed.

As to what shall be fed, the first thing given, therefore the first to discuss, is water. When the physician can be sure that the water does not contain harmful microbes it is better to use it unboiled, but care should be taken that all containers are sterile. It is always dangerous to disturb the balance of nature, for the trusted remedy sometimes proves worse than the disease. It is probably true that it is beneficial to both adults and babies to swallow certain kinds of microbes. Under normal conditions the beneficial microbes will keep the pathogenic bacteria in check, *i. e.*, reduce their numbers or their virulence so much that they will not do harm. Under existing conditions this normal balance is generally found to be disturbed, and so when there is doubt it is safer to boil the water. But when it is certain that the water is free from harmful microbes, the baby will do better if the water is given unboiled. Water from deep driven-wells, which clinical experience has shown to be harmless, can be trusted, but care should be taken that it is not contaminated between the time it is drawn from the faucet and the moment it is given to the baby.

A healthy baby fed according to the natural method, and who has plenty of unboiled pure water, and proper care, will invariably do well, if he must be artificially fed, on a simple mixture of milk, cream, water, salt and sugar. Chapin says, "the less milk is manipulated the better." Kerley says, "the milk used for an infant's food should be handled as little as possible." The closer the baby is to the cow the better will it thrive. After milk has lost its animal

heat it is not the same food and not as good food as it was before. Milk used within four hours of milking is better for the baby if it is not cooled below 65° F. If it is to be given older than four hours it is better to cool it at once on milking and keep it at 50° or lower, until warmed for use. Pasteurizing does not kill spores, but it does kill many beneficial microbes. Pasteurized milk if kept a little too long or a little too warm becomes nasty, and is more harmful than raw milk. It is quite possible that some cases of infantile diarrhœa do not get well because of the absence of beneficial microbes. Cleanliness is better than pasteurization, asepsis is better than antisepsis. With these primary principles in mind, select the best milk available and use it raw, at least at first. If it does not agree get the milk from another source. Different babies thrive better on different milks, although all the milks may seem to be equally desirable. Chapin says, "Large numbers of ordinary dairy bacteria in milk are not harmful to adults." It is quite probable that some of them are beneficial to both adults and infants, and this may be the reason one milk will agree when another will not. When it is reasonably certain that the milk is clean and fresh it is better not to sterilize it, but if it is sterilized it must be done thoroughly or it will do more harm than good. Cooling does not eliminate bacteria from milk, it merely prevents for a time their activity and increase. My directions to the nurse are to place the thumb against the side of the bottle for an index, and to pour out slowly the upper two-thirds of the bottle, after the cream has risen. This will approximate twenty-one ounces, and is called "top-milk." To this is added water in quantity suitable to the age of the baby, two heaping teaspoonfuls of milk sugar, or one of granulated sugar and as much salt as it will take without becoming distasteful. The kind and amount of sugar and the amount of salt are variable quantities and must be adapted to the taste of the baby, for if the baby does not enjoy the food it will not take enough at a feeding, nor digest it well. If on this mixture the baby is inclined to have loose bowels without marked signs of indigestion, leave out the salt, and instead of plain water use lime-water in whole or in part. Chapin says, "lime will cause milk or cream to become thick and viscid, its action being on the mucoid proteid," and I do not care to use it much, but sometimes it seems to act well. If, on the other hand, the baby is inclined to constipation, leave out the salt and in its place use sodium bicarbonate, from an even teaspoonful to a heaping teaspoonful to two-thirds of a bottle of top-milk. The sugar, salt, lime-water and baking-soda are to be used in proportion to the top-milk, not in proportion to the quantity of the mixture after the water is added. For the first few days one part of top-milk to four, six or eight parts of water should be given, according to the size and condition of the baby. The strength of the mixture should be increased as rapidly as the child's age and digestive abilities will allow.

If on this food the baby does not keep fat enough it is better to give a little cod-liver oil before each feeding, than to increase the cream-strength of the mixture. When it is necessary to resort to cereal water as a dilutent for the food of a baby under eight months of age, there is something wrong with the baby, its care, or its environment. Kerley says, "Pediatric writers and teachers in their enthusiasm with percentage methods and milk formulæ have been entirely too technical in this teaching, and have not greatly advanced the knowledge of infant feeding by the use of cow's milk among the profession at large. They have issued series after series of intricate formulæ to be used in definite amount at the various ages of infancy, but devoted surprisingly little attention to the infant who is to be fed, or to the instruction of the physician as to how he is to judge of the child's food capacity, or how he is to meet the many phases of the infant's digestive peculiarities. There can be no set formulæ for the various ages of infancy. For this to be possible, it would mean that all infants must be socially, financially, and physically alike, living in one climate, having but one season. Further, among infants living under like conditions one will require stronger food than another of the same age and weight, one child will have a weak proteid and a high fat capacity, another will have a low fat capacity and a high proteid. One will thrive as well as the other when the food is properly adapted." It is quite true that the many intricate formulæ issued by pediatrists are of little or no help to the busy general practitioner, who has not easy access to a milk laboratory, but the working out of these formulæ, and their publication, has in a way enlightened the general practitioner on the subject, broadened his mind, and caused him to observe closer and study his cases more carefully. Teachers of pediatrics seem to take the position that every baby is living under a death sentence, and that our duty is limited to delaying that sentence as long as possible.

The natural tendency of babies is to live; they are stronger and have better resistive powers, weight for weight, than adults, and with proper attention to feeding, clothing and environment, they will live, if healthy when born, and we should expect them to do so.

Wounds and Their Treatment.—Henry D. Michler emphasizes the fact that some wounds which appear at first to be trivial may result most disastrously. He believes that much of a physician's success depends upon the way in which he handles these cases. In the treatment of incised wounds, hemorrhage should be arrested at once by forceps and catgut ligature. The parts are then thoroughly cleansed and the skin shaved. Irrigation follows. All foreign matter should be picked out with forceps. The wound should not be touched with the fingers any more than is possible. Nerves and tendons should be sutured with fine chromicized catgut, and the wound then closed. If the wound is superficial, it should be sutured with silkworm gut, and several strands of silkworm gut are placed in the most dependent corner for drainage. If the wound is deep, catgut is used for suturing it. Capillary drainage is then used. The sutures should never be drawn tight. Adhesive strips should never be used to close wounds. A splint is often an advantage. Some contusion is always present in lacerated wounds, and the thorough cleansing of such wounds is difficult. But this part of the work should not be slighted. Hopelessly damaged tissues must be trimmed out. Sutures are not often advisable in these cases. The wound should be dressed with an abundance of gauze, and the part kept at rest. An ice-bag is often beneficial. In the case of complications, such as gangrene or sepsis, continuous irrigation is the best treatment. In smooth, punctured wounds, the hemorrhage should be arrested, antisepsis procured, and the part dressed and placed at rest. In the case of face injuries, nature will do marvels, and a good result should not be despaired of. If the hand, after being injured, becomes infected, it should be put into a hot 5 per cent. lysol bath for one hour. Fresh hot solution is occasionally added. Or the entire infected area may be painted with pure carbolic acid. The acid remains on the part one minute, after which the part is bathed freely with alcohol and dressed with an alcohol dressing. Ichthyol also acts well. Even if the infection has spread along the lymphatics, it can usually be overcome in one of these ways.—*Pennsylvania Medical Journal.*

FATTY DIET AND ACETONURIA.

IT is not infrequently assumed that in a diabetic diet, the fats are the one element which can do no harm. This view is, but only to a limited extent and with important qualifications, confirmed by Dr. E. P. Joslin, who, in the *Journal of Medical Research* for October, reviews critically former work regarding the influence of various fats on the formation and excretion of acetone, and gives a report of his own experiments, the practical bearing of which on the proper diabetic diet is obvious. Most previous work is invalidated by lack of proper control of the diet, which is usually described merely as strictly albuminous, albuminous and fatty, or that plus varying amounts of carbohydrates—descriptions which tell nothing inasmuch as both albumin and carbohydrates diminish acetonuria. To be of value such experiments must take account of the B-oxybutyric and diacetic acids, and acetone, all being interrelated bodies to be estimated together; and the pulmonary excretion of acetone must be measured, as much as 7 per cent. at times escaping in the breath. In general, no demonstration of the amount of absorption of the fats administered has been furnished; and soaps have been used, though the power of alkalies to increase acetonuria is well known; and no account has been taken of the acetone-inhibiting power of the glycerin component of neutral fats. While numerous observers have shown that the addition of large quantities of fats to a mixed diet results in greatly increased acetonuria, Geelmuyden showed that this was largely conditioned by the simultaneous administration of carbohydrates, an acetonuria of 223 mgm. artificially produced in a healthy individual by an albumin-fat diet, falling to one of 26 mgm. as soon as 150 grams of carbohydrates was taken; and Schwarz saw an acetonuria disappear entirely within 75 minutes after the ingestion of 150 grams of glucose. If with healthy individuals, the diet be merely albumin and fat, while matters are simplified, it is, nevertheless, as Geelmuyden has pointed out, important to know just how much of each is given, as the acetonuria rises with a decrease in the albumin, by reason, Geelmuyden believes, of the liberation of a considerable amount of carbohydrate material in the metabolism of the albumin, and to large quantities of albumin sparing the consumption of the body fat. Examined from this point of view, the literature offers few satisfactory observations. Geelmuyden's experiments further show in the plainest manner that butter increases acetonuria; also the great increasing effect of inanition, an acetonuria of over 300 milligrams increasing when the total calories were reduced from 3,000 to 700, though the fact was diminished at the same time from about 300 to 30. When more than 100 grams of fat was given, at least 80 per cent., and usually 90 per cent., was absorbed. Geelmuyden further showed that during phloridzin diabetes in a dog, acetonuria increased under sodium butyrate, but was prevented or lowered by a neutral (beef) fat. But no determination was made of the absorption factor. Schumann-Leclerq and Hagenberg also note the increase of acetone excretion after the use of butter.

The relation between fats and acetone excretion in diabetes is universally acknowledged. Thus Schwarz found this increase under the use of butter during a strictly albuminous regimen; Waldvogel, the same following the administration of oil; while Lépine saw an increase in diacetic acid after the use of cream. Grube found butter to have a marked action in the direction of increase; a moderate increase occurred with cream, but none with hog fat. Schwarz's cases were the most thoroughly studied. He concluded that not only butter with its volatile fatty acids, but also other kinds of fat poor in those acids, increase the acetonuria. Butter, he believed, increases it more than fats composed of the higher fatty acids, and oil he thinks acts chiefly by its content of volatile fatty acids. On this Joslin remarks that the first conclusion is amply warranted by the facts, but that the others have to be qualified by the lack of proof as to extent of absorption. Schwarz also studied in diabetics the effects of palmitic and oleic acids, and of sodium stearate, valerianate, caproate, butyrate, propionate, and bicarbonate; but these experiments again are inadmissible as not taking account of all the factors.

To eliminate the foregoing sources of error, Joslin carried out twelve experiments on men, each experiment lasting four days, on the second and third of which nothing was taken but a liter of water. In most cases the stools were examined for fat; in all the acetone was estimated in the breath as well as in the urine. During the starvation days tests were made with oleic, stearic, palmitic, and butyric acids, sodium palmitate and bicarbonate, tristearin, triolein, and glycerin. Joslin considers that his experiments show that conclusions as to the action of various fats (whether neutral fats, fatty acids, or soaps) upon the elimination of acetone are of little value without proof of their absorption. Neutral fats, whether of the lower or higher fatty acids, do not increase acetonuria, their glycerin component sufficing to prevent it. Oleic acid produces marked acetonuria; butyric does not produce such result. The poor absorption of palmitic and stearic acids suffices to explain the negative result obtained in this and other experiments. Sodium palmitate produces a marked acetonuria not explicable merely by the presence of the alkali.

STREPTOCOCCUS AND TETANUS ANTITOXIN INJECTIONS.

DR. VICTOR VAUGHAN, in the *Physician and Surgeon* for May, reviews the reports of recent work on the streptococcus and tetanus toxins. The literature on streptococcus toxin of late has been fairly voluminous, but the results of researches have been unsatisfactory and to some extent conflicting. The most important paper which has recently appeared on the toxin of streptococcus is that of Simon

(*Centralblatt f. Bakt.*, xxiv, 1903). Simon's conclusions are as follows: (1) In the cellular substance of streptococci intracellular poisons can be demonstrated, but their action is relatively weak and uncertain, so much so that the symptoms and the rapidly fatal course of acute streptococcus infection cannot possibly be due to these poisons. (2) The toxicity of the streptococcus cells is not always proportional to the virulence of the strains employed. (3) Streptococci excrete toxins, the toxicity of which is markedly greater than that of the intracellular poisons. (4) The elimination or elaboration of toxin by the streptococcus is independent of the amount of intracellular poison in the cocci. (5) Streptococci are not permanent toxin builders, as are diphtheria and tetanus bacilli, but they require a certain amount of external stimulation, especially that of the bactericidal juices of the body, before they produce soluble toxin. Therefore the condition necessary for the elaboration of a toxin by the streptococcus is that the multiplication of the germ should be interfered with by the antibacterial substances of the animal body. (6) The toxin and the hemolysin of the streptococcus are two different bodies, which owe their origin to different conditions. Furthermore, it is highly probable that the streptococcus produces a hemolysin only when it can no longer elaborate a toxin, that is, when it is overcome by the antibacterial substances of the body.

Vaughan does not altogether agree with the conclusions reached by Simon. As yet, he thinks, we know too little concerning the conditions necessary for the splitting up of the molecules within the bacterial cells. We must ascertain whether or not this molecule which constitutes the essential part of the bacterial cell has certain definite lines of cleavage, and what the conditions are and must be before the molecule will split along such lines. That a streptococcus toxin exists, there can be no doubt. That it is intracellular in origin there are many reasons for believing; but we are ignorant of the conditions under which the toxic part of the bacterial molecule is split off from its other constituents. Until, then, we have the streptococcus toxin in fairly large amount, it will be quite impossible for us to have or produce an antitoxin of definite reliable strength. After commenting upon the various streptococcus antitoxins in use, Dr. Vaughan quotes Ogle's conclusions from his experience with antistreptococcus serum published in *The Lancet* of March 14, 1903: 1. That the greatest symptoms combined with streptococcic infection, even of the blood stream, are not incompatible with recovery if treated by injections of antistreptococcus serum. 2. That this is true also in malignant endocarditis, but that here the chances are probably less favorable on account of the colony of micrococci involved in the vegetations in constant contact with the blood stream. 3. That in malignant endocarditis staphylococci are frequent, or a mixed infection of staphylococci and streptococci: 4. That if an examination of the blood be negative it would be prudent to use injections of both antistaphylococcic and antistreptococcic serum. Concerning the toxin of tetanus Vaughan notes that little has been attempted in the chemistry of this subject in recent years.

As to the action of the toxin some very valuable work has been done. Marie and Morax (Annales de l'Institut Pasteur, 1902, xvi, 818, and May, 1903) conclude that tetanus toxin is absorbed by the peripheral nerves and that this is due to a special affinity between the toxin and the substance of the axis cylinder. Marinesco (Compt. Rend. de la Soc. Biol. 24, 1896) claims to have found by Nissl's method histological changes in the cells of both the anterior and posterior horns of the cord in animals poisoned with tetanus toxin. According to Marinesco, the chief change found consists in enlargement of Nissl's granules. However, according to other investigators, these cell changes are by no means characteristic of tetanus. Babes, in the Supplement volume "Twentieth Century Practice of Medicine," concludes that antiserum inoculations, as they are used to-day in the treatment of tetanus, give unsatisfactory results. He states that inoculations of carbolic acid and brain substance give better results than does the specific treatment.

Behring (Beiträge 3, exp. Therap., 1904, Heft 7) states that the tetanus toxin is probably an albumose, while the antitoxin is a true proteid. This conclusion is reached largely because a solution of the toxin dialyzes much more readily than one of the antitoxin, thus indicating that the antitoxin molecule is much larger than that of the toxin. Furthermore, Behring has shown that when a solution of a toxin is placed inside the dialyzer and the solution of the antitoxin outside, the toxin passes more rapidly outwards than when dialyzed against water or physiological salt solution, or when dialyzed against other than the antitoxic proteids. This, says Vaughan, demonstrates that the antitoxin attracts chemically the toxin, and offers an explanation for the observation that the toxin of tetanus travels centripetally in the axis cylinder.

Vaughan concludes that we must know much more about streptococcus toxin than we do, and must be able to prepare a soluble streptococcus toxin before an antistreptococcus serum of value can be prepared; and further, that there is no satisfactory proof that any of the antistreptococcic sera now employed by the profession have decided therapeutic value. Regarding antitetanic serum, he says there is at present no satisfactory method of standardizing it. When we use the serum we are quite ignorant of the value of the preparation which we are employing. There is, however, no danger apparently of using too much, as it has been shown that antitetanic serum is harmless. Vaughan considers that the prophylactic value of antitetanic serum has been abundantly demonstrated, and he would recommend that prophylactic doses be given whenever the surgeon is called upon to dress a wound which in his opinion might be infected with tetanus bacilli. Indeed, he recommends that a prophylactic injection be given at the time of dressing, and that this be repeated on the third, fifth, and seventh days after the receipt of the wound.

THE IMPROVIDENT HEALTH SEEKER.

There is hardly a question before the practising physician involving greater responsibility in its decision than that of the course to take with the consumptive still in the early stages of his disease and dependent on his own exertions for a livelihood. The health-giving properties of the climate in several regions of the West are so marvelous that the temptation is to disregard all other considerations and to hurry the sufferer as rapidly as possible from his humid and otherwise unsuitable surroundings to

the dry air and sunny weather of Colorado, Arizona, or New Mexico. Of late the tendency has been in favor of the southern localities, since, while the prospects of a cure are just as good, the patient on his return home is not deprived of the additional stimulus to which one living in high altitudes has become accustomed. Phœnix, the center of the Salt River District in Arizona, has become the rallying point of these health seekers, and that their trust is not ill-founded is attested by the fact that a local estimate goes so far as to say that ninety per cent. of those who go to Phœnix in the first stages of tuberculosis have been cured, sixty per cent. of those in the second stage, and ten per cent. of those who had been considered incurable have been restored to health and usefulness.

There is another and very terrible side to the picture, however, and to this Frank D. Witherbee directs attention in an article entitled "Health Drifters of the Great Southwest," appearing in a recent issue of *Charities*. The climate may do much in the way of restoring health, but it is not all-powerful, and according to the estimates of local physicians from two-thirds to four-fifths of those sent to Phœnix are hopelessly incurable and beyond the help of any power on earth. Out of a winter population of fifteen thousand fully five thousand are health seekers, and the streets are filled with them—thin, wretched, homesick, and suffering, and, worst of all, in many cases utterly destitute.

The conditions are not what heedless physicians and relatives think them when they send patients to Phœnix alone and with scant means of support. The sick man is told that all he needs is to get to that country and that there he will be able to support himself by light and healthful work. But what the incapacitated one finds on his arrival is a country already overcrowded with people looking for similar opportunities, and that competition has forced down prices until it is difficult to earn even a mere pittance. The country is essentially a ranching and agricultural one where the rough farming and herding work to be done requires previous training and a healthy body to support its hardships. Board and lodging are high even on the ranches, and the food is rarely of the expensive kind necessary for tuberculous patients. Friendless and alone the despairing patient sees his small reserve fund rapidly consumed, and soon becomes dependent on the charity of strangers in a community that has no interest in him, and where he finds on many sides an almost hardened indifference to his pitiable need. This is not because residents of Phœnix are lacking in the finer feelings which prompt to charitable service, but because the people of the East and Middle West are, by their lack of forethought, putting upon them a burden which in no sense belongs to them. The supervisors say that the poor in the almshouse cost the county $20,000 a year, and three-quarters of this is spent in the care of ailing consumptives, while the resources of the local lodges, the church, and the one free sanatorium are all strained to the uttermost.

The duty devolves upon every physician considering the question of sending a consumptive away from home, to determine first whether the lesion is still slight enough to offer reasonable prospect of cure, and secondly, whether the patient's finances are such as to enable him to secure the comforts his illness requires and which his protracted isolation from home and friends makes doubly needful. Such progress is being made in the home treatment of tuberculosis by careful management and attention to details that one assumes a serious responsibility in sending an invalid into a strange country where there is more than a possibility that he will be exposed to all the horrors of sickness and want in a community so overburdened with similar appeals as to make adequate assistance impossible.

The Fourth Disease.

It required centuries of medical observation of the acute infectious exanthemata, which had always been collectively grouped under the one heading of variola, before Sydenham, in the seventeenth century, separated one type from the other forms and created the new classification of morbilli. Fothergill made the next step when, in the eighteenth century, he segregated another set of cases, which he called scarlatina, and it is only comparatively recently that rubella has become universally recognized as a distinct affection *sui generis*. The question now before the profession is whether further subdivision should be made and the identity of another affection be accepted which shall stand in the same relation to scarlatina as does rötheln to measles. The first observations in this direction to attract universal attention were those of Clement Dukes, who, in 1900 (*Lancet*, July 14), advanced the hypothesis that a mild form of exanthematous affection might be differentiated which closely resembled scarlatina, except in the greater length of the incubation period, the absence of prodromes, and limited period of infectiousness. Other authors, such as Weaver (*Journal of State Medicine*, 1901), promptly came forward with observations of epidemics similar to those described by Dukes, whereas some writers, including Dawson Williams (*British Medical Journal*, December 21, 1901), who described a school epidemic of undoubted German measles, in which morbillous and scarlatiniform types existed side by side, are equally emphatic in considering such a classification as premature.

The picture which Dukes considers as characteristic of the fourth disease, comprises an incubation period of from nine to twenty-one days, and a prodromal stage conspicuous through its mildness, though sometimes headache, loss of appetite, and backache are observed. The eruption is usually the first symptom and covers the entire body in a few hours. It is finely punctate, very slightly raised, and of a pale red color. The conjunctiva and pharynx are congested, but the strawberry tongue is not seen. The cervical glands are swollen, but less so than in rötheln. The eruption fades quickly and is usually followed by a slight desquamation, which may, however, be quite pronounced. Renal complications are unusual, the systemic disturbance is only slight, and rapid pulse and high temperature are uncommon. The patient can get up on the fifth to sixth day, and the period of infectiousness is over in two to three weeks.

Bokay (*Deutsche medizinische Wochenschrift*, October 20, 1904), who is a believer in the disease as a separate entity, refers to the publication of an observation in point as long ago as 1885 by a Russian pediatrist, Filatow, who has since died. This author recognized a separate group, and gave to it the name of rubeola scarlatinosa, saying that it was characterized by a scarlatiniform eruption, but was distinguished from scarlatina by its uniformly mild course and by peculiarities of the contagium. Bokay says that the fourth disease can be definitely accepted only when observations of such epidemics

have been reported in which children who have already had scarlatina and measles are not immune, and in which the patients are not protected against subsequent infections with these two diseases. If then the condition is received into the family of the exanthemata, he makes the suggestion that it should be given the name of the Filatow-Dukes disease—just as though there were not more than enough eponyms in medical terminology already.

The Treatment of Cancer.

In spite of the fact that nothing is really definitely proven as to the origin of cancer, Dr. Robert Bell, formerly of Glasgow, and now of London, reiterates his belief that he has discovered a means of successfully combating all forms of malignant neoplasms.

He dismisses the parasitic or microbic theory of malignant disease as a myth, and gives as his opinion that the adventitious bodies which have been recognized in cancerous tissue are a result of morbid metabolism rather than of cell activity. He believes that while cancer is not hereditary, yet that the physiological conditions which tend to its development are inherited, and that in the pathogenesis of malignant disease the power of the thyroid gland has been overthrown in one way or another.

Dr. Bell mentions, as a support to this theory, that Dr. Lorand of Carlsbad has ascertained that cancer has in many instances been found associated with atrophy of the thyroid, whereas in diabetes this gland is frequently observed to have undergone fatty degeneration. The causes at work which tend to interfere with the physiological reciprocity of the thyroid, the writer names as, in the first place, the toxic effects of a continuously contaminated blood supply, which is bound to interfere with the functional activity of every organ of the body. Then, he thinks, when the fact is borne in mind that the thyroid gland inhibits to a large extent the injurious effect due to the absorption of fetid matter, which in constipation is derived from the colon, the conclusion cannot but be that, if the amount of this poisonous material is in excess of what the thyroid can render harmless by its inhibitive power, the gland itself must necessarily suffer in conjunction with other organs which are thus made dependent upon a vitiated blood supply. Injudicious diet and overeating, and the presence in excess of highly nitrogenous food is pointed out as a contributing cause.

The treatment recommended by Dr. Bell is founded upon his belief that some species of saccharomyces, which is invariably present when cancer has manifested itself, is an important factor in the pathogenesis of the growth. This fungus has the power to a limited extent of producing fermentation in saccharine fluids. But when it is coexistent in the blood with an excess of nitrogenous impurity, it would appear to be able to tell much more energetically as a ferment, or at all events as a chemical agent, and by its catalytic effect in propagating itself to act upon the foreign material contained in the blood, transforming this into uric acid or a substance closely allied to this.

Arguing thus, Dr. Bell contends that our first duty is to adopt measures which we know have a destructive effect upon the fungus above mentioned, and he invariably supplements treatment by thyroid extract, by giving in conjunction with it 15 grains of salicylate of sodium three times a day. The latter part of the brochure by Dr. Bell chiefly consists in an arraignment of the *x*-rays in the treatment of cancer, and he concludes by expressing the opinion that overeating and drinking, whereby the various organs of the body are overtaxed, are accountable for very many diseases to which mankind is susceptible, and this to an extent of which few have any conception.

The Hygienic Condition of the Subway.

The atmospheric conditions in the subway seem suddenly to have improved. A week or two ago we were told the percentage of oxygen at the stations was lowered from twenty nearly to twelve, and a ride in the leisurely express trains was said to induce such an air-hunger as to raise the number of respirations to twenty-five or thirty in the minute. The results of various analyses of the air, made by practising physicians, druggists, and amateur sanitarians, were published, and all showed that the Harlemite took his life in his hands when he rode on the asphyxia line. Finally a chemist made an analysis of the air at numerous points in the subway, and found that the percentage of oxygen was very little below that at the surface, and practically the same as that in the average well-ventilated dwelling. Prof. Chandler's report is somewhat optimistic, and we cannot agree with all his conclusions, but the facts regarding the comparative purity of the air three weeks after the subway was opened are undoubtedly as stated and are essentially reassuring. But we were told, further, that while the danger of asphyxiation was great, that of acquiring any one of a number of infectious diseases was greater. The dark tunnel was represented as one gigantic culture-tube, in which all forms of pathogenic bacteria swarmed and pullulated. It is true many bacteria grow better away from the light, but they also need other conditions which the subway does not furnish. We have not seen any reports of culture experiments made after exposing plates in the underground stations, but we question whether the results would show more germs below than at the level of the city streets. Until a scientific investigation of this sort has been made, all talk on the subject is pure speculation.

The hygienic conditions in the subway are, of course, not ideal; neither are they on the elevated road, nor elsewhere in any large town. They will probably tend to grow worse than better, unless great care is taken, but that again is true of health conditions in general in any crowded city. It is manifestly the duty of the public health officials to study the sanitary conditions of the subway, and to insist upon their betterment whenever this is possible and practicable, and we may trust the present efficient health commissioner to do this. In the meanwhile, the citizens of New York can go about their business, under ground or above it, calm in the assurance that the microbe is not the only factor in disease, and that the human organism is so constituted that it can usually adapt itself to the changing conditions of its environment, whatever these may be, unless they are overwhelmingly bad—and such they are not yet in the subway.

The Goose Step.—Every one witnessing a military review in Germany or Austria for the first time must have been impressed by the peculiar stiff-kneed, slamming step adopted on parade by the infantry. At the Congress of Naturalists and Physicians, which recently met in Breslau, this "goose-step," as it is popularly called, was strongly condemned. Dr. Thalwitzer read a paper on the subject in which he showed that the adoption of this ridiculous step accounts for numerous knee and foot complaints among the troops. Sixty per cent. of the sores on the feet of the men are in consequence of persistent adherence to this antiquated step.

News of the Week.

Incorporation of the American Medical Association.—A petition is being circulated among Chicago physicians asking for a special act of Congress incorporating the American Medical Association. The change is said to be merely a nominal one for the sake of business convenience, as the association is not incorporated in several States in which it has membership.

The Middleton Goldsmith Lecture of the New York Pathological Society will be delivered at the New York Academy of Medicine, on Wednesday evening, November 30, at 8:30 o'clock, by Dr. Charles Wardell Stiles, Chief of Division of Zoology, Hygienic Laboratory, U. S. Public Health and Marine-Hospital Service. Subject, "Zoological Pitfalls for the Pathologist."

Red Tape Binds the Pneumonia Commission.—The committee appointed at the instance of the Health Commissioner of New York to investigate the subject of pneumonia, its cause and prevention, is seemingly to be seriously hampered in its work by the action of the Municipal Civil Service Commission. At the preliminary meeting, held not long since, the committee reported that it would be necessary as a first move to employ physicians in Baltimore, Philadelphia, and Boston to gather data and make reports for comparison. A salary of $100 a month each was recommended. The Municipal Civil Service Commission, however, declined to authorize such appointments, unless the physicians in question would present themselves to the board in this city and pass a regular civil service examination.

Microscopical Exhibits at the Natural History Museum.—The directors of the American Museum of Natural History have added to the other collections in the new hall of invertebrates a large series of microscopes with slides containing mounted specimens of some of the minute organisms which represent the lowest forms of animal life, such as are found in stagnant water, and in some pathological conditions. The intention is to supplement this collection by a series of bacteriological specimens.

An Antivaccination Revolution.—The city of Rio de Janeiro has been placed under martial law for thirty days, in consequence of rioting on November 13, ostensibly in opposition to a compulsory vaccination law, recently enacted. Military and naval detachments were called upon to restore order. Seven persons were killed and thirty others wounded. It is believed that the opposition to vaccination was only a pretext for disorder, and that the disturbances were really instigated by discontented politicians.

Dr. Simon Baruch, of this city, delivered an address on "Fallacies, Aims, and Methods of Hydrotherapy in Fevers," at a meeting of the Medical Society of the City Hospital Alumni of St. Louis, on November 17. The discussion was participated in by Drs. Barker, Deutsch, Jacobson, Smith, Shattinger, and others.

Civil Service Rules in the Cook County Hospital. Application for an order enjoining the Cook County (Ill.) authorities from placing members of the medical profession under civil service rule, was made before Judge Dunne, November 17, and resulted in a pledge by County Attorney Wilkerson that the examination for membership on the county hospital staff would be postponed indefinitely. The court expressed the opinion that the county board had exceeded its authority in attempting to hold an examination for the attending physicians. The applicants for the injunction included many representatives of the three different schools of medicine. The opinion of Judge Dunne was based on an Illinois statute providing that all civil service examinations within the State shall be open to "all citizens of the United States," with definite restrictions on residence, age, health, and moral character. He sustained the contention of attorneys representing the petitioners that the examinations for physicians were limited to persons of a particular class, and therefore would be a violation of the statute.

Civil Service Examination for Physicians.—Open competitive examinations will be held in various cities throughout the State, December 3, 1904, for the following positions: *Resident Physician,* State Industrial School, Rochester; $1,500 and maintenance. Candidates must be licensed medical practitioners of New York State and have had at least one year's experience on the staff of a public general hospital. Subjects of examination and relative weights: Materia medica and therapeutics, theory and practice, surgery, hygiene and sanitation, pathology and diagnosis, hospital management, 7; experience, education, and special training, 3. *Fourth Grade Physician.* This examination is intended to provide eligibles for the position of Medical Interne and other medical positions of similar grade in the State hospitals and other State and county institutions. The usual salary is $600, with maintenance, including quarters, board, laundry, etc. It is open to men or women who have graduated within three years from a registered medical school. Candidates of the Homœopathic school will be admitted without regard to date of graduation. Candidates may be either non-residents or residents of New York State, and a license to practise is not required. Subjects of examination and relative weights: Written examinations covering anatomy, physiology, chemistry, materia medica, therapeutics, obstetrics, surgery, theory and practise, 8; education, experience, and personal qualifications, 2. In order to be eligible for appointment, candidates must obtain a minimum standing of 60 per cent. on the written examination and 60 per cent. on education, etc., and a general average of 75 per cent. The medical service of the State comprises the sixteen State hospitals, with about 160 salaried medical positions, and about thirty positions in the Pathological Institute, the Craig Colony for Epileptics, and other institutions. All higher medical positions, from assistant physicians at $1,200 to $1,500 and maintenance, to superintendents at $3,500 to $4,500 and maintenance, are filled by promotion through regular grades from that of sixth grade or junior physician. Persons desiring to enter these examinations must execute applications on forms supplied by the Commission and file them in the office of the Commission before noon of November 28. Application blanks and further information regarding the character of the service and the nature of the examination for Fourth Grade Physician may be obtained by personal or written application to the superintendent of any of the State hospitals, of the Institution for Feeble-Minded Children, Syracuse, the State Custodial Asylum, Rome, the Craig Colony, Sonyea, the director of the Pathological Institute, Ward's Island, New York, or the Chief Examiner, State Civil Service Commission, Albany, N. Y.

New York and New England Association of Railway Surgeons.—The fourteenth annual meeting of this society was held at the New York Academy of Medicine, November 17, the first vice-president, Dr. G. P. Conn, of Concord, N. H., in the chair. The following officers were elected for the ensuing year: *President,* Dr. G. P. Conn, of Concord, N. H.; *First*

Vice-President, Dr. J. P. Creveling, of Auburn, N. Y.; *Second Vice-President,* Dr. Henry T. Dana, of Cortland, N. Y.; *Secretary,* Dr. George Chaffee, of Brooklyn, N. Y.; *Treasurer,* Dr. J. K. Stockwell, of Oswego, N. Y.; *Assistant Secretary,* Dr. Clinton B. Herrick, of Troy, N. Y. The morning session was devoted to the symposium on "Surgical and Relief Service on Railways," the following contributing: Dr. R. S. Harnden, Waverly, N. Y.; Dr. G. G. Thomas, Wilmington, Del.; Dr. D. S. Fairchild, Clinton, Iowa.; J. D. M. Hamilton, Esq., Topeka, Kan.; Dr. J. P. Kaster, Topeka, Kan.; L. L. Gilbert, Esq., Pittsburg, Pa.; W. C. Wilson, Esq., New York, and Sanders McDaniels, Esq., Atlanta, Ga. On the day following the meeting, Dr. Howard Lilienthal gave a general surgical clinic at the new Mount Sinai Hospital, in the morning, and Dr. A. J. McCosh, at the Presbyterian Hospital, in the afternoon.

The American Public Health Association.—The thirty-second annual meeting of this association will be held at Havana, Cuba, on January 9-13, 1905, under the presidency of Dr. Carlos J. Finlay. The executive committee has selected the following topics for discussion, but papers upon other sanitary subjects will be received: 1. Purification and Preservation of Water Supplies. 2. Disposal of Sewage and Industrial Wastes. 3. Animal Diseases Common to Man. 4. Etiology of Yellow Fever. 5. Tuberculosis. 6. Plague. 7. Demography and Statistics in Their Sanitary Relation. 8. Infectious Period of Communicable Diseases. 9. Public Health Legislation. 10. Causes and Prevention of Infant Mortality. 11. Disinfectants and Disinfection. 12. Teaching of Hygiene and Granting of Diploma of Doctor of Public Health. 13. The Sanitation of Travel. 14. The Tenement House Problem. 15. Methods to Control the Milk Supply of Large Cities. 16. Hygiene of Dress. 17. Sanitary Agreement Between Adjoining Nations. In the Section of Bacteriology and Chemistry, the subjects for discussion will be: 1. Standard Methods of Water Analysis. 2. On Diagnostic Procedures. 3. The Significance of Bacillus Coli in Water Supplies. 4. On Bacillus Tuberculosis in Man and Animals. 5. On Laboratory Tests of the Efficiency of Water Filters. 6. Action of Formaldehyde as a Disinfectant. 7. On Antitoxic and Immunizing Sera. 8. The Relation of Protozoa to Disease. 9. Varieties and Action of Anærobic Bacteria in Sewage. 10. Standard Methods for the Identification of Bacterial Species.

The Southern Surgical and Gynecological Association.—The seventeenth annual meeting of this association will be held in Birmingham, Ala., on December 13, 14, and 15, under the presidency of Dr. Floyd W. McRae, of Atlanta. The memorial to the late Dr. Davis, of Birmingham, will be presented to the city by the association. The address of presentation will be made by Dr. C. M. Rosser, of Dallas, Texas; the address of acceptance on behalf of the State of Alabama, will be made by Governor R. M. Cunningham, who is a medical man, and that on behalf of the city of Birmingham by the Hon. W. M. Drennan. The preliminary programme contains the titles of thirty-six papers. All communications regarding the presentation of papers should be sent to the secretary, Dr. W. D. Haggard, 302 North Vine street, Nashville, Tenn.

Charity Reforms in Illinois.—At the meeting of the State Conference of Charities, held November 16, at Rockford, Ill., what the conference of charities wants of the State legislature was outlined in brief by the resolutions adopted. Most of the provisions look to legislative action. Some can be obtained without the aid of the general assembly, but with the coöperation of the authorities. The resolutions recommend the transfer of the Dunning Asylum of Cook County from the care of the county to that of the State; the transfer of all insane patients from the various county poor-houses to the State institutions; the substitution of a more modern system for the present grand jury system; the establishment of an epileptic colony, and an appropriation for that purpose from the State legislature; investigation and correction of all faulty tenements and dwellings in Chicago; passage of a bill compelling the disinfection of houses in which there has been a death from consumption; more adequate appropriation for the State Factory Inspector's office, to enable a more rigid enforcement of the laws pertaining to space and light; and finally, custody of all feeble-minded children by the State.

Nurses Return from Japan.—Dr. Anita McGee and her eight associates, of the American Red Cross Society, who arrived in San Francisco on November 17, say that they were honored in every possible way during their stay in the country, by the officials and representatives of the Japanese army. Before they left, a farewell reception was given them, at which a large number of dignitaries were present. The way they performed their duties in the hospitals is said to have won the highest praise from the surgeons at Hiroshima, the receiving hospital for all the Japanese wounded in the war, where they were stationed.

Martyr to Medical Science.—Information has reached Mexico City to the effect that Dr. Zaldo Gocchi has died of yellow fever at Merida. He was sent by the Italian government to study the disease, and contracted it himself in the course of his investigations.

Smallpox in Washington.—One of the employees of the Department of Commerce and Labor was taken ill on November 15, with what was discovered to be smallpox. As the man had been about the department for four or five days, complaining of feeling ill, much apprehension is felt by the other employees, who have all been vaccinated.

Hospital Interne in Court.—A member of the house staff of one of the large hospitals of this city was last week held in $500 bail, in the West Side Court, for an alleged assault upon a lawyer's clerk. The latter was making inquiries in behalf of a woman who is suing the hospital for damages for an autopsy upon her husband, said to have been made without proper authorization.

Delirious Patient Leaps from Bellevue Windows.—A patient suffering from pneumonia plunged through a closed window at Bellevue Hospital, a few days ago, to the pavement, twenty feet below. He sustained a fracture of the skull.

A Proposed War on the Opium Trade.—Secretary Hay gave a hearing, recently, to a committee of the International Reform Bureau, on a petition asking this government for diplomatic action toward a world movement for abolishing the opium traffic in China. Secretary Hay promised the committee to lay the matter before the President.

New York Orthopedic Dispensary and Hospital.—Dr. Russell A. Hibbs will give a course of clinical lectures on orthopedic surgery at the Institution, on Tuesday and Thursday afternoons, at 4 o'clock, from December 6 to January 5, both inclusive. The course will be free to the medical profession and students.

Hospital Founded at Muskegon, Michigan.—Hackley Hospital, Muskegon, Mich., was dedicated, November 17, with a gift of $220,000 by Charles H. Hackley. Mr. Hackley had already endowed the

institution with $100,000 in six per cent. bonds. He has also donated $40,000 for the establishment of four free beds.

Condemnation of the Division of Fees.—At a recent meeting of the Council of the Chicago Medical Society, Dr. Arthur Dean Bevan offered the following resolution which is to be voted on at a subsequent meeting and then, if adopted, to be incorporated as an amendment to the Constitution: "Any member who is guilty of giving or receiving a commission, or of entering into any arrangement for the division of a fee for professional services, which arrangement is not known and fully understood by the patient or party by whom such fee is paid, shall be guilty of unprofessional conduct."

Hospital Ships Sunk at Port Arthur.—A refugee from Port Arthur has reported that on October 30, two hospital ships in the harbor, and on November 1 a third, were struck by the indirect fire of the Japanese, and sank immediately. All on board the three vessels were lost.

The War Against Tuberculosis.—The Board of Directors of the National Association for the Study and Prevention of Tuberculosis held a meeting, last week, in the United Charities building, in this city. Dr. William Osler presided. The plan of organization for the first annual meeting of the association was discussed. This will be held in Washington, the third Tuesday in May, 1905. It was decided to appoint an advisory committee of prominent physicians and laymen throughout the United States. It was also decided to appeal to philanthropic people throughout the country for contributions. The association wishes to have it understood that not only physicians, but all laymen, should be interested in the movement. The help of municipal bodies throughout the country will be sought.

Adulterated Milk for Jersey City.—Dr. Gordon K. Dickinson, president of the Jersey City Health Board, is reported as saying that the board has found it impossible to stop the sale of adulterated milk in that city, and that it will accordingly give up the fight. He said that the board had done its best to prevent unscrupulous dealers from doctoring their milk with formaldehyde to preserve it, but it was impossible to secure juries that would punish dealers who sold milk not up to the standard.

Dr. E. J. Brown has been appointed professor of histology in the Chicago Eye, Ear, Nose, and Throat College.

Bequests to Hebrew Charities.—Mr. Solomon Rothfeld, who died on November 3, made a number of charitable bequests, among which were the following: To Mount Sinai Hospital, $5,000; $1,000 to the German Hospital and Dispensary; $2,000 to the Montefiore Home for Chronic Invalids; $1,000 to the Hebrew Benevolent and Orphan Asylum; $1,000 to the Home for Aged and Infirm Hebrews; $1,000 to the United Hebrew Charities of the City of New York; $500 to the Colored Home and Hospital; $1,000 to the Educational Alliance of this city; $1,000 to the Beth Israel Hospital Association, at Jefferson and Cherry streets.

The Late Dr. Pryor.—The Faculty of the New York Polyclinic Medical School and Hospital, through its committee, appointed at the annual meeting, held November 10, 1904, adopted the following minute: "That the death of Doctor William Rice Pryor, Professor of Gynecology in the New York Polyclinic Medical School and Hospital, which occurred on August 25, 1904, was a great loss and sorrow to the Faculty of the Polyclinic, and to his many friends. Graduated from Princeton College in 1878, from the College of Physicians and Surgeons in New York in 1881, and from Bellevue Hospital in 1882, Dr. Pryor was particularly well equipped for his life work, and the eminent position he attained in the special branch of medicine to which he gave his attention was due in no small degree to this thorough preparation. His ability, perseverance, originality, and thoroughness were recognized by all who knew him, and will always serve as a stimulus to his fellow workers. Throughout his entire career he was in the highest sense the friend of the needy and the afflicted. The amount of time he devoted to charity work was enormous, and in many instances, where those under treatment could not afford to pay for little delicacies needed, he supplied them from his own purse, besides giving his services free. His attention to details and his personal supervision and care of those he treated was most painstaking. His services to the Polyclinic were most valuable. Appointed as Clinical Assistant to the Chair of Gynecology in 1886, he filled all the intermediate positions most creditably until, in 1895, he was made full Professor of Gynecology. His clinics drew students from all over the country, and his writings attracted marked attention both at home and abroad. He was a frequent contributor to medical literature, and shortly before his death had completed a text book of gynecology. We assure his bereaved family of our deepest sympathy, and do hereby resolve that this record be inscribed at length upon the minutes of the Faculty, that it be published in the medical journals, and a copy, suitably engrossed, be sent to the family of our late colleague. Signed, W. R. Townsend, Chairman, J. Riddle Goffe, Brooks H. Wells, Committee."

Obituary Notes.—Dr. Hunter A. Bond, of this city, died on November 13, at the home of his parents in Petersburg, Va. He was a graduate of the Bellevue Hospital Medical School in the class of 1891, and had for twelve years been on the medical staff of the Manhattan State Hospital on Ward's Island.

Dr. H. H. Woods, probably the oldest man in Missouri, died recently at Granby, in that State. He is said to have been born in New York State, in 1800. He resided in Granby fifty years, thirty in active practice, and the remaining twenty years managing a drug store.

Dr. Henry Moore Humphrey died in Dresden, on November 13, at the age of eighty-three years. He had been in failing health for the past two years, death being due to gastritis. He was born in Philadelphia, his father being Dr. Gideon Humphrey, a prominent physician of that city in the early part of the last century. He was a graduate of the College of Physicians and Surgeons in New York. He practised his profession for a few years, and then became interested in finance. He was the cashier of the Ninth National Bank of New York, and later founded the National Bank of Stamford, Conn., and was its first president. For the last twenty years he had lived the greater part of the time in Europe.

Dr. Benjamin F. Sides died at Furniss, Lancaster County, Pa., in November, at the age of eighty-two years. He was graduated from Jefferson Medical College in the class of 1871.

Dr. Thomas M. Drown, president of Lehigh University, died at Bethlehem, Pa., on November 16, at the age of sixty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863, and he entered the

United States army as a surgeon. At the close of the war, he pursued his studies abroad, and on his return to this country became instructor in metallurgy in Harvard College. From 1871 to 1881 he was professor of chemistry in Lafayette College. For ten years he occupied a similar chair in the Massachusetts Institute of Technology, whence he went to Lehigh University, in 1895. From 1887 to 1895 he was chemist to the Massachusetts State Board of Health, and, since, consulting chemist.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MILK AND TYPHOID IN COURT—PAROTITIS—LEUCOCYTOSIS—TOTTENHAM HOSPITAL—LEPER ASYLUMS AND HOMES—THE LATE DR. RUSSELL—DR. ROSS.

LONDON, November 4, 1904.

ONE of the large dairy companies has been cast in damages £106 for the sale of milk alleged to have caused death from typhoid. In the summer of 1903 there was an outbreak of typhoid at Ealing, which the several inspectors and others traced to the milk supply of the company. A customer of long standing lost his wife in the epidemic, and sought to recover the expenses caused by her illness and the injury from her death. The action began on Monday and closed yesterday, when the jury, without leaving the box, gave the verdict for £106. There was a regrettable difference of expert medical opinion between the two sides, but even the defense had to admit the case was suspicious. The judge, in summing up, said he had never known a case in which the evidence called for the defendants did more damage to their case. It appeared that not a drop of milk came from where the dairy was supposed to be, and had not for many years, and the judge doubted if any ever had. They went to a district where the water was admittedly bad, and had therefore been carrying on business under false pretenses, he did not say illegally false, but certainly morally false.

It is certainly discouraging that a company, founded with a great flourish of trumpets for the purpose of ensuring complete protection from contamination, should have been shown to be blameworthy. It is strange that with their vaunted system of inspection of farms from which their supply was taken they should have accepted one where the water was so bad that they put in the contract it should be brought daily in carts from a spring three miles distant. When this fact transpired, the judge asked whether a farmer who had a well on his farm was likely to send three miles for water. Being told that he had contracted to do so, and the witness believed he had, his lordship remarked, "Well, wonders will never cease." It seems clear the company's inspections were not what they should be. But what about milk from farms where no kind of check is in force?

Parotitis offers an interesting field for investigation, and perhaps of speculation, especially as its pathology and the possibility of preventing its occurrence under the circumstances which commonly accompany its appearance. At present those who are agreed that symptomatic parotitis is due to secondary infection, are by no means agreed as to the path of infection—some maintaining that it is through Stenson's duct, while others hold that it is through the blood stream. These divergencies were well seen at the Medico-Chirurgical Society's meeting on the 25th ult., when two papers were read and discussed on the subject.

The first of these was by Mr. Rupert Bucknall, and was illustrated by a series of lantern slides showing the blocking of the ducts of the gland, while the blood-vessels remained free. The previously published evidence in favor of the view of duct infection was thus strengthened, and a study of six successive cases of secondary parotitis added as further proof. From this Mr. Bucknall went on to argue that parotitis might be prevented. Experiments go to show that the healthy parotid cannot be infected by smearing the orifice of the duct with microorganisms or by passing them into its lumen or even through a fistula. On the other hand, such experiments will lead to parotitis when the vitality of the animal is depressed by starvation or otherwise, or when the secretion is abnormal, or if the organisms introduced are excessively numerous or virulent. Clinical evidence was added to show that in secondary parotitis the predisposing conditions of duct infection are present—the dry mouth, the diet, the drugs (opium, etc.). To the avoidance of these conditions, it was held, we must look to prevent the occurrence of secondary parotitis.

The second paper was by Dr. B. N. Tebbs, who regarded secondary or metastatic parotitis as a complication rather than a disease *sui generis*. It mostly occurs as a sequel to abdominal operations or disorders, and to some specific fevers, but is also met with as a complication of other diseases. Dr. Tebbs based his paper on seventy-seven cases, of which sixty-four were observed in St. George's Hospital. He thought some cases septic, others toxic, and others again, perhaps, vasomotor. In septic cases he held the infection to be through the blood stream, not through the mouth, on the ground that they were closely associated with other septic states, especially those of abdominal or pelvic origin, the severity of the parotitis varying with the intensity of the other infections. Further, parotitis is less frequent since antiseptic surgery is practised; the socia parotidis is only involved after the main gland and the complication cannot be prevented by disinfecting the mouth.

Mr. S. Paget admitted that some cases might be infected through the blood stream, but Mr. Bucknall's sections proved that it was mostly through the duct. Mr. Malcolm also held that the sections were conclusive. He added that he had seen parotitis follow abdominal operations when there was no sepsis, and he had found the orifices of Stenson's ducts inflamed in such cases. Mr. McAdam Eccles suggested that both views might be correct. He had seen parotitis follow severe intestinal hemorrhage. Mr. Mummery said that the specific gravity of the blood was shown by Prof. Sherringham to be raised after abdominal operations and that would account for dry mouth and tendency to duct infection. Dr. Hawthorne mentioned two cases following hæmatemesis, but he admitted that the sections exhibited proved that infection might take place through the duct.

The diagnostic value of leucocytosis, though much insisted on by some, is hardly yet generally recognized and its limitations are such that even with rapid accumulations of facts much caution is required in formulating conclusions. The subject was, therefore, a good one for the discussion introduced by Dr. J. H. Drysdale, at the Medical Society, on the 24th ult. He pointed out that personal variations were often as great as pathological ones. The conditions of pregnancy and parturition, of the digestion, etc., had to be considered; age, also. In pathological leucocytosis the increase may be due to any variety or to a combination of varieties of leucocytes. The term leucocytosis is more commonly used to denote polymorphic, but a differential count is essential. Polymorphonuclear leucocytosis is found in many pyogenic infections, in certain specific fevers, in some toxic states, secondary anæmia (especially post hemorrhagic), and in prolonged cachexia. The causes may be grouped as inflammatory, toxic, cachectic, and anæmic. Allowing for physiological variations, 10,000 probably, 15,000 certainly, must be considered pathological. In the detection of appendicitis the occurrence of leucocytosis was said to be of value, but not in its differentiation from pyosalpinx. Pus may be present without it; above 15,000 indicates severe sepsis.

Dr. A. E. Wright did not accept Ehrlich's theory of hæmotaxis. Experimentally, leucocytosis could be produced by injecting irritating substances into the blood; or by supplying the blood with pabulum for the formation of the leucocytes. In the latter course white cells were formed up to the limit of the nutriment supplied, not further. Dilution of the blood might neutralize the value of the count.

On this point Dr. C. G. Watson remarked that dilution would not account for differences in the kinds of leucocyte found. In tuberculous peritonitis there is no leucocytosis; in septic there is. He thought a long series of progressive counts in appendicitis would be of value.

Mr. G. E. Gask said leucocytosis was in no way pathognomonic by itself of deep-seated suppuration, but in conjunction with other signs was important.

Dr. John Broadbent commented on the relative proportion of the several leucocytes and the value of differential counts. The phagocytic function should not be overlooked.

The Tottenham Hospital has had a successful career. It was founded in 1869 and its annual dinner took place on Wednesday evening, when more than £4,000 was contributed. Last year 1,000 in-patients were treated and 19,000 out-patients. The latter seem in excess of what ought to be the requirements at Tottenham. There are 73 beds and the committee want to add 50 more. King Edward's fund has granted £4,000 and the Drapers Company £5,000.

During the last two years sixteen new asylums or homes have been added to those already established by the Mission to Lepers in India and the East. To sustain these and to mark the 30 years' work a fund of £8,000 is being raised.

One of the most eminent of our sanitarians, Dr. James B. Russell, of Glasgow, died on the 22d ult. You will know him by reputation, for he had been regarded as in the foremost rank of sanitarians for the last thirty years. He occupied a seat on the local government board for Scotland in 1898, though he declined it some four years previously. He represented Scotland on the Royal Sewage Commission. He was M.D., 1863, Glasgow, and received from his university the honorary LL.D. in 1885. He

had been president of the Royal Philosophical Society, and for a whole generation was held in the highest esteem by his fellow citizens, as well as by his professional brethren. In 1899 the London College of Physicians awarded him the Bissell-Hawkins medal for zeal in promoting public health. Four years previously the British Medical Patrick Stewart Prize, of £50, was awarded him for his works on the prevention of disease, etc. He was not only a worker, but a great inspirer of others, so that much of their work owed its origin to him. His most intimate friends knew that his failure of health spoken of outside their circle would have but one termination, but to those who were not aware of it the sudden close gives a sense of shock at the loss Glasgow and sanitary science have sustained.

Deputy Inspector-General Ross, R.N., died on Monday, at the age of 81. He served through the New Zealand war of 1846-48, and received the medal. In 1861 he was in the *Virago* at the capture of Chilean pirates in the Straits of Magellan. In 1853 he was in medical charge of exploring expeditions across the Isthmus of Darien, and in relief of the lost U.S. exploring expedition, for which he received the thanks of the U.S. Navy Department. In 1854 he was at the bombardment of Petropavlovsky, and landed in the attack on that settlement. He served in the Black Sea and the Sea of Azof in 1855, and in India and Burma during the mutiny. A Greenwich Hospital pension was awarded to him in 1895.

OUR PARIS LETTER.

(From Our Special Correspondent.)

TREATMENT OF PHLEBITIS—PROPHYLAXIS IN MALARIA—RÔLE OF THE TRICHOCEPHALUS IN TYPHOID FEVER—FRENCH SURGICAL CONGRESS—FRENCH UROLOGICAL CONGRESS—DEATH OF PROFESSOR TILLAUX.

PARIS, October 28, 1904.

At the Académie de Médecine, Reynier spoke in opposition to the treatment of phlebitis advocated by Lucas-Championnière in a former meeting. Lucas-Championnière recommended substituting for rest and immobilization, methodical movements and massage as the treatment of choice. Reynier cited observations on cases of phlebitis in which fatal embolism had occurred immediately after voluntary or passive motion. He concluded by saying that in the case of old phlebitis even exaggerated carefulness should always be the basis of treatment. At the beginning of phlebitis, immobilization, later, absence of fatigue, serve, more than massage or passive movement, as protection from the dreaded embolism.

Laveran has been making some interesting investigations in regard to the contagium and prophylaxis of malaria in Madagascar. He called attention to the intimate relation between the presence of the anopheles and malaria. Prophylaxis should, then, consist in exterminating mosquitos. It is to be considered that one of the important factors in the development of mosquitos is the method of rice culture. After harvest, the natives leave the rice stalks to rot in place so as to act as fertilizer, but the resulting stagnant water becomes a good soil for the growth of mosquito larvæ, and, in consequence, a means of disseminating malaria. Laveran proposes as a means of combating the cause of infection, drying of the rice fields after harvest, and the cultivation of rice in running water. Moreover, he proposes protection of houses during the nights by metal screens in the windows, and also free distribution of sulphate of quinine for prophylaxis and cure.

Professor Blanchard read a paper by Dr. Guiart on the rôle of the trichocephalus in the etiology of typhoid fever. The author thinks that the intestinal parasite, the trichocephalus, is, in a majority of cases, a cause of typhoid fever: an indirect cause, however, for, fastening itself deeply in the intestinal mucosa, by its tapering anterior extremity, the parasite at the same time makes a wound through which the bacteria enter, thus causing an infection. The bacillus of Eberth is none the less specific, but, according to the author, so long as the intestine is free from parasites, one can drink with impunity water contaminated with the bacilli. On the other hand, if this same water is taken into an intestine in which there is the trichocephalus, it is by means of the wounds made by this parasite that the bacilli penetrate and infect the whole system.

The seventeenth Congress of Surgery was opened in Paris, October 17, with the President of the Republic present, and Professor Pozzi presiding. A number of foreigners took part in this meeting, and among them were Professors Bergmann and Sonnenburg of Berlin, Czerny of Heidelberg, Mikulicz of Breslau, Kocher of Berne, Fargas of Barcelona, Thiriar of Brussels, Roux of Lausanne, Ceccherelli of Parma, and Tilanus of Amsterdam. Three questions formed the program: 1. Surgical treatment of cirrhosis of the liver, Montprofit of Angers being the first speaker. 2. Examinations of the blood in surgery, Tuffier of Paris opening the discussion. 3. Traumatic separation of the epiphyses, Kirmisson being the introductory speaker. In the first meeting there was a discussion concerning the treatment of cancer in general. Tuffier, claiming good effects by the action of Röntgen rays on limited cutaneous epitheliomata, stated that he had not been able to obtain any result by the action of these rays in deep visceral cancers. He still thinks that the only treatment for deep visceral cancers is surgical, namely, excision, as complete as possible, of all cancerous masses.

Dr. Calot of Berck described an attempt to find a better method of obtaining extension of the spine in Pott's disease. He proposes making an opening in the dorsal part of the plaster apparatus, at the level of the affected vertebræ, about the size of the hand, through which are introduced, between the gibbosity and the apparatus, thirty squares of wadding, about a centimeter in thickness, held at the proper level by a band of moist gummed muslin. Every three or four months three or four squares of wadding are added. This compression is as vigorous as could be desired, and, at the same time, is very gentle. It is, therefore, both effective and well tolerated.

Morestin cited an interesting observation on a perisplenic hæmatocele following traumatic rupture of the spleen. It occurred in a man who had had intermittent fever, and whose spleen, friable in consequence, was ruptured by traumatism. Hæmatomata had formed which were encysted, and were afterwards removed by laparotomy.

The Congress of Urology, which is a part of the Surgical Congress, held its meetings at the same time. A number of foreign specialists took part in these meetings, among whom were Professor Casper of Berlin, and Drs. Nicolish of Trieste, Heresco Bardesco of Bucharest, Guizy and Kallienzies of Athens. The question for discussion was prostatectomy. Two papers were presented, one by Proust of Paris, and the other by Escat of Marseilles. These papers gave a history of the operation to date, showing the comparative values of the perineal route and the abdominal transvesical route, and giving the indications and contra-indications to operation. Among the contributions at this congress, one of the most notable was that of Luys of Paris, who showed the practical application of his urethroscope in the diagnosis and treatment of cystitis in women. Thanks to this method, which has been used for a long time in America, vesical lesions can be treated directly, and are seen as they would be by means of a hypogastric incision, but without the inconveniences of this operation. Hamonic of Paris presented an interesting modification which he had added to the lithotrite ordinarily employed. This modification consists in the manipulation of the arms of the lithotrite by means of a strong lever, through the power of which the calculus, once grasped, can be crushed, whatever its resistance. Dr. Freudenberg of Berlin also demonstrated a new cystoscope for single or double catheterization of the ureters. Muret and Le Fur laid stress on the rapid dilatation of urethral strictures by electrolysis, to which Desnos called attention last year. They showed the good effect of this method when progressive mechanical dilatation is combined with a weak electrolytic current. Nicolich of Trieste presented specimens of three cases of total removal of the genital organs for cancer.

Dr. Tillaux, professor of clinical surgery in the Faculté de Médecine in Paris, has recently died. He was the author of a well-known work on topographical anatomy. For a long time he had charge of the hospital amphitheatre, where his lectures in anatomy attracted large numbers of students.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

TETANUS—CONCEALMENT OF TRACHOMA—AMŒBÆ IN MANILA WATER.

MANILA, September 30, 1904.

Recently a very regrettable accident occurred, which resulted in the death from tetanus of an American who had been inoculated by the health authorities with antiplague serum, on account of his being a plague "contact." The newspapers took the matter up and for a time it appeared that in the future the work of the health authorities would be very much handicapped in this direction. The results of the investigation which was subsequently made were rather conclusive and the public uneasiness was allayed. It appears that this individual was injected with antiplague serum, but it was not until more than thirteen days had elapsed that he showed symptoms of tetanus. The evidence also shows that he removed the dressings which had been applied to the wound and scratched the same with his unwashed hands. Furthermore, a number of other individuals who were inoculated at the same time with the same serum did not develop any symptoms of tetanus. From this it would seem that the tetanus must

have been contracted some time after the inoculation Since the foregoing case of tetanus occurred there has been another case which was contracted in an entirely different manner. A Filipino workman was run over in the street by a vehicle, and as a result thereof he received a number of lacerated and contused wounds. Eight days afterwards he exhibited symptoms of tetanus and on the tenth day he died from this disease. The case received some publicity and it served as a valuable lesson to the public in showing that it was possible to contract this disease through an open wound, regardless of the fact as to whether it was produced by the inoculation of serum or otherwise. At the same time it served to remove much of the unjust suspicion with which the course of the Board of Health was regarded.

The tetanus organism seems to be quite abundant in the soil in and about Manila and considerable care is necessary to prevent infection of the operative cases at the hospitals. At the First Reserve Hospital, for instance, the surgeon in charge uses screens to guard against the entrance of dust and requires that all persons who desire to enter the operating room remove their shoes outside and wear the footgear which is provided at the hospital. Since inaugurating these precautions no further cases of tetanus have occurred among the operative cases.

A fine demonstration was given recently by the arriving Japanese immigrants that this race is fertile in resource not only with regard to things military, but also in other directions. The Japanese are badly afflicted with trachoma and rejections among immigrants from this one cause alone is from ten to thirty per cent. The officers of the Public Health and Marine Hospital Service, stationed at Manila, have noticed for some time past on everting the eyelids of Japanese immigrants that they presented a peculiar blanched appearance. At first it was thought that this was due to the treatment which they might have received prior to embarkation in Japan. Recently, however, several hours after the first inspection was completed and all suspicious cases had been set aside, it was decided to make a re-examination of the entire number; while this work was going on a number of additional cases of trachoma were found. Upon following some immigrants behind a convenient enclosure, they were found to be busily engaged in instilling a substance into their eyes, which subsequent investigation showed to be adrenalin. Experiments with this drug proved that if instilled into the eyes of mild cases of trachoma practically all evidence of the disease could be obliterated for about one half hour. To sum up, then, it seems that on arrival at Manila, and just before the medical inspection was made, they had been in the habit of instilling adrenalin into their eyes.

The government laboratory still continues to report the presence of amœbæ in the Manila tap water. Recently there has been a large increase in the number of dysentery cases among the American population. The cause for the increase has not been accurately determined. It is the opinion of some of the physicians that, owing to the disappearance of cholera, the public has become more or less lax about the water that is used for drinking purposes. Others think that the recent flood from which Manila suffered so inundated the truck farms that they were more than usually exposed to the risk of infection, and that for this reason many of the fresh vegetables sold in the local market contain amœbæ. In order to alleviate somewhat the danger from Manila drinking water it is proposed to try copper sulphate on a large scale, as suggested in Bulletin No. 64 of the Bureau of Plant Industry, published by the U.S. Department of Agriculture, and written by George T. Moore, Physiologist and Algologist, in charge of the Laboratory of Plant Physiology, and Karl F. Kellerman, Assistant in Physiology. The plan is to have copper sulphate drip from a barrel into the intake of the city reservoir in such quantities as to make a solution of one to four million. Careful bacteriological and chemical examinations are to be made of the ordinary tap water before the method is started, and at daily intervals during the experimental period. Since at best it will be some years before the proposed supply of undoubted purity for which arrangements are now being made can possibly be furnished to the city, it would be a great boon for Manila even if the copper sulphate method should prove only partly successful.

A Question of Longevity.—The newspapers have discovered an old gentleman in the Bronx who has used tobacco and liquor since he reached the age of discretion, and is now active and hearty at 103. He seems to have carefully shunned danger, for it is asserted that he has never ridden on a trolley car or elevated train, has never used soap, and has never called in a doctor.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 17, 1904.

The Differential Diagnosis and Treatment of the So-Called Rheumatoid Diseases.—Joel E. Goldthwait presents five types of rheumatoid disease, outlining the treatment for each. First, he describes the chronic, villous arthritis, or "dry joint." It represents entirely a local process, with no tendency to progression. The condition is most commonly seen in the knee, and is commonly associated with flat foot. After a time degenerative changes take place, the most common being fatty degeneration of the villi. The treatment consists in improving the tone of all the joint structures concerned in the action of the joint. All irritation should be avoided. Operation may become necessary. Atrophic arthritis is the second type. It is a progressive disease resulting in marked distortion and great crippling, with atrophy. The etiology is unknown. Tonics, fresh air, stimulating bathing, massage and forced feeding are recommended. Hypertrophic arthritis may be either local or general. In the finger joints, Heberden's nodes are the type. In connection with the spinal process, the costo-vertebral articulations are often involved. The etiology is unknown. The treatment consists of fixation, or at least of protection of the affected part during the active or painful stage. Internal treatment is of little importance, except as symptoms arise or as eliminative functions need supervision. Infectious arthritis is by far the most common. The result of the infection will depend upon the organism from which the infections element is absorbed. The pathological process is a local inflammation. The treatment concerns both the general condition and the local process. Large quantities of water internally are of advantage. If the joint process be acute, fixation will give relief. Chronic gout is far less common than the other types. It is usually slowly progressive, with periods of acute exacerbation. Of the bone changes, the lesion is a local one, but considerable portions may be destroyed. The etiology is not known, and comparatively little is known in regard to treatment. Rest in bed during the active part of the attack and local warmth are indicated. "Sweating" is helpful. Large amounts of water should be taken during the acute stage. The diet in general should be nutritious. Colchicum or the salicylates seem to be the most valuable drugs to cut short the attack, after which tonics are indicated.

Types of Rheumatoid Disease.—C. F. Painter, in speaking of the confusing nomenclature of this disease, states that it is partly the fault of the clinician and partly of the pathologist, but principally of the former. He believes that so far as we have data to work with, it is more valuable to rely upon a careful study of the clinical course and physical signs, coupled with the pathological evidence obtained from good *x*-rays, than upon any purely pathological classification, whether it be gross or microscopical or both. It is necessary to recognize the evidences of inflammatory changes due to the presence of organisms or their toxins in the joints, but it must also be recognized that there are probably chemico-physiological changes going on in the body which have nothing to do with direct septic intoxication, local or general; that although some of these metabolic changes do resemble in certain ways true inflammatory processes, still, careful clinical observation will generally distinguish them from each other. The writer then shows how the external appearances of these so-called rheumatoid joints correspond to their internal appearances. The atrophic joint is generally swollen in a spindle-shaped manner, covered with shiny and parchment-like skin. Inside the joint the swelling is in the synovial capsule of the type known as villous arthritis. There is rarely an excess of fluid. The bone is atrophic as well as the cartilage. In hypertrophic arthritis, if there is general swelling of the joint, it is due to fluid. There is very little villous arthritis as a rule. The bone is unusually dense. The cartilage is increased in thickness. The infectious joint from the outside is much congested. The fibrous as well as the synovial capsule is infiltrated. Adhesions form easily in the joint. The cartilage appears fairly normal, and the bone is not notably altered. In some cases these types shade into each other.

New York Medical Journal, November 19, 1904.

Ideal Tent Life for Consumptives.—H. B. Masten declares that the best conditions for the cure of incipient pulmonary tuberculosis are those under which the disease is seldom or never contracted. He extols the climatic conditions found in northern New Mexico and southern Colorado, and gives an illustrated description of a series of tent cottages so arranged as to have a common veranda, together with the necessary directions for the care of patients housed in such structures.

The Treatment of Diffuse Peritonitis.—J. A. Blake records his experience with nineteen cases of diffuse peritonitis; five of these were generalized and fourteen were

cases of spreading peritonitis. Of the cases of general peritonitis, one was caused by appendicitis and the patient died, two by the perforation of gastric ulcers with one death, one by a rupture of the jejunum whch ended in recovery, and one by what was apparently an acute pancreatitis, which also ended in recovery. The best results come, according to his experience, from an early and rapid operation, though not necessarily a large incision; the least possible handling of the intestines (if they escape from the wound and cannot be returned they should be emptied through a small enterotomy incision); thorough lavage; the omission of drainage when possible; and an after-treatment in which the main features are absolute rest for the alimentary canal and the exhibition of large quantities of fluids.

Passage of a Tooth Plate Through the Alimentary Canal.—M. K. Elmer reports the case of a man, aged fifty-nine years, who swallowed a plate about two inches square, with three teeth attached, and passed the same by the bowels about four years later. During this period he had some difficulty in swallowing food (this disappeared later), epigastric pain, eructations, metallic taste, indigestion and alternating periods of emaciation and recovery of body weight.

Medical News, November 19, 1904.

A Case of Typhoid Fever Complicated by Polyuria.—J. C. Wilson reports this unusual case. The patient, a man aged twenty-nine years, entered the hospital September 25, 1904. The disease seemed to run a typical course, except that delirium of a low, wandering type, but later becoming very active, manifested itself early and was quite constant, abating only after the plunges, when generally the mind remained clear for a short time. The quantity of urine began to increase on October 5. The highest amount voided was 215 ounces, on October 16. The patient suffered from unquenchable thirst. While the polyuria was most marked, micturition was so frequent that it was necessary for the patient to have a urinal constantly either upon his bed or upon the table adjoining it. The total amount of urea for periods of 24 hours was increased at the height of the polyuria. Convalescence was uninterrupted. The writer declares that he has no hypothesis to offer as to the significance of the polyuria in this case. It was evidently the cause, not the effect of the great intake of fluid. The patient was neurotic and overworked, but did not present the symptoms of any organic disease of the brain or nervous system.

Feigned Insanity; Malingery Revealed by the Use of Ether.—Charles G. Wagner describes this case. The pateint was 32 years of age and had murdered his wife. In court the man was incoherent, and answered questions irrelevantly or not at all. He appeared unable to walk without assistance, or to stand erect with his feet squarely on the floor. At each step, as he rested his weight to some extent upon the ball of his foot, a violent, coarse tremor agitated the entire leg. The patient exhibited these abnormal mental and physical phenomena throughout his trial and after conviction. Throughout the following eighteen months he was not caught off his guard, and as the day for his execution was approaching, the prison warden, being in doubt as to his mental condition, requested an examination of the prisoner by a commission. The writer was one of the experts named for this purpose. The most careful examinations were made, but the results were to a considerable extent negative and unsatisfactory. The prisoner did not appear to realize that he was in prison, and his face wore an imbecile expression. The writer then suggested etherizing the patient. Just before complete unconsciousness and thorough muscular relaxation were induced, the patient became talkative, profane, and abusive; his voice was loud and strong and his language coherent, forcible, and expressive; whereas previously he had talked but little, and always in a low tone. While still profoundly unconscious, he was lifted from the table and stood upon his feet. As he began to regain consciousness, with a little assistance, he walked across the floor without difficulty or muscular tremor, and at each step placed his foot squarely upon the floor. He walked to the elevator and to his cell without assistance. The plea of lateral spinal sclerosis was thus disposed of. The commission was satisfied after this examination that the pretense of insanity was without foundation. A day or two later the prisoner confessed that he had been "under an awful strain for a year and a half" and that he would "rather go to the chair than go through the same experience again." He was perfectly intelligent and discussed the whole period of his malingering, as well as his past life in detail.

Uncinariasis as Seen in North Carolina.—J. L. Nicholson and Watson S. Rankin conclude concerning the etiology of hookworm disease, that ground-itch is by far the most important portal of infection, and that dirt-eating, and the use of a contaminated water, while capable of infecting, are not nearly so important as ground-itch as a source of infection. Some of the grounds for their conclusion are as follows: It has been noted that in localities where ground-itch is frequent, there hookworm disease is also frequent. Where there is no ground-itch, there is little or no hookworm disease. Over 99.5 per cent. of 150 cases gave a history of ground-itch. Probably the cases without ground-itch were infected through water or dirt-eating. The severest cases give a history of severest ground-itch. The disease is definitely associated with the period of life when the child goes barefooted. Uncinariasis is a family disease. When the patient ceases to be troubled with ground-itch, it is the rule for improvement to begin. The symptoms are anæmia, poor appetite, malaise, headache and diarrhœa. Thymol is used in the treatment of this disease, while the anæmia indicates the employment of iron.

American Medicine, November 19, 1904.

The Postdischarge Mortality Among the Patients of the Adirondack Cottage Sanatorium.—Lawrason Brown and E. G. Pope conclude from their observations that: The real test of the sanatorium treatment is not the immediate, but the ultimate results. The lack of uniformity in classification renders the comparison or the combination of the result of various sanatoriums extremely difficult. The classification on "the ability to work" is beset by so many difficulties in America that it is rendered of very little value. The mortality among patients discharged in various conditions affords the best method of studying the permanent result of sanatorium treatment. Of those discharged apparently cured, 93 per cent. of the expected living are alive; of the disease arrested, 65 per cent.; of the cases discharged with active symptoms, 23 per cent. The death rate among the apparently cured patients is, during the first ten years, about three times the ordinary death rate. The death rate among the patients discharged with the disease arrested increases during the first few years to many (10 to 15) times the normal death rate, but afterward decreases. Nearly half of the patients discharged with an active disease died in the first two years. Patients between 30 and 40, when discharged apparently cured, seem to relapse less than younger patients. This tendency is little, if at all marked among the patients discharged with the disease arrested. Incipient cases seem to relapse less than advanced, when both were discharged in the same condition.

The Finsen Light, Röntgen Rays, and High Frequency Electric Currents in Certain Diseases of the Skin.—L. Duncan Bulkley explains the extraordinary results obtained with the Finsen light at the Finsen Institute as being due not solely to the application of light for a longer or shorter period, but to the perfect technique which has been shown to be necessary to secure the desired end. One factor in the success is that an attendant devotes an entire hour daily to holding the compressor. The writer believes that if sufficient time, intelligence, and patience can be given to it, the Copenhagen light treatment is one of the greatest advances yet made in the treatment of lupus. As to the value of the Röntgen ray, the writer believes that it is a most powerful means of influencing nutrition and overcoming certain forms of disease. If properly used, this treatment cures a considerable number of patients with superficial epithelioma, especially of the rodent ulcer type. It is often valuable in recurrent, inoperable cases of malignant disease, both in relieving pain and in checking the progress of the disease. Especially in epithelioma about the eye and nose, the Röntgen ray finds its greatest benefit. The writer reports three patients with lupus vulgaris who have done remarkably well under this treatment. The writer considers this treatment the best and most feasible that has yet been proposed for this disease. Six patients with late syphilis of the palm have been recently treated with satisfactory results. In cases of hirsuties, in which the hair is fine and downy, it is believed that a reasonable amount of repetition of the treatment by the Röntgen ray will result in freedom from the trouble. Great care should be taken in the application of this treatment. Commonly, the exposure given by the writer does not exceed five minutes. During the past year the writer has treated twenty-seven private patients with nine different cutaneous conditions by means of hyperstatic electricity from Piffard's generator, and it has proved a very valuable method in many instances. Finally, the writer states that radioactivity has active powers in connection with certain tissue changes. In regard to these various methods of treatment, it is only by honest and diligent experimentation and by truthful statement of personal experiences that advance along these lines can be made.

The Treatment of Basedow's Disease, with Report of a Case.—O. E. Lademann, after touching upon various methods of treatment of Graves' disease, states that the simplest, most inexpensive and safest method of treatment is that of Lanz, suggested by him in 1894. He fed exophthalmic goiter individuals with the milk of thyroidectomized goats.

Favorable results have followed the use of this method. The writer reports a most interesting case of this disease, in which he tried the milk treatment with excellent results. He believes that instead of the milk having direct antagonistic action, the process is more one of neutralization, or possibly combination, and the effects last only as long as the milk is given; he believes also, that the severer the exophthalmic goiter, the more milk is required to neutralize. He suggests the use of dessicated thyroidectomized milk in the form of tablets as preferable to that in its natural state.

Journal of the American Medical Association, November 19, 1904.

Œsophagoscopy and Bronchoscopy.—E. Fletcher Ingals reports his experience with the Killian instruments in removing a pin from the œsophagus and one from a bronchus. A history of previously reported cases is given, followed by his own personal experience. Diagrams illustrate the positions of the foreign bodies in situ and of the various pieces of apparatus employed for their extraction. For illumination of the passages he prefers a small electric lamp introduced to near the distal end of the bronchoscope. This enables the operator to work in a light room, a fact which is of great advantage also to the anæsthetist. This method enables the operator to move his head at will without interfering with the illumination. Chloroform is the best anæsthetic in these cases, and to avoid having it blown into the surgeon's eyes, a pane of glass may be held between the latter and the end of the bronchoscope. In view of the interference in respiration by the unaffected lung, when the bronchoscope is passed into one of the main bronchi, Killian had a large oval opening made in some of his bronchoscopes, some distance above the end. To meet this indication, Ingals has had a number of holes, each 2x4 mm., made in his bronchoscope, from 5 to 10 cm. above its distal end. He can see no objection to these, and finds that they overcome the difficulty fully, without in any way interfering with the use of the instrument.

A New Material for Sutures and Ligatures.—For this purpose C. F. Kieffer advocates the use of the long and strong tendons of the bird commonly known in this country as the blue crane. He finds that they are very slowly absorbed in the tissues, and serve admirably the purpose named. The tendons of the species of the same genus of birds may be used. They are regularly flat, like ribbon, and are easily rendered aseptic. Moreover, the supply is universal, and as the author observes, the surgeon in isolated places may have the comfort of knowing that he has a "reliable suture material at the end of his shotgun." The tendons must be rendered aseptic by immersion in some solution (the author prefers the Claudius method for catgut), and not be boiled, as the temperature of boiling water soon converts them into a jelly-like mass.

Differential Diagnosis Between Pseudomembranous Angina of Syphilis and Diphtheritic Angina.—The former of these conditions is, according to R. R. Campbell, not rare, and the diagnosis between the two cannot always be made from the clinical picture. We should never fail to utilize the culture test, and the microscope, and in cases of doubt should employ antitoxin while awaiting the result of the culture test. Several illustrative cases are deported.

The Lancet, November 12, 1904.

Carcinoma of the Appendix.—C. J. Cullingworth and E. M. Corner report a case, and analyze the records of previous cases. Their patient was a single woman of thirty-one years. Four months before coming under observation she had severe pain in her right side, and experienced several subsequent attacks, especially marked over the right iliac fossa, low down. On deep palpation there was a little tenderness over the McBurney point. Per vaginan a hard mass was found to the right of the uterus, depressing the vaginal fornix. Abdominal section revealed the latter mass to be a fibromyoma of the broad ligament. The appendix was found to have a thickened and bulbous top, examination of which showed it to be a spheroidal carcinoma. Recovery from operation was without incident, and three years later the patient was well, and free from all abnormal symptoms. It was a question to the authors which of the symptoms in this case were due to the fibromyoma, and which to the appendix. It seems, on the whole, that most of them were due to the former, though it is not easy to refer the sudden and severe pains in the right side to this cause. Perhaps the tumor may have caused some temporary obstruction to the right ureter. On the other hand, the nodule might be thought to have excited painful peristalsis (colic in the appendix), but as it affected the tip of the organ it would seem hardly able to do so. The tenderness over McBurney's point seems rather more likely to be due to the diseased appendix than to the fibromyoma. Finally, it may be pointed out that the concurrence of fibromyoma of the uterus and carcinoma of the appendix has never been recorded before.

Inflammation of the Muscles with Special Reference to Two Cases of Infective Myositis.—J. H. Abram calls attention to the particularly fatal character of many cases of muscle inflammation, and gives outline descriptions of the various forms of this class of diseases. Of the instances reported, Case 1 was a male, aged nineteen years, with history of a strain eight weeks before. He had had chest pains, limitation of movement, swelling of the chest, and axillary gland enlargement. A diffuse brawny swelling later extended from the clavicle to the nipple, while below the lower border of the pectoral muscle was an area of softening, incision into which was followed by very slow healing, hastened apparently by the internal administration of protonuclein. Case 2 was a woman of forty-five years, with an evident infection, which seemed to focus over the right upper chest region. Incision revealed suppuration in the pectoriolis major, but no definite abscess formation. Death ensued in a few hours. A smear test of the pus revealed typical streptococci. In the first case, no bacteriological finding could be made out. In similar cases the author would strongly advise free incision as being far more efficacious than drugs or serum infections.

Case of Exophthalmos in the Newly Born.—H. H. Borland records the case of an infant whose eyes, owing to severe pressure on the head during parturition, were in a state of exophthalmos. A few hours later it was noted that there was an effusion of blood under the conjunctiva in the upper sclera of the right side. The next day the effusion was increased, and the right bulbus oculi projected downward and forward, bulging out the lower eyelid, all evidencing a paralysis of the superior rectus muscle. On the third day an ecchymotic patch was observed on the right upper lid. On the fifth day a similar condition was noted on the left upper lid. From this time on the evidences of paralysis gradually disappeared. On the nineteenth day a clot of coagulated blood came down the right nares. Three weeks after birth there was still evident, but only occasionally apparent, a slight degree of paralysis of the superior rectus.

A Case of Attacks of Temporary Loss of Consciousness and Memory.—The patient of W.O'Neill was a woman of fifty years, who first had fainting spells, which were succeeded later by attacks of loss of consciousness, followed by complete loss of memory of acts that occurred during the period of unconsciousness. For instance, on one occasion the patient and a friend walked some distance to a butcher's shop to buy meat, but from putting on her bonnet immediately before leaving the house to taking it off on returning home, she had not the slightest recollection of what happened in the interval, although she bought the meat, and paid for it, and, of course, spoke to the butcher. These attacks consisted of two parts—namely, the oblivion with the power the patient had while in this state of performing many of her ordinary household duties, no doubt in an automatic way, and, secondly, the loss of memory of what she had been doing and saying while under the influence of the fit. It was suggested to the author that these seizures resembled somnambulism. They might be, in his own view, a species of epilepsy, regarding the earlier fainting turns as attacks of *petit mal*. In the intervals between the attacks, the patient was apparently normal in every way.

British Medical Journal, November 12, 1904.

Discussion on Intraocular Hemorrhage and Systemic Disease.—A. Hill Griffith confines his attention in this paper to the consideration of intraocular hemorrhages in eyes otherwise free from disease. Such primary or independent hemorrhages may, like hemorrhages elsewhere, occur from the following general conditions: Blood changes (pyæmia, infective endocarditis, septicæmia, purpura, scorbutus, pernicious anæmia, phosphorus poisoning, and parasitic blood affections). Diseased state of finer vessels. Back pressure of cardiac disease. Embolic processes, and thrombosis. Intraocular hemorrhage may occur in the retina, the choroid, the vitreous, or the anterior chamber. The writer has never seen spontaneous hæmorrhage into the anterior chamber; nor choroidal hemorrhage, with one exception, save in staphyloma posticum, choroiditis, choroidal growths, etc. In most of the retinal hemorrhages the retina was apparently otherwise unchanged, but in some there were slight changes recognizable, such as localized swellings and exudations, probably secondary to the blood effusions. Intraocular hemorrhages cannot be very common, for among 6,500 consecutive cases of all kinds in the writer's private practice, there were only thirty-three cases of spontaneous hemorrhages, a proportion of 0.5 per cent. Besides these, he has records of fifty cases in his hospital practice. These eighty-three cases he classes as follows: Retinal hemorrhages, 41; hemorrhagic retinitis, 20; so-called subhyaloid hemorrhage, 14; hemorrhage into vitreous, 8. Some of these patients were examples of more than one of the groups. The prognosis both

as to sight and life is much better in the case of subhyaloid hemorrhage than in any other form of intraocular hemorrhage, for, with the exception of two patients, none showed signs of systemic disease. In a little over half of the sixty-one cases of retinal hemorrhages and hemorrhagic retinitis, a definite cause was made out: Constipation, 2; bronchitis, 3; severe fit of coughing, 1; gout, 4; syphilis, 5; purpura, 1; Bright's disease, 2; diabetes, 2; organic heart disease, 4; hemiplegia, 2; hemianopsia, 2; alcoholism, 3; high arterial tension, several; rheumatism, 3. The writer believes that tobacco amblyopia is not infrequently the cause of retinal hemorrhage. In seven cases, marked sclerosis of the retinal arteries was noted. The writer describes one strange case, which he believes to be an arterio-venous aneurysm on each retina. One of the cases of hemorrhage into the vitreous had splenic leucocythæmia, and another died of angina pectoris. Of the thirty-three private cases, six died within twelve months or some years of apoplexy or other disease. Hemorrhage occurring as the result of embolism, the writer thinks, must be far less frequent in the retina than in other organs. He also thinks that pulsation in the retinal veins is of no pathological import. Aortic pulsation was made out in ten cases; eight of these were in aortic regurgitation; one in a case of general cardiac dropsy, and one in a case of cardiac muscle failure. Retinal hemorrhages were found in fourteen out of 500 hospital patients, who were suffering from various affections. From his study of the subject, the writer concludes that Nature is very well able to safeguard the eye even in grave disorders of the general circulation, but against changes in the blood she is not so efficient.

Investigations on the Comparative Visual Acuity of Savages and of Civilized People.—W. H. Rivers gave the results of his investigations on the comparative visual acuity of savages and civilized people. He came to the conclusion, after examining a large number of people of all tribes and nationalities, that apart from errors of refraction, man, all the world over, had practically the same amount of vision, and in instances in which savages appear to possess greater visual acuity than white men, it is entirely due to practice and education, and to their being thoroughly familiar with their surroundings.

Summary of Twenty Years' Treatment of Myopia.—Ernest Clarke advocated in this paper the full correction of all cases of myopia and compound myopic astigmatism. His method was to estimate the ametropia under a mydriatic, and to order the full correction for all cases. In high degrees the patients sometimes refused to accept the full correction, but with this exception he never reduced the spherical glass for near work. Out of 532 cases which had been under observation for more than two years, the majority showed no increase in the myopia, and in only three instances had the myopia increased as much as 4 D, and in only sixteen had there been any increase worth mentioning. In some it was necessary to stop all near work, but for these full correction was always given. If this principle were carried out generally, he felt sure that progressive myopia and high degrees would become almost unknown.

A Modification in the Usual Method of Using Cocaine in Operations Upon the Eyeball.—Carl Koller states that it is the experience of all operators, when operating upon the iris in a patient whose eye is under the influence of cocaine, that the anæsthesia of this part is by no means complete. To get over this, the author uses it as follows: A few drops of cocaine are put into the conjunctival sac, and then at the point where the fixation forceps will be placed, and opposite to where the incision is to be made, a few drops of a 5 per cent. solution of cocaine are injected beneath the conjunctiva, but not into the episcleral tissues. After five or six minutes the operation can be performed, and the iris will be found to be quite anæsthetic.

Berliner klinische Wochenschrift, October 31, 1904.

Movable Cæcum.—Hausmann says that this condition is not a very rare one, and that it explains many of the peculiar abdominal symptoms sometimes encountered. The cæcum in these patients has an abnormally long mesentery, which is continuous with that of the small intestine, and permits a variable degree of mobility to this portion of the large gut. In many cases this dislocation of the cæcum can be detected by simple palpation, and manifests itself by the presence of a movable mass on the right side of the abdomen and unnatural emptiness in the right pelvic fossa. The displaced cæcum may form a mass not unlike a movable kidney in size, shape, and consistency, and it may be possible to bring it as far upward as the free border of the ribs so that there is some likelihood of confounding the condition with one of nephroptosis. The differential diagnosis is easily made by the fact that the cæcum under these circumstances always gives rise to a gurgling sound in manipulation. Symptoms produced by the condition are fecal accumulations and constipation due to kinking of the gut, and local colicky pains which may go on to more or less serious intestinal obstruction.

The Serum Treatment of Puerperal Fever.—Bumm describes the results obtained in sixty-seven cases of postpartum infection treated by means of antistreptococcus serum. The mortality in these cases, which include all types and degrees of puerperal fever, was 11 per cent. Although at present the sera still leave much to be desired, the author is strongly in favor of their employment, and believes that the method can be perfected so as to yield greatly improved results. No serum so far devised has any effect in cutting short or modifying the disease process once it has spread beyond its original site, and the many septic complications produced in this way cannot be influenced, no matter how large the dosage employed. In cases, however, where the streptococci are still localized in the endometrium, or are but sparingly present in the blood, the injection of serum is likely to be advantageous and is to be recommended. The results are better the earlier recourse is had to the treatment, and the serum should be used freely. Intravenous injections are dangerous and should be made with the utmost caution.

Münchener medizinische Wochenschrift, November 1, 1904.

Experiences with Marmorek's Antituberculosis Serum.—Frey considers that Marmorek's serum has not received fair treatment by the medical world. In so serious a question as this is, the merits of the question should be made the subject of a carefully considered, unprejudiced, judicial inquiry, and not be overhastily condemned, as has been done in this instance. The author has made over three hundred and fifty injections of the serum, and considers the results of a nature to deserve further investigation. The detailed histories of nine cases are given, and from these he draws the important conclusion that the serum is well borne, and never gives rise to toxic symptoms. Whatever reaction is produced is local, and of the same nature as that caused by other sera. Urticaria was observed in a few instances, but toleration was established in all cases but one, in which the injections were discontinued on this account. In general it was found that temperature of purely tubercular nature was favorably influenced by the serum. Toxic dyspnœa and diuresis are also said to have been modified for the better, as well as the expectoration, which was first increased, and then diminished in amount. The author recommends that the injections be frequently interrupted by intervals of rest, and that itching, urticaria, or redness about the site of injection, also indicate the necessity of a few days' cessation of the treatment. The author's standpoint is that the unfavorable judugment that has been passed upon the method is premature, and that further observations are necessary to establish its ultimate status.

Inoperable Carcinoma of the Rectum as an Impediment to Delivery.—Moritz describes a case in which a carcinoma of the rectum formed an obstacle to delivery, but did not seriously complicate the labor. The patient, who was a multipara, only thirty-six years old, had four months previously been subjected to colostomy for an inoperable new growth of the rectum. After the labor had progressed thirty-six hours without getting the head to do more than engage, the pains ceased completely. The author was able to deliver the slightly asphyetic child by forceps without much difficulty, and takes the case as a text from which to deduce the doctrine that in cases of carcinoma of the rectum, unless rapid delivery is demanded for other reasons, it is safe to use patience and the ordinary methods of treatment before resorting to so radical a measure as cæsarean section.

The Sacrifice of the Living Child for the Sake of the Mother.—Herff is opposed to craniotomy on living children, but does not go so far as do other recent writers, particularly Veit, who considers that the operation may be entirely dispensed with. These writers attempt to put craniotomy, symphyseotomy and cæsarean section on the same footing as regards material mortality, saying that it is now practically always possible to gain access to a hospital in which to perform them. The author considers that the dangers of these operations are underestimated, and that even if performed in a hospital under perfect conditions, there will still remain the risk of previous infection by midwives and others outside, which is always a serious danger in these protracted cases. In outside work the chances for the mother are much better in craniotomy, and it will probably still require to be done in rare cases, though it should be restricted in its application as much as possible.

Yellow Fever Expedition.—The Liverpool School of Tropical Medicine is about to send a second expedition to the Amazon to discover, if possible, the actual cause of yellow fever.

Book Reviews.

KOMPENDIUM DER RÖNTGEN-THERAPIE. Von Dr. H. E. SCHMIDT, Assistent am Universitäts-Institut für Lichtbehandlung zu Berlin. Berlin: August Hirschwald, 1904.

DR. SCHMIDT, who is associated with Professor Lesser in Berlin, has given us a practical brochure of 62 pages, divided into two parts—physico-technical and therapeutic. The first includes chapters on the cathode and *x*-rays, and instruments; the second reviews development of methods, therapeutic considerations, and indications. The work is too brief to be seriously considered alongside the numerous productions of recent times in Germany and France, as well as at home.

UEBER DIE ANTHROPOLOGISCH-ORTHOPÄDISCHEN MESSMETHODEN DER RÜCKENS. Von Dr. OSKAR V. HOVOSKA, Chefarzt für Orthopädie am Wiener Zanderinstitute. Wien: Sellstveslag der Anthropologischen Gesselschaft, 1904.

THIS is an exhaustive monograph on methods and apparatus for measuring and recording the curvatures of the spine and back in health and disease. It is illustrated with twenty-five outline drawings and half-tones, and is (worthy of remark) provided with a quite complete index. It is a reprint from the latest volume of transactions of the Anthropological Society of Vienna. Orthopedic surgeons will find in it much to interest and instruct.

SAUNDERS' QUESTION COMPENDS: ESSENTIALS OF ANATOMY; including the Anatomy of the Viscera. By CHARLES B. NANCREDE, M.D., Professor of Surgery and Clinical Surgery in the University of Michigan, Ann Arbor. Seventh edition, thoroughly revised. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

NANCREDE'S compend of Anatomy is well known; and this new, seventh edition will be found as serviceable as its predecessors have proved themselves to be in the past. The revision is chiefly confined to the chapter on the Nervous System.

THE MEDICAL EPITOME SERIES. TOXICOLOGY., a Manual for Students and Practitioners. By EDWIN WELLES DWIGHT, M.D., Instructor in Legal Medicine, Harvard University. Series edited by VICTOR COX PEDERSEN, A.M., M.D. Philadelphia and New York: Lea Brothers & Company, 1904.

THIS is a carefully compiled compendium, and contains the main facts belonging to toxicology. After an important introductory chapter, the chief poisons are considered in some detail with regard to properties, toxic dose, symptoms, treatment, post-mortem appearances, tests, and illustrative cases. The book will be useful to students and practitioners.

BERIBERI: Its Symptoms and Symptomatic Treatment. By PERCY NETTERVILLE GERRARD, B.A., B.Ch., B.A.O., M.D. Philadelphia: P. Blakiston's Son & Company, 1904.

THIS is an essay written from the point of view of one to whom beriberi has long been the "burning question." After a discussion of characteristic symptoms, the author enumerates and describes the forms which this disease of surprises may take. He claims that its origin, though still in doubt, is probably bacterial, and that the most successful treatment is symptomatic. The book is accompanied by a smaller one, comprising an epitome of the first, the necessity for which is not apparent, since the original essay is brief enough to be read through at a single sitting.

SAUNDERS' QUESTION COMPENDS: ESSENTIALS OF BACTERIOLOGY. By M. V. BALL, M.D., formerly resident Physician at the German Hospital, Philadelphia. Fifth edition, thoroughly revised. By KARL M. VOGEL, M.D., Assistant Pathologist at the College of Physicians and Surgeons (Columbia University), New York City. With 96 illustrations, some in colors, and six plates. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

THE careful revision to which this book has been subjected in the present edition is noticeable, especially in the sections dealing with Immunity, Tuberculosis, Bacillus Icteroides, Dysentery, and Bubonic Plague. The volume contains, in a condensed form, the present day teachings of bacteriology.

LEHRBUCH DER PHYSIOLOGIE. Von L. HERMANN. Dreizehnte, durchgehends umgearbeitete und vermehrte Auflage. Mit 245 in den Text eingedruckten Abbildungen. Berlin: Verlag von August Hirschwald, 1905.

FORTY-TWO years is a long period of vitality for a textbook on so progressive a branch of medicine as physiology, yet the thirteenth edition of this veteran work is as fresh and modern in spirit as any recent publication. The author has not let the younger workers of the new century outstrip him, but has kept pace with every advance and subjected each innovation to a judicial scrutiny, to which decades of experience have given unusual authoritativeness.

Owing to developments in this accessory science it has been found necessary to introduce a series of chapters on the general principles of physics as they are applied to physiology, and this, together with a similar discussion of physiological chemistry, forms an admirable introduction to the more specific portion of the book which follows. Another radical change consists in the alteration of the arrangement of the chapters which are now disposed so that the animal functions are treated before the vegetative functions, a method that is more in accord with modern courses of instruction. The chief value of the work still consists in the completeness with which everything that is definitely known concerning each subdivision of the subject is given, while what is uncertain or disputed is relegated to the background. If each subsequent edition is to mean as thorough a rejuvenation of the book as this one has been the volume should have an indefinite lease of life still before it.

INTERNATIONAL CLINICS. Edited by A. O. J. KELLY, A.M., M.D., Phila., with the collaboration of Wm. Osler, John Musser, and others. Vol. III. Fourteenth Series, 1904. Philadelphia: J. B. Lippincott Company.

THIS volume has as frontispiece a colored plate of specific roseola, reproduced from Fox's Atlas, which is advertised on a back page. There are some 25 other plates and about the same number of figures. Though some excellent men are found amongst the contributors, the average of interest and importance of the papers and illustrations is behind that of some years ago. Rest Cure in Chronic Constipation, Syphilis and Suicide, Uncertainty as to Syphilitic Inoculation, are some of the titles.

The advertisements, front and back, do not add to the artistic value of the book.

SAUNDERS' QUESTION COMPENDS: ESSENTIALS OF MATERIA MEDICA AND PRESCRIPTION WRITING. By HENRY MORRIS, M.D., College of Physicians, Philadelphia. Sixth edition, thoroughly revised. By W. A. BASTEDO, Ph.G., M.D., Tutor of Materia Medica and Pharmacology at the Columbia University (College of Physicians and Surgeons), New York City. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

THIS compend contains in condensed form the principles of materia medica. The new edition contains the more recent preparations such as adrenalin, stypticin, and the synthetic silver compounds. In its present form the book will be found both trustworthy and up to date.

SAUNDERS' QUESTION COMPENDS: ESSENTIALS OF NERVOUS DISEASES AND INSANITY: their Symptoms and Treatment. By JOHN C. SHAW, M.D., late Clinical Professor of Diseases of the Mind and Nervous System, Long Island College Hospital Medical School. Fourth edition, thoroughly revised. By SMITH ELY JELLIFFE, Ph.G., M.D., Clinical Assistant, Columbia University, Department of Neurology; Visiting Neurologist, City Hospital, New York. Illustrated. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

THIS is a useful little book on nervous diseases and insanity. Within the compass of less than 200 pages will be found all that the medical student needs on these subjects; and in addition there is a brief but serviceable bibliography appended to the chief diseases. The book is well arranged, well written, and well illustrated.

THE ESSENTIALS OF CHEMICAL PHYSIOLOGY, for the use of Students. By W. D. HALLIBURTON, M.D., F.R.S. Fellow of the Royal College of Physicians, Professor of Physiology in King's College, London; Author of "Text-Book of Chemical Physiology and Pathology." Fifth edition. London, New York, and Bombay: Longmans, Green & Company, 1904.

THE chief changes in the new edition of this well-known work are the addition of an introductory chapter on the detection of the elements contained in physiological compounds; the lessons on milk, pancreatic digestion, muscle, and Kjeldahl's method of estimating nitrogen have been rewritten; some new exercises have also been inserted. The book is well abreast of modern scientific advances; it contains all that the title claims for it, namely, the essentials of chemical physiology; and it is written by a recognized authority on the subject.

THE SURGICAL TREATMENT OF BRIGHT'S DISEASE. By GEO. M. EDEBOHLS, A.M., M.D., LL.D. New York: Frank F. Lisiecki, 1904.

THIS subject has been widely discussed since Edebohls, some years ago, first proposed to treat chronic nephritis by removing the capsule of the kidneys, after he had observed the favorable effects on the disease when it was found necessary to do a nephropexy. The claim that decapsulation would be followed by a favorable result more or less permanent in character, has been put to the test by numerous experiments and observations. Many surgeons who have attempted the operation have not been blessed with as favorable results as are reported by Edebohls, and lately Theleman, on the basis of his experiments, comes to the conclusion that the new capsule is formed in a relatively short time from the remnants of the old one left at the time of operation. A transitory improvement takes place, owing to the relaxation of the kidneys, but, as this writer claims, it is very questionable whether a permanent cure can be

obtained. Edebohls acknowledges that a new capsule may be formed after operation, but insists that the new is more succulent than the old capsule and always more vascular. He does not believe that there is any danger from the contraction of the new capsule, but if a return of symptoms justifies a second operation, he does not hesitate to recommend it.

The book under discussion forms one of the most elaborate treatises on this subject thus far presented as the collected experiences of any one writer. The first part of the work comprises the author's contributions to the literature, and previously published in various medical journals. The second part includes the detailed histories of seventy-two cases operated on by the author, and his conclusions. The operation is charged with seven deaths, all in advanced cases, but this number, he claims, is offset by the nine patients who were at death's door when operated upon, whose lives were prolonged, and some of whom are alive at the present day. Of the twenty-two ulterior or remote deaths, none was due to the operation. Thirteen died from the chronic nephritis or its complications, and in six of these the operation had done no good, but the remainder were benefited. Of the seventy-two patients, it seems that thirteen received no benefit from the operation, while fifty-nine experienced amelioration varying all the way from slight or temporary improvement to complete cure. In nine cases the operation proved life saving by rescuing the patient from impending death. In the author's opinion, the evidence submitted in his book not only justifies the surgical treatment of Bright's disease, but establishes surgery as at present, the main, if not the only hope, of sufferers from a hitherto incurable malady. Whether these sanguine expectations will be borne out by the results achieved by other surgeons, is a matter for the future to decide. It may be some time before so large a series of cases can be gathered by any other operator, and final judgment must remain suspended.

La Radiothérapie. Son Application aux Affections Cutanées. Par. Le Docteur J. Belot. Paris: G. Steinheil, 1904.

The author is introduced, as it were, by his chief, Dr. Brocq, in a preface which tells of the work done at the Broca Hospital. His peculiar qualifications, embracing those appertaining to engineering, mechanics, physics, and scientific medicine, have enabled the author to make good use of the time devoted to this newer method at present dominating skin therapy. The work is written in a deeply scientific spirit and still is sufficiently elementery for the beginner to profit. American work has received due recognition and extensive quotations are made from cis-atlantic writers. The bibliography includes many well-known American names. The importance of radiotherapy in general is suggested by the fact of a volume of this size being devoted exclusively to the treatment of skin affections. While this country is not without its excellent works, covering the same field, dermatologists employing the rays will find in M. Belot's book a painstaking résumé of prevailing views and personal experience.

The Nervous Affections of the Heart. Being the Morison Lectures, Delivered Before the Royal College of Physicians of Edinburgh in 1902 and 1903. By George Alexander Gibson, M.D., D.Sc., F.R.C.P., Ed.; F.R.S.E. Honorary Member of the Medico-Chirurgical Society of Norwich; Honorary Corresponding Member of the Therapeutical Society of Paris; Physician to the Royal Infirmary, and Lecturer on Medicine and Clinical Medicine in the Medical School of the Royal Colleges, Edinburgh; Examiner in Medicine in the University of Oxford. Edinburgh and London: Young J. Pentland, 1904.

The author has divided these six lectures into two sections, namely, sensory disturbances and motor disturbances, and discusses in them the symptoms, the possible causes, and the treatment of this ill-defined group of heart irregularities. The subject matter is adapted rather for the advanced student than the beginner, and, as the author states, is rather suggestive than exhaustive. The well-known clinical experience of the writer lends interest to his theoretical explanations, and this work merits a careful perusal by all internists.

Refraction and How to Refract. Including Sections on Optics, the Fitting of Spectacles and Eye-Glasses, etc. By James Thornton, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia, etc. Third edition. Philadelphia: P. Blakiston's Son & Company, 1904.

This very excellent work of 315 pages is now in its third edition, having been first published in 1899. The book contains all that is necessary for the student to know to enable him to correct errors of refraction properly, provided, of course, that he has a good knowledge of the normal and pathological conditions that affect the eye.

The methods advanced by the writer have evidently been carefully tried, and their true value is here given. The chapters on "Muscles," "Cyclopegias," "How to Refract," and "Applied Refraction" presents views that are excellent and that can be followed to the advantage of both patient and physician. The work is fully illustrated. The text is free from verbiage, is clear, and concise. This is one of the best small works on this subject, for the student, in the English language.

Manual of Physiological and Clinical Chemistry. By Elias H. Bartley, B.S., M.D., Ph.G. Professor of Chemistry, Toxicology, and Pediatrics in the Long Island College Hospital; Author of Medical and Pharmaceutical Chemistry. Second edition, revised and enlarged. With 47 illustrations. Philadelphia: P. Blakiston's Son & Company, 1012 Walnut street, 1904.

This little book of less than 200 pages gives all that the medical student and practitioner will require on Physiological and Clinical Chemistry. It is a thoroughly reliable guide to the ordinary chemical examinations of the blood, urine, gastric contents, fæces, and milk. Microscopical work is considered where absolutely necessary; but the book is essentially a work on chemistry, and not on microscopy. At the same time, it is to the practitioner and his wants that the writer appeals, and not to the scientific chemist who has no concern with the clinical side of the question. The chapter on the urine is a model of what the physician needs, and is of more real value than many more pretentious and costly works on the subject; it contains useful sections on the significance of albuminuria, the diagnosis of renal diseases accompanied by albuminuria, the significance of variations in the physical and chemical characters of the urine, and cryoscopy and its uses.

A Manual of Practical Medical Electricity. The Röntgen rays, Finsen light, Radium and its radiations, and High-frequency currents. By Dawson Turner, B.A., M.D., F.R.C.P., Ed., M.R.C.P., Lond. President of the Royal Scottish Society of Arts; Vice-President of the British Electro-Therapeutic Society; Fellow of the Physical Society; Lecturer on Experimental Physics, Surgeon's Hall, Edinburgh; Additional Examiner in Experimental Physics, the Edinburgh University; Medical Officer in charge of the Electrical Department of the Royal Infirmary, Edinburgh. Fourth Edition. Revised and Enlarged. New York: William Wood & Company, 1904.

We have several times in the past made favorable comment upon this handbook. In the present output more attention has been paid to sinusoidal currents. Amongst new matter added is a section on radium and its radiations. High-frequency currents have received more extended consideration, and over thirty illustrations have been added. Part VI. which treats of the *x*-rays, has been enlarged and rearranged and the whole has undergone scrutiny and revision. The author expresses the hope that the renewed interest on the part of regulars in these matters will tend to stem the tide of unqualified electrical practitioners. He likewise deems it derogatory and injurious to the profession and patient alike to call in instrument makers for radiography and nurses and masseurs for electro-therapeutic treatment.

How to Cook for the Sick and Convalescent. Arranged for the Physician, Trained Nurse, and Home Use. By Helena V. Sachse. Second Edition, Revised and Enlarged. Philadelphia: J. B. Lippincott Company, 1904.

The author of this excellent cook-book has the double qualification for her task of being a practical and experienced cook, and a scientifically trained nurse, and not only knows how to prepare food in an appetizing form, but how to prepare it to meet the indications present in the individual case. At the beginning of the book there is, besides the ordinary table of contents, a classification of the recipes, for ready reference, into liquid, semi-solid, and solid foods, foods containing a large percentage of fat, highly nitrogenous foods, those free from starch or cane sugar, those rich in phosphorus, those rich in iron, recipes for farinaceous or starchy foods, etc. The directions for preparing the special dishes are so clear as not to be misunderstood by the stupidest of persons, exact measurements are given of each ingredient, and the precise length of time for cooking is stated. The modest claim for the book is that it teaches how to cook for the sick or convalescent, but happy would be the well man whose food was prepared according to these formulæ, and the physician who gets the book to lend to the nurses of his patients will do well to leave it, when not in use, in some convenient spot where the mistress of his own household may see it. He will find himself looking forward to his homecoming with a keener relish and a better appetite, and his cares will be forgotten as he feasts at the end of the day upon the dainty dishes prepared under Helena Sachse's directions.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

Stated Meeting, Held November 4, 1904.

Dr. Robert T. Morris, Chairman.

Carcinoma of the Stomach.—Dr. William S. Bainbridge presented a man, 43 years old, a tailor, who for two years or more prior to last December had complained of a few gastric symptoms, chronic dyspepsia, and had been under treatment at six or eight dispensaries during that time. The symptoms gradually increased, and he lost flesh and strength until he presented himself at the Skin and Cancer Hospital last December. No growth then could be detected in the stomach or abdomen. Only a trace of hydrochloric acid was found in the gastric contents. An exploratory laparotomy was asked for and refused. The patient returned to the hospital last January, stating that he had lost 15 pounds in weight and was vomiting everything taken into the stomach. Pyloric obstruction was diagnosed, and on January 5 he was operated upon in a condition that was anything but promising. During the entire operation the pulse practically could not be felt at the wrist, and the question arose as to whether this was really a proper case for operation. A gastrojejunostomy was performed, a point about sixteen inches below the pylous being taken. A carcinoma was found situated upon the posterior wall of the stomach encroaching upon the pyloric orifice. There was some dilatation of the stomach and carcinomatous nodules were found in the transverse mesocolon and in the great omentum, matting together the viscera. Nodules were also found in the liver. The Fowler-Mayo suture was used in closing the wound. The patient left the hospital in three weeks, having gained three pounds in weight; three weeks later he went to work on part time. He had no vomiting. In May he returned saying that he had some pain and some nausea. He gained in weight steadily, until April, when vomiting again set in and he ceased working. He vomited everything taken. The character of the vomiting was peculiar and he stated that he was unable to empty his stomach unless he pressed upon the lower part of his abdomen. Dr. Bainbridge thought this showed that he not only expelled the stomach contents, but the intestinal as well. On June 4, a second operation was performed, and he found a growth which extended over the anterior wall of the stomach and encroached upon the opening made between the stomach and jejunum at the first operation. The proximal end of the jejunum was found to be dilated as large as the transverse colon. He did a second gastroenterostomy, using the McGraw ligature. The patient had been at work since the end of July. The pathologist's report confirmed the diagnosis of carcinoma. To-day he weighed 140 pounds, ate well, and worked from 8 A.M till 6 P.M.

Dr. Torec thought it was remarkable that a man with such an advanced cancer should be able to eat so well and gain so much weight. It was the custom to refuse operation when the disease was so far advanced. He did not think the McGraw operation as good as the button operation.

Dr. Erdmann said that in cases of carcinoma of the stomach, in which there was a pyloric stenosis, the McGraw ligature was not an acceptable means in making a gastric anastomosis. In one case in which he had used this ligature, expecting it to cut through, the patient died from exhaustion, and the specimen showed perfect cohesion and adhesion of the parts, a sloughing process and not a cutting one, as it was said to be. The McGraw method was a simple one and gave good results, but was not to be advised in cases of pyloric stenosis.

Dr. Willy Meyer had used the McGraw method and could subscribe to all that had been claimed for it by McGraw. No leakage had occurred in his cases and he would continue to use it.

Operation for Neuralgia of the Inferior Dental Nerve.—Dr. A. V. Moschcowitz presented a patient upon whom he had operated for neuralgia of the inferior dental nerve, an operation that had not been very frequently done. The patient had suffered for one and a half years from typical attacks of neuralgia, confined to the cheek and lower jaw; he had had most of his teeth withdrawn, but without relief. The pain was so severe that he could not masticate and he lost in weight. He complained, too, of dryness of the mouth, which was probably due to his continually sucking, so drawing the saliva from the parotid gland. The operation performed was a modification of Velpeau's original one. Velpeau's operation was accompanied by so many cases of palsies on account of the division of so many nerves that he attempted a modification of it. A small incision was made corresponding to the angle of the jaw; this was continued through the masseter muscle and the periosteum. A narrow groove was chiseled in the ramus of the jaw until the nerve was reached. The nerve was resected and the patient was perfectly well. The case was of particular interest because there was no noticeable palsy.

Dr. Collins said that the palsies following the Velpeau operation were not so serious, for no more fibers would be divided than those upon the cheek. He believed the incision demonstrated was a superior one because of the cosmetic effect.

Dr. Robert T. Morris said that in a certain proportion of the cases of inferior dental neuralgia it was well to look for errors of refraction. He said he had had three or four cases in which operation was avoided by so doing.

Dr. Moschcowitz said he had not examined the patient for any errors of refraction.

A Case of Inguinal and Femoral Hernia on the Same Side.—Dr. William A. Downes presented a woman, 36 years old, who gave a history of having had a hernia since childhood, but did not know its type. Six years ago she noticed a swelling in the femoral region and had a truss applied. She had no further trouble until last May, when she noticed another swelling along Poupart's ligament which came on suddenly after lifting. A combined truss failed to give relief, and so she was operated on in the General Memorial Hospital last August. By dissecting out both sacs he was able to reduce a small piece of omentum in the femoral sac. An instrument introduced through the femoral opening came out through the inguinal opening, thus showing the passage between the two. The case was interesting because of its rarity. Dr. Coley had told him that out of 1,400 operations at the Hospital for Ruptured and Crippled, only two instances had been found.

Dr. Erdmann had seen two such cases during the past summer. The method of repair had been the Gordon for the femoral and the Bassini for the inguinal hernia.

Dr. Moschcowitz had seen one such case last summer, as also had Dr. Berg. In looking over the statistics, he learned that Berger of Paris reported on 10,000 cases of hernia, and found 222 cases of femoral and inguinal hernias occurring on the same side.

Dr. Downes said that there was a case at the Hospital for Ruptured and Crippled of a double inguinal, a double femoral, and an umbilical hernia.

Primary Carcinoma of the Omentum with Peritonitis Carcinomatosa.—Dr. Arnold Sturmdorf presented this paper, in which he said that it was not unusual to find the omentum involved in malignant disease by continuity or metastasis from other organs, but it was rare to find it the site of a primary malignant growth. There still existed much confusion in terminology and in fundamental conceptions as to the histogenesis and development of such primary peritoneal cancers. The primary development of an epithelial growth in parts in which epithelium does not normally exist as such is incompatible with advanced conceptions of histogenic and biological processes. As a result,

either the primary nature or the carcinomatous type of such cases had been questioned. This misunderstanding had led to much confusion in the literature of this class of cases. Delafield and Prudden had described endotheliomata as "a group of tumors, closely related on one hand to the sarcomata in genesis and in some cases in appearance, and on the other, resembling some forms of carcinoma so closely as to be difficult of distinction from them." He said that the bizarre nature of the histological criteria in these tumors explained the contradiction as to their prevalence and frequency, and he would leave his case to more advanced doctrine to relegate to its proper category. The history of his case was as follows: Mrs. E. C., 62 years old, married 30 years, widow 8 years. Father died of Bright's disease and mother of pulmonary tuberculosis. She had been normally delivered of three children, all of whom died of tuberculous disease. Menstruation began at 14 and ceased twenty-five years ago, without any climateric abnormalities. With the exception of a traumatism which resulted in the destruction of the left breast twenty-six years ago, her previous history had no bearing on the present condition. For four months she had had increasing tenderness, with recurring pain, and the gradual development of a hard mass occupying the middle of the right half of the abdomen. The mass grew rapidly, while pain, abdominal distention, dyspnœa, and loss of flesh developed to a distressing degree. When examined in August, 1904, she was pale, fairly nourished, with normal pulse and temperature, with slight dyspnœa, evidences of a compensated mitral insufficiency, lungs normal, abdomen symmetrically enlarged and very tense. Abdominal tenderness was most marked in the right half, which contained the greater part of the hard quadrilateral mass, the upper border of which could be defined by a nodular ridge extending across the epigastrium from points continuous with the mamillary lines. The lateral borders of this mass converged towards its lower pole, which seemed to project free into the pelvic cavity. The mass was hard and presented a rough, irregularly nodular surface, and was uninfluenced by respiration, slightly mobile from side to side, and in a less degree in an upward direction. Its lower free pole could be subjected to ballottement in an excessive amount of ascitic accumulation. The presence of intestine between the liver and the upper border of the growth was demonstrated. The spleen was not demonstrable; the genito-urinary organs were intact and free from involvement. There was marked œdema. The urine was normal. The blood showed 60 per cent. hæmoglobin, and no corpuscular changes. On September 14 the specimen of infiltrated omentum, which was exhibited, was removed without unusual difficulties. The parietal peritoneum was studded with countless papillary excrescences, presenting hard, flattened nodules varying in size from miliary dots to a split pea, very hard, yellowish-white in color, and showing a tendency to umbilication. Each papilla presented a small area of inflammation around its base. A painstaking search failed to reveal the presence of a similar neoplastic growth as a possible primary or secondary focus of the disease. Dr. Schnaper furnished positive microscopical evidence of its carcinomatous character. The epithelial cells were varied in shape. The nucleus stained well. The epithelial masses were varied in size and shape, the cells filled the alveoli and were in close relationship to one another. The Van Gieson stain revealed no stroma between the cells. Whether true carcinoma or endothelioma, and if carcinoma, whether primary or secondary, would probably remain an open question for the present. The patient made an uninterrupted recovery, and thus far presented no functional disturbances that might point to a possible involvement of any particular organ. The multiple papillary excrescences studding the parietal peritoneum could not be interpreted as merely passive metastatic deposits, but represented a type of malignant subacute efflorescence, clinically similar to that which was recognized in tuberculous and other infectious processes and productive of profuse serous exudate. Such a form of primary acute miliary carcinosis of the peritoneum had been described by Bauer and Nothnagel. In no other way could the enormous ascitic accumulation in so short a time, in the absence of circulatory obstruction, be explained.

Ten Years' Experience with a Radical Operation for Carcinoma of the Breast.—Dr. Willy Meyer presented this paper, which was read before the New York State Medical Association (see Medical Record, October 22, p. 672).

The following gentlemen discussed Dr. Meyer's paper: Drs. Sturmdorf, Torec, Syms, McWilliams, Hartwell, Moschcowitz, Gibbons, Morris, and Meyer.

Section on Pediatrics.

Stated Meeting, Held November 10, 1904.

Dr. David Bovaird, Jr., Chairman.

Abdominal Tuberculosis. —Dr. J. Finley Bell, of Englewood presented a patient, twenty-two months old, who came under his observation last January. At that time she had indefinite symptoms, peevishness, and febrile attacks, with a dry and persistent cough. The throat was red and the tonsils large, and the cough was supposed to be due to this condition. There was some slight enlargement of the abdomen, which was tympanitic. There was some constipation. The febrile attacks became more frequent, and their intermittent character soon became remittent. The abdomen continued to enlarge until February 20, when there was a sudden rise of temperature to 104°, and then all the signs of a bronchopneumonia appeared. The abdominal enlargement continued and the pneumonia ran its course. The patient was admitted to the Englewood Hospital in March, and was observed for a considerable length of time. She was seen by Dr. Koplik, who thought the case to be one of bronchopneumonia with a sarcoma of some abdominal organ, probably the kidney. After being in the hospital for three weeks, the tympanites subsided. A tumor was then made out, which extended from the umbilicus to the left flank. Clear serum was withdrawn, which showed 2 per cent. albumin (Purdey's test) and small mononuclear leucocytes. The smear stained with precipitated serum showed no tubercle bacilli, but 10 c.c. injected into the abdomen of a guinea-pig caused an enlargement of the inguinal glands, and a general tuberculosis. No further changes occurred in the child's chest after the bronchopneumonia. The abdominal growth was still present, but was constantly diminishing. The treatment employed was plenty of fresh air and guaiacol in moderate and continued doses.

Dr. L. E. LaFetra congratulated Dr. Bell because he had not operated upon the case. He said that the consensus of opinion among those who had the most experience in recent years with such cases, was that it was better to treat cases of tuberculous peritonitis without operation. Those cases that did well with operation were those that did better without operation. He thought the child would eventually make a perfect recovery.

Clinical Experience with Diphtheria Antitoxin.—Dr. Louis Fischer said that the dose of antitoxin required must still be considered empirical, as we could not accurately determine the quantity of toxin in the system, and it was his object to invite discussion as to the relative merits of large and small doses on the strength of accurate statistics kept at the Willard Parker Hospital. In July, 1903, there were treated 135 cases, 107 tonsillar and pharyngeal, with eighteen deaths and 82.3 per cent. recoveries, and thirty-four tube cases, with seventeen deaths and 50 per cent. recoveries. The average dose was 1,500 units of antitoxin. In August, 1903, 132 cases were treated; 103 tonsillar and pharyngeal, with six deaths and 94.5 per cent. recoveries, and nineteen tube cases, with eleven deaths and 42 per cent. recoveries. The average dose of antitoxin was 1,700 units. In September, 1903, there were 104 cases treated; eighty-eight tonsillar and pharyngeal, with ten deaths and 88.7 per cent. recoveries, and sixteen tube

cases, with fourteen deaths and 12.5 per cent. recoveries. The average dose was 2,500 units. In July, 1904, there were treated 134 cases; 100 tonsillar and pharyngeal, with eleven deaths and 89 per cent. recoveries, and thirty-four tube cases, with twenty deaths and 73.5 per cent. recoveries. The average dose was 2,500 units. In August, 1904, there were treated 121 cases; ninety-seven tonsillar and pharyngeal, with six deaths and 93.5 per cent. recoveries, and twenty-four tube cases, with ten deaths and 58 per cent. recoveries. The average dose was 5,000 units. In Septembmer, 1904, there were treated 137 cases; 105 tonsillar and pharyngeal, with seven deaths and 93.3 per cent. recoveries, and thirty-two tube cases, with eleven deaths and 65.6 per cent. recoveries. The average dose was 5,000 to 10,000 units. This showed about 21 per cent. mortality when the small dose was used, and 14 per cent. when the larger doses were used. McCollom of the Boston City Hospital commenced with an initial dose of 4,000 units, repeated in from four to six hours, depending upon the severity of the attack. When the patients had been ill for some time he gave an initial dose of from 8,000 to 12,000 units, and continued to use the antitoxin until there was a marked improvement in the condition of the patient. The shortcomings mostly to be met with were the placing of too much reliance on antitoxin regardless of vital necessities, the failure to stimulate emunctories. Hot saline colonic flushing of 115° to 120° should be administered for this purpose. The heart should be watched and supported by caffeine, sodium benzoate, strychnine, and small tonic doses of quinine.

Rashes usually appeared between the fifth and seventh days after the injection of antitoxin. The size of the dose did not vary the intensity, form, or time of appearance. The average duration of the rash was about three days. In some cases two distinct rashes could be found, which corresponded in time with different injections. Before the appearance of the rash there was usually a sudden rise in temperature, although the rash might appear without any febrile exacerbation. The proper dose of antitoxin was such a one as would inhibit the extension of the pseudomembrane, subdue the fever, and check the progress of the disease in general. For a mild case this was from 2,500 to 5,000 units. If an improvement was not noted within twelve hours this dose should be repeated. If there was a large exudate on the tonsils and pharynx, 5,000 to 10,000 units should be given on the first day, and if improvement was not noted, the same dose should be repeated within twelve hours. This dose should be repeated from day to day until all visible exudate had disappeared, glandular swellings had subsided, and temperature became normal. The condition and not the age of the patient should be the guide to the dosage. He had never seen ill effects from large doses of antitoxin. In cases of laryngeal stenosis, due to diphtheria, the primary dose should be 10,000 units. In some cases the immediate effect of antitoxin on the temperature and pulse was to produce a slight reaction, such as a rise of temperature of from one to two degrees, though in many cases a decided fall was noted after an injection of from 5,000 to 10,000 units. As a rule, the pulse rate was not affected, but in some instances a very rapid pulse, as of 160, had fallen to 140 within twelve hours after the injection. The temperature usually fell after the required dose had been administered. Proper nutrition was highly important. Milk diluted with some cereal decoction was better borne than milk alone. In older children raw eggs might be added to the milk, and concentrated broths administered. Acid fruits seemed to be well borne. Food should be administered about every three hours. When rectal feeding was necessary, one ounce of predigested milk, one ounce of starch water, and one minim of laudanum should be injected slowly through a colon tube after the bowels had been thoroughly cleansed. More than two ounces should not be given at one time, but if well retained the enema should be repeated every four hours. Dr. Fischer never used forced feeding in private practice.

Dr. Henry W. Berg said the question of the dosage of antitoxin was very interesting, and there seemed to be a great difference of opinion regarding it; he accounted for this because the relation between the toxin of diphtheria and the antitoxin, always a quantitive one, was not known. If one could tell definitely just how much toxin was absorbed, then one could tell exactly how much antitoxin was necessary. He believed it was always safer to give more than less of this agent. He said that Dr. McCollom's figures did not compare with those at the Willard Parker Hospital, and he gave enormous doses. Real knowledge of antitoxin in diphtheria had not been reached, and he believed we were still groping in the dark. The question of giving large or small doses of antitoxin depended upon whether the attack was a severe one and the lesion localized. If the lesion was severe and involved the pharynx or nose, the dose should be large, but, in such cases, he did not believe that better results were had from 5,000 than from 3,000 units. He usually started in with 3,000 units; at the end of three hours, another dose of some size was given; sometimes he gave a double dose. He laid a great deal of stress upon the rapidity of the pulse. If the heart beat 140 a minute, and with a temperature of only 100°, showing a toxic myocarditis, he gave large doses of antitoxin; if at the end of twelve or twenty-four hours the pulse was not down, he repeated the dose, sometimes doubling it. The temperature in diphtheria was never very high, and a typical effect of the antitoxin was to reduce it within twelve or twenty-four hours. Increase in the size of the lymph nodes was an important sign, and somewhat of a guide in the giving of antitoxin. The further away from the seat of the lesion were the lymph nodes the more serious was the case, and larger doses of antitoxin were indicated. The enlargement of the glands showed an attempt of the system to prevent the spread of the toxin. The question of what constituted a large or small dose of antitoxin was not answered. Some believed 1,500 units to be a large dose. In giving such doses as 60,000 units the emunctories were overworked; they were trying to get rid of the toxin of diphtheria, and the giving of such large doses placed extra work upon them. The serum introduced was a heterogeneous one, and the emunctories must rid the system of it. The rashes were not due to the antitoxin, but to the presence of a foreign serum. If a horse's serum should be injected into healthy persons, in 25 per cent. of them would rashes occur. The rashes were the conservative expression on the part of the skin in attempting to get rid of foreign material in the blood.

Dr. William H. Park said regarding the relation between the toxin and antitoxin, that if the two were mixed before injection, the exact quantitative relationship might be established; otherwise it would be a very difficult matter to decide. If one should take three guinea-pigs and give all fatal doses of toxins, and then immediately give the antitoxin, the guinea-pigs would be saved. But if one waited four hours, and then gave the same amount, it would not protect the pig; after four hours it would require ten times as much antitoxin. If one waited six or eight hours, it would require one hundred times as much. The question regarding the amount of serum to administer was a very important one. Dr. McCollom had pointed out to him the splendid results he had obtained from the use of very large doses. Dr. Park had experimented with large and small doses, but was unable to state definitely whether the small gave better results than the large doses, but in only three or four instances did the cases seem to do worse under the small doses. In bad cases of diphtheria he believed in giving large doses. The amounts the speaker gave were about as follows: In the mild cases, when seen early or late, involving the pharynx and tonsils, 2,000 units; severe early cases, 4,000; ordinary laryngeal cases, 5,000; in severe malignant tonsillar or nasal cases, 10,000, the dose being repeated at the end of twelve hours unless the patient was distinctly better. He emphasized the fact that antitoxin should be given for the diphtheria, and not for any coexisting pneumonia or other conditions.

Dr. Koester referred to those foul smelling cases of diphtheria, with subnormal temperatures, and said that one was safe in giving 10,000 units at least, and repeating it in tewlve hours; if only 3,000 or 5,000 units were injected, the next day would show the same amount of membrane present in all probability. In some instances, as much as 10,000 or 20,000 units might be given, and the membrane still be present on the following day; but if one would take a swab and wind it over the membrane, the membrane would come away; it had simply been lying there loose. With regard to the rashes, he said that when the first serums were used in 1894, few rashes appeared; but with the use of the more potent serums they appeared. He did not think they were due to the large doses of the antitoxin.

Dr. John Howland said that the statistics regarding the effects of large doses of antitoxin were not at all convincing. He believed it was far preferable to give a large initial dose of antitoxin than several smaller doses, even though they be repeated often, because the toxins in the blood were producing a deleterious effect upon the tissue cells, and unless we were prompt in action, the antitoxin would be powerless to help. With regard to pneumonic patients although the staphylococci, streptococci, and pneumococci were present in the majority of the cases, the Klebs-Löffler bacilli were also present, and an increased amount of diphtheria toxins must be caused by these germs. According to Councilman, in 15 per cent. of the cases of pneumonia following diphtheria, the Klebs-Löffler bacillus alone was the cause. Therefore, Dr. Howland believed that the dose of the antitoxin should be three, four, or five times larger than under ordinary circumstances.

Dr. Matthias Nicoll, Jr., said that personally he did not believe that increasing the dosage of antitoxin serum in diphtheria reduced the death-rate. The statistics of 1903 compared favorably with those of later years.

Dr. Sara Welt-Kakels said that years ago the *Lancet* reported cases of diphtheria treated with antitoxin serum in even larger doses than Dr. McCollom's, the patients receiving from 6,000 to 20,000 units as a single dose. In bad cases the dose was administered intravenously. The largest single dose given was 30,000 units, and the largest total amount given in one case was 82,000 units. Dr. McCollom used in a single case 60,000 units. In the report, the mortality was given as 6 per cent., although there were but fifty cases.

Dr. Scott said that the dose of the antitoxin depended upon the severity of the case, and the severity of the attack depended upon the extent of the lesion. A distinction should be made between a pure and mixed diphtheria infection. The mixed infection was only partially helped by the antitoxin; the pure infection was helped by small doses of antitoxin. He had worked with Dr. McCollom in the Boston City Hospital, and Dr. McCollom had given as high as 90,000 units in a single case. Dr. Scott said the dose of the antitoxin should be according to the lesion, according to the patient's condition, and according to the environment.

Dr. J. Finley Bell thought that the administration of antitoxin to the extent of producing rashes and other systemic effects would undoubtedly seriously modify the progress of diphtheria.

Dr. Louis Fischer expressed the wish that the Health Department would produce antitoxin in larger doses and in one bottle. With regard to the rashes, he said that last summer 500 instances occurred, and then the small doses were being given. With the administration of larger doses he did not think so many rashes would appear. With regard to the dosage, he said that it was his habit to give 2,000 units for the mild, 5,000 for the severe, and 10,000 for the laryngeal cases. He advocated dropping the word "thousand" in speaking of the amount of antitoxin, because so many physicians seemed to be frightened when the suggestion was made that so many "thousand" units should be used. He believed that the larger doses of antitoxin had a better effect than the smaller ones. It certainly would enable physicians to extubate earlier than formerly.

Chicago Pediatric Society.

At a meeting held October 18, 1904, there was a discussion on "Summer Diarrhœas of Children." Dr. A. C. Cotton reviewed the recent literature on summer diarrhœa. Among other things, he stated that Duval and Bassett, at the Wilson Sanatorium, Baltimore, found the bacillus of dysentery in forty-two out of fifty-three cases of diarrhœa examined, and they did not find it in healthy children. Knox found the bacillus in eighteen cases, in which no blood or mucus was found in the stool. The bacillus had been found in winter as well as summer diarrhœa. The New York Hospital found it in 78 per cent. of the cases examined, the New York Health Department found it in 53 per cent., Bellevue Hospital in 51 per cent., Johns Hopkins in 40 per cent., the Boston Floating Hospital in 93½ per cent., and the Philadelphia Children's Hospital in 52½ per cent. Dr. George H. Weaver presented charts showing results of cultural work. In 103 cases taken from the Sanatorium at Lincoln Park during the last summer, 76 were negative and 27 yielded the dystentery bacillus. In the 76 negative cases, 27,050 colonies were made. Of the 27 cases showing the dysentery bacillus, 17 gave the bacillus Y. This distinction had not been made in other reports. The true Shiga bacillus was not found at all. Miller of Toronto examined the intestinal flora after death in fifty cases. In ten of these the bacillus pseudodysenteriæ was found, but it could not be agglutinated by the antidystenteric serum, this being the only difference. Dr. May Michael read a clinical report of 102 cases examined by Dr. Weaver, giving the age, diet, character of stools, range of temperature, complications, and termination of the cases. Mucus and blood were found in all but two of the cases in which the dysentery bacillus was found. The bacillus was not found in any child under six months of age, the largest number being between one and two years of age. Most of the patients were artificially fed. Twenty-seven of the children in whom the dysentery bacillus was found, died, but recovery was the rule. Rickets, pneumonia, bronchitis, marasmus, whooping cough, were the most common complications, but many of the cases were in good physical condition at the outset of the diarrhœa. The antidysenteric serum was used in one case, with no result. Dr. John C. Cook reported 18 cases, in none of which was he able to isolate the dysentery bacillus and none gave a clinical picture of dysentery. He found in cultures from the throat or stools one or more of the following organisms: Diplococcus, lactic acid, pneumococcus, typhoid bacillus, sarcina, yeast, a short thick bacillus, and a long slender bacillus. The clinical symptoms were varied. There were complications of marasmus, brought on by improper feeding at home, and especially pneumonia. Five died, two of pneumonia, one of typhoid fever, in which the Widal test was positive. Antidysenteric serum was used in one case without result. One child recovered, the organisms contained in whose stool injected into a guinea-pig caused its death. Two cases, one the typhoid fever case, and another reported by the nurse as having had two severe hemorrhages from the bowels, showed in culture a pigmenting organism staining the media a red color. The suggestion was advanced that the color in the stool might be due to the action of this organism on the mucus. Most of the deaths were due either to pneumonia or to toxæmia resulting from improper feeding. Dr. William J. Butler reported ten cases from Cook County Hospital, in all of which the antidysenteric serum was used, without results in any case. All these children had blood and mucus in the stools, but in only two was the dysentery bacillus found. Clinically, the cases varied, but the stool was usually green, the temperature high, and the pulse and respirations rapid. One patient improved while using the serum, but the improve-

ment was thought to be due to the use of calomel and whey rather than to the serum. One child on milk and barley water diet showed no change in temperature, pulse, or stool for five days under the serum treatment, but improved in every respect when the didet was changed to albumin water.

Chicago Medical Society.

At a meeting held October 5, Dr. Edward F. Wells read a paper on "Diabetes." This disease, he said, was probably due to insufficiency of the pancreatic internal secretion, and was an important disorder, since it was increasing in prevalence. That diabetes was due to pancreatic disease was rendered probable by the fact that such disease was frequently accompanied by glycosuria; that lesions of the pancreas were found post mortem in a large proportion of diabetics, and that extirpation of the pancreas was regularly followed by diabetes. The most significant lesion in diabetes was pancreatic interacinar inflammation and hyaline degeneration. The symptoms varied with the type of the disease; those which first attracted attention were nocturnal dryness of the mouth and throat, increased frequency of urination, and excessive thirst. The other well-known symptoms followed. Coma, probably due to oxybutyric acidemia, was often the cause of death in severe cases. Glucose in excess, and the presence of morbid acids, combined with bases, were the most important changes in the blood. These were excreted with the urine, and were specific features. Diabetes was, broadly speaking, an incurable disease. The severe cases, especially in the young, died in a few months or years; the mild cases, in middle-aged or older persons, which formed the vast majority of all cases, lived moderately long lives, and died of other affections; all died with, comparatively few died from, diabetes. The treatment was almost exclusively dietetic, and should begin with the "therapeutic diagnosis," which measures the patient's capacity for carbohydrate assimilation. The patient was at once, or gradually, if diacetic acid was present, placed upon a strict anti-diabetic diet, with daily examinations of the twenty-four hours' urine, until sugar disappeared or reached the lowest point to which it could be brought. Carbohydrates, in the form of bread, were now gradually added to the diet until sugar reappeared or increased in the urine. From this a moderate proportion of carbohydrate should be deducted, and this would constitute the appropriate diet for the particular case. Readjustment of the diet should be undertaken two or three times a year. Codeine would but rarely be required. As a rule, the patient might be allowed to choose from a prescribed list those foods which he fancied, but the attendant should satisfy himself that, with such choice, the diet was properly balanced, and that the caloric requirements of the body were more than met. The severe cases would require the most stringent diet, *plus* an amount of carbohydrates, to be carefully estimated in each case, as would reduce the abstraction of glucose from the body tissues to a minimum.

Dr. Alice Hamilton read a paper on "The Invisible Droplets of Sputum Expelled in Coughing." In it she embodied the results of experiments that were carried on in the Memorial Hospital of Infectious Diseases. Recent bacteriological investigations had shown that the streptococcus was invariably present in cases of scarlet fever, yet in many cases it was of low virulence. Scarlet fever might run its course without any streptococcus complications when streptococci were present upon the tonsils. A number of instances were cited in which doctors and nurses contracted streptococcus infections of the throat soon after taking charge of scarlet fever patients. To prove whether the streptococcus was actually disseminated in the air by scarlet fever patients, plates were held before the mouths of children, who coughed or cried, from half a minute to one minute, the expirations being forcible. The colonies on the plates varied from one to seventy-five, and the proportion of streptococci varied also, owing probably to the degree of dryness of the mouth, etc. Of fifty patients, forty-seven were found by cultures made from swabs to have streptococci upon their tonsils; thirty-three expelled streptococci in coughing, crying, or breathing forcibly with the mouth open. In some the number of streptococcal colonies was less than one per cent.; in others it rose to over fifty per cent., an average of twenty per cent. Of thirty-four children who coughed or cried, twenty of them had streptococcus colonies. Of sixteen, who simply breathed heavily, thirteen expelled streptococci. These cases represented almost all varieties of scarlet fever, and the observations and cultures were made during the first three weeks of the disease. The author also called attention to the possibility of infection being transmitted to patients through the unprotected mouths of the surgeons or nurses present at operations or engaged in preparing dressings.

Dr. Alfred C. Crofton discussed the subject of "Newer Conceptions of the Management of Bright's Disease." He said that for most cases at least we had been forced to abandon the older views attributing this disease to a primary lesion of the kidneys, in favor of the idea that the condition was a cardiovascular one, which might even go on to a fatal termination with practically no renal involvement. After considering the possibility that some poison or group of poisons affected simultaneously the heart, the arteries, and the kidneys, the author stated that the other most important signs of Bright's disease were to be attributed to serious impairment of the kidneys, and were the invariable result of any nephritis. Prophylactic and causal treatment must be directed towards the correction of any gastrointestinal perversion, or any hepatic insufficiency that might be present. Next, the chief points of attack must be the cardiovascular apparatus, then the kidneys themselves, and, lastly, much attention should be given to the treatment of the patient's general condition.

Philadelphia County Medical Society.

At a stated meeting, held November 9, Dr. G. Erety Shoemaker read a paper entitled, "Cases of Hysterectomy and Salpingitis." Dr. James Anders read a paper entitled, "The Schott Treatment of Diseases of the Heart and Blood-vessels," in which he pointed out the superiority of physiological means over drugs as curative agencies. The bath-waters contain from 2 to 3 per cent. of sodium chloride, and from 2 to 3 parts of calcium chloride in 1,000, together with a certain amount of iron, and a large amount of carbon dioxide. The baths are of varying strength and duration. Thermal baths are first employed; then thermal effervescing baths; next pure effervescing baths; and finally the so-called flowing effervescing baths. The baths are useful in the treatment especially of cardiac insufficiency of varied origin, bringing about a more vigorous systole, with a diminution in the size of the dilated heart, and a reduction in the pulse rate. The arterial blood paths are opened, and venous stasis is relieved, while at the same time the blood-pressure is raised. In consequence of a freer coronary circulation, the nutrition of the myocardium is improved, the labor of the overburdened heart is greatly diminished, and recuperation is to a like degree assisted. The resistance movements bring into play different groups of muscles, more especially those of the extremities, in orderly succession, without inducing fatigue. They exert a marked influence on both the pulmonary and the general circulation. They tend further to drive the venous blood to the right side of the heart by compression of the veins. The method has proved valuable further in the treatment of chronic valvulitis, cardiovascular degenerations of varied kind, and angina pectoris. It is contraindicated in the presence of fever, advanced arteriosclerosis, far advanced myocarditis, the closing stage of valvulitis, with extreme dilatation of the chambers of the heart, aneurysm of the aorta or its larger trunks, except in the incipient stage, when the blood-pressure is lowered by the treatment, when the blood-pressure is below from 60 to 65 mm.

of mercury, and in cases of chronic bronchitis and asthma.

Dr. Thomas S. Githens read a paper entitled, "The Influence of Hunger and Hemorrhage on the Composition of the Blood-plasma."

Dr. Horatio C. Wood, Jr., read a paper entitled, "The Use of Methylene-Blue in the Treatment of Malarial Fevers." The drug was used in six cases, three of quotidian and three of tertian type. In all there was a cessation of symptoms and a reduction of temperature, although in four there was at least one distinct rise in temperature after commencement of the treatment, but in no case was the rise in temperature equal to that which had been present prior to the administration of the drug. In one case there was more than one paroxysm after the institution of the treatment. The dose generally employed was two or three grains every three hours. None of the patients remained under observation for more than three weeks, so that no positive statement could be made as to the permanency of the cure. In one case only was there any return of the symptoms, and in this case the relapse yielded readily to renewed treatment. The action of quinine was supposed to be expended principally upon the chromatin of the malarial parasite, and thus to affect especially the younger forms, while methylene-blue attacked chiefly the protoplasm, and thus destroyed the adult parasites. Treatment with the latter drug should be continued for a period of several weeks. No ill effects were observed from the drug in the cases reported.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending Nov. 19, 1904:

	Cases.	Deaths.
Measles	83	7
Diphtheria and Croup	323	36
Scarlet Fever	174	15
Small Pox	4	.....
Chicken Pox	114	.....
Tuberculosis	275	147
Typhoid Fever	107	18
Cerebro-Spinal Meningitis	.....	13
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	1,080	236

The Instrumental Dilatation of the Cervix and Orifice of the Womb During Pregnancy and Labor.—R. de Seigneux, in reviewing the history of the uterine dilator, from the time when Bossi described the instrument which he invented, states that the efforts of the inventors have been directed towards three principal improvements: The attainment of a true pelvic curvature; a simplification of the instrument, so that it would be lighter and more easily susceptible of disinfection; and an enlargement of the surface of the blades or an increase in the number of acting points in order to prevent the risk of rents, which is always possible. It was only after fifteen years of assiduous labor that Bossi succeeded in producing his instrument. Many other models have since been made. The writer explains what is meant by pelvic curvature in an instrument of this kind as follows: The direction of the cervix of a pregnant uterus on the point of delivery being perpendicular or about on the plane of the inlet of the true pelvis, it is not enough to give the instrument a more or less pronounced anteroconcave curvature to make of it a pelvic curvature in the obstetrical sense of the word. This will be really obtained only when the plane, in which the extremities of the blades of the instrument move, is found to be absolutely parallel with the plane of dilatation of the uterine orifice. Then only will it be possible to effect the opening desired without any dislocation and at the very point where the physiological dilatation takes place. But neither does Bossi's instrument nor any of its successors up to this time fulfil this condition. It is to this lack of a pelvic curvature that must be attributed the greatest number of rents made during the use of the instrument. On account of the fact that the position of the blades has been out of keeping with the plane of the opening of the uterine orifice, the result has been that no dilatation was possible without producing dislocation and excessive tension highly prejudicial to the integrity of the orifice. As to increasing the number of acting points, Kaiser and Frommer in their models have overlooked the fact that an increase in the number of points of contact is by no means the same thing as an enlargement of the surface of application. Nowakowski in his model has attached to the extremities of the instrument something resembling a napkin ring, which expands progressively. The idea is ingenious, but it is reasonable to ask if it would be an easy task to withdraw the instrument without causing rents, in cases in which under the influence of labor pains the head is caught in the inside of the napkin ring. The writer then describes his new dilator, and illustrates the description with cuts. This instrument is composed of an elongated handle containing a screw on which two sliding nuts turn inversely, and of four movable blades, the extremities of which are turned up. The handle can be easily taken to pieces for the purpose of cleaning. All the blades move in a plane parallel to the longitudinal axis of the instrument, which is so made that larger or smaller blades can be adapted to the handle as desired. A small spur is attached to the posterior and to the two lateral blades. This prevents them from slipping when inside the uterus. The extremities of the dilating blades all spread out equally from the same central point, and form during the operation a circle, the plane of which is parallel to the longitudinal axis of the instrument. The writer sums up the most important advantages of his instrument as follows: It is possible to adapt to the same handle, according to the progress of dilatation, a succession of blades of wider and wider surface in such a way as to reduce to a minimum the risk of rents. Since the dilatation is effected in a plane paralled to the axis of the instrument, the dilator thus presenting the proper pelvic curvature, it is possible to bring the dilating part of the instrument easily into the plane of the inlet of the true pelvis, without any dislocation of the uterine orifice. Each of the blades can be introduced separately like the branches of a forceps and they can be fixed to the handle when they are in perfect position. Thus much larger blades can be utilized than those in the Bossi instrument. As soon as the dilatation begins, the blades can be withdrawn one after the other, thus preventing the danger arising from not being able to withdraw the instrument easily on account of the descent of the head during the operation. The writer states that his dilator should not without a clearly defined indication be used in the case of a woman not in labor. Dilatation should be followed by the immediate extraction of the fœtus. The writer thinks that it is probable that this method will in time replace the habitual use of the Krause bougies. Except in urgent cases the method should be used only when the cervix is quite obliterated and the dilatation of the external orifice has already begun. In cases in which the dilatation has been brought about only for the purpose of shortening the first stage, it is not at all necessary to bring labor to an end by an operation. It is experiment alone which must determine all of the indications for and against the mechanical method of dilating the uterus. The writer from force of circumstances has employed his dilator in absolutely normal cases. He gives the results of his experiments with this instrument in a few words: This dilator renders the immediate termination of labor possible, with or without narcosis, when the orifice is not yet sufficiently dilated to admit of obstetrical intervention, and when the state of mother or child calls for immediate delivery. It also renders equally possible a rapid termina-

tion of labor in all cases in which the life of the mother is in any danger on account of pregnancy, and when this risk can be avoided only by the extraction of the child at a time when the cervix is still intact.—*Journal of Obstetrics and Gynæcology of the British Empire.*

Reform Costume.—In Europe at least, the advocates of a more rational plan of dress for women are meeting with considerable success in gaining proselytes. One sees many of the modified Empire costumes which the converts affect. On the streets of all the larger continental cities and in Vienna the movement has become so popular that there has been a great slump in the manufacture of corsets, which the Chamber of Commerce attributes in great part to the publication of medical opinion condemning tight lacing.

Pathology vs. Zoology.—At the recent meeting of the British Association Dr. Adamkiewics read a paper upon "Ist der Krebs erblich?" (Is Cancer Hereditary?") Unfortunately the programme had it "erdlich." So the London *Times* next day announced that the doctor had read a paper upon "Is the Crab a Sea or Land Animal?"

Heredity as a Determining Cause of Disease.—R. M. Phelps defines heredity as the transmission from parent to child of mental and physical characteristics. Heredity accounts for the likenesses to parents or type, and also for many of the apparent differences. But for the latter there are three other apparent origins: (1) The "antenatal" causes of temporary character (which become a part of the inheritance); (2) The environment of our growing period; (3) The action of our "will" or volitional power. The writer further elaborates these statements: 1. In general, our whole endowment of form, strength, and passions—all our physical and mental characteristics—are inherited. 2. This endowment includes to a considerable, though vaguely outlined degree, things that seem to us voluntary, and even the quality of the will itself. 3. Antenatal temporary causes acting upon the parents have effect on the child, although to just what degree is rather vaguely known. 4. The environment of the child can change superficially the qualities endowed, but does not wholly uproot any of them. 5. Man's will similarly seems to have power only to modify and repress the endowed qualities of the person, not to uproot any of them. As to the application of these laws to the study of disease, the writer points out that rarely will all the children in a family show exactly the same trend, even in the most strongly marked diseases, such as tuberculosis, insanity, or hereditary chorea. The same rule applies as in inheriting the more normal qualities. There is, however, an unmistakably strong trend toward inheritance. The writer believes that there has been present recently an undue tendency to magnify extrinsic causes, the predisposition and not the disease being said to be inherited. Insanity is probably the most common disease recognized as strongly hereditary. The inheritance in cases of insanity is far greater even than statistics indicate. In the case of tuberculosis, the writer believes that the contagion of the disease is not so great as is often thought. Clear mathematical proof, however, cannot be had for either heredity or infection. It is difficult to bring evidence in the case of tonsillitis and rheumatism. The writer has noted a marked trend in certain families toward tonsillitis; toward rheumatism, more vaguely. Asthma has clearly been noted to be inherited. Gout, cancer, leprosy, and goitre have more vague proof. "Old age" is inherited in the sense that some families age sooner than others. It is known that even in the most contagious of fevers, not all that are exposed catch the disease. Is immunity all chance? The writer believes that it cannot be. It seems within reason that sometimes we may have tests to recognize natural or inherited immunity, and its opposite predisposition, and be able to take steps to prevent the fulfilment of the predisposition, perhaps by producing artificially the immunity that is recognized. It is difficult at present, however, to recognize even the relative power of each.—*The St. Paul Medical Journal.*

The Influence of Slight Traumata on the Localization of Tuberculosis.—Edoardo Salvia has conducted experiments on rabbits with a view to learning whether injuries have a marked effect in localizing foci of tuberculous infection. He produced an injury in the animal and then injected a virulent culture of tubercle bacilli. After some time the animal was killed and an exhaustive histological examination made of the body. He draws the following conclusions: (1) A slow injury of moderate severity and repeated for a short time, predisposes the liver substances to a localized tuberculous infection, and rapid formation of nodules. (2) The location of the lesion is not due to hemorrhage into the tissues after injury, but to marked disturbance of the lymphatic circulation in the liver. (3) On the ribs and flat bones a firm blow produces a localization of tuberculosis—circumscribed, but involving all parts of the bone, periosteum, and pleura. (4) The injury to the ribs extends to the lung substance. (5) On the long bones of the limbs, the articular surfaces and synovial membranes of the knee, slight trauma has no effect to localize tuberculosis. (6) The added action of a small amount of ammonia increases the effect of a slight trauma, producing an extension of the virus into the soft articular tissues.—*Il Policlinico.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended November 19, 1904:

THE TREATMENT OF EPILEPSY IN CONNECTION WITH AUTO- AND HETERO-TOXIS.

BY ALLAN McLANE HAMILTON, M.D., F.R.S.E.,
NEW YORK.

THE treatment of epilepsy from remote times has for the most part been empirical, if we may except that of a surgical kind, and even the latter has until the discovery of cerebral localization been largely experimental.* The list of available drugs which have been more or less confidently recommended, is formidable enough, and in its diversity exceedingly curious, as it contains a large number of widely differing substances, some of which have little or no medicinal value under any circumstances. Much of the therapeutic guesswork which has been applied to the treatment of epilepsy is due to an imperfect knowledge of the pathology of a disease which is even to-day explained by many persons in many different ways, with more or less success. Putting aside those forms due to premature ossification of the cranial bones, to prenatal or early cerebral injury or disease, or when the convulsions are the symptoms of the formation of neoplastic or adventitious growths, there is a large number of so-called idiopathic cases which are exceedingly obscure, as it is impossible with any certainty to trace either a cause or an underlying morbid process. These have been of the obstinate and refractory variety that have tried the general practitioner, and even the neurologist, who have learned perhaps to depend to too great a degree upon the routine use of the bromides or other sedative drugs, with the idea of in a way smothering the activity of the excitable cellular elements. We therefore find these advocated, and in general use, and for years they have been given the first place as therapeutic agents in text-books, and in consequence of their indiscriminate use and abuse the attainment of results of a most unsatisfactory character has been the rule. The late E. C. Seguin more than a decade ago, while conceding the importance of the bromides, made an attempt to diminish their use in large quantities by substituting chloral, which was found to some extent to be an efficient substitute,† and in an exceedingly valuable series of lectures in which he declared himself a pessimist as to the curability of idiopathic epilepsy, warned his hearers in regard to the reckless administration of the bromides. "To see a case of epilepsy once and prescribe a bromide treatment is a most reprehensible, careless practice." Not only have Seguin and others found that there is a wide difference in the susceptibility to these drugs, but that where organic cardiac disease, or even a feebleness of circulation, exists, or where there is organic cerebral disease, there is an increased liability to bromism, and more or less serious consequences are to be expected. The writer, whose experience has been extensive, has realized what must have been observed by others—that in a comparatively large number of cases, the attacks are not only undiminished, but are sometimes aggravated by the use of the bromides, even in small doses. When injudiciously given for any length of time the effect is often a general disorder of metabolism, and perhaps intestinal autotoxis which is associated with gastrointestinal disorders primarily through atony of the intestines and impaired peristaltic action, which undoubtedly leads to the causation of attacks. Starr[2] is most pessimistic in regard to the curability of the disease under all circumstances, and this is reasonable enough considering how rarely these patients are rationally treated, and how generally they are the victims of routine medication, and that the malady is an organic one. It too often happens that after indulging in a course of proprietary medicine, or after consulting the advertising quack, they come to the regular physician in a broken-down state, with ruined digestive and cardiac and vascular atony. Even then they are too often "put on bromides," and sent off, to report from time to time, or to use their own judgment in diminishing the dose when they become more or less brominized. Possibly some of this is due to the reputation of the disease for intractibility, and the trial of the physician's patience; and in a certain number of cases the knowledge that the fits may be suppressed by the use of these remedies, leads to their universal employment.

It seems, therefore, that we should study our cases more thoroughly for the purpose of ascertaining if there is not more that may be done.

For some years the writer has been impressed with the facts forced upon him not only as the result of the study of his own cases, but by the accumulated researches of Raymond Petit,[3] Voisin,[4] Smith and Herter[5], Mott and Haliburton,[6] and later by Carlo Besta[7] and other Italian investigators, that toxemia enters much more largely than is generally supposed into the pathogeny of epilepsy, and this is apparent, as Voisin has pointed out, in the general resemblance and mode of occurrence between the epileptic attack and certain ordinary forms of poisoning in which the nervous system is affected. In such cases the element of convulsion and the mental disturbance have features in common, and it would appear that the occurrence of the fit betokens the accumulation in the body of some particular toxic agent, the unwelcome presence of which gives rise to a convulsion when the point of cell-tolerance is reached. This is particularly significant in those cases of epilepsy where the attacks either occur periodically when the toxemia reaches a certain cumulative stage, and there is an explosion, or in others where the paroxysm has no adequate

* B. Sachs says: "I would say, under favorable conditions, and by the methods described in this paper, the surgeon may be able to cure a few cases of epilepsy. He will be able to improve many, but surgeons and neurologists should in future make an earnest effort to *prevent* epilepsy."—*The New York Medical Journal*, February 20, 1892.

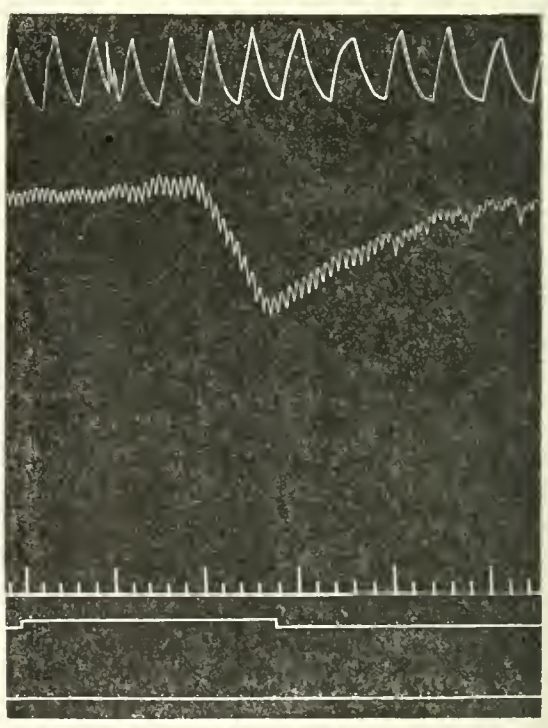
† Wallis (W. R. Reports, Vol. V, 1875) had previously recommended it for the relief it afforded in the status epilepticus.

ascertainable cause. Then, again, the condition of the blood, urine and circulation are those common to many forms of toxemia, and are so constant in the large number of cases observed, as to indicate a definite morbid mechanism. We should therefore devote more attention than we do to the chemical origin of the disease, for the time has come when this, as well as other diseases of the nervous system, bear a direct connection with morbid chemical changes and toxemia both autogenous and heterogeneous. In making this statement the writer takes into account the existence of the familiar predisposing and primary causes, such as heredity, brain injury and coarse disease, and it is their connection with secondary processes which has led to the new consideration of the disease itself, and the time has certainly come for a radical change in the treatment of the affection, which should be followed by decided improvement, if not cure, of this most obstinate of the diseases of the nervous system.

Reference is not alone made to eclamptic conditions and functional epilepsies due to temporary toxemia, but the attention of the reader is directed to cases of long standing, either idiopathic, or as the result of trauma or disease, in which a degeneration of the nervous elements of greater or less degree has been established. The conclusions clinical and chemical of the investigator in this field show that autotoxemia may occur in three different ways, all of which bear some relation to the development of fits, and the selection of appropriate treatment. *First*, in the existence of a toxemia of gastro-intestinal origin which was described originally by Bouchard,[8] and later by Herter and Smith and the writer.[9]

This consists primarily in quantitative changes in the uric acid and xanthin, and by the ethereal combinations of sulphuric acid; by the absorption from the intestines of poisonous substances during digestion, or by toxic materials produced by foreign bacteria which have found their way into the intestines.

Second, by the introduction of certain familiar cocci into the circulation, and in this connection attention may be directed to the researches of Comberale and V. Bué,[10] who found the staphylococci aureii and albii in the blood of epileptic subjects. The *third* division includes a far more important kind of toxemia which absolutely explains the causation of attacks in individuals in whom exists organic disease of the cerebral substance, and undoubtedly accounts not only for the familiar type of general epilepsy, but the Jacksonian and symptomatic forms as well.* The admirable work of Mott and Halliburton, whose experiments and conclusions were presented to the Royal Society in 1901, were the first to indicate the formation of a specific poison which was the result of tissue disorganization. These observers determined beyond question that in the blood of patients suffering from a variety of diseases characterized by breaking down of nerve tissue, it was possible to extract a varying amount of *cholin*, and for this purpose cases of beriberi, disseminated sclerosis, and neuritis were chosen for examination. Mott also found in general paresis that if the cerebrospinal fluid, especially after an epileptiform convulsion was tested there was found a decided accumulation of this toxic material. Pursuing their experiments still further it was demonstrated that when section and disorganization of a nerve trunk occurred that the process of degeneration was attended by the disintegration into lecithin, the liberation of the phosphorized portion of the molecule, and also of cholin. These observers obtained the blood of patients during life by venesection, and the blood from the body of a subject who died of alcoholic neuritis, and by a method to be subsequently described extracted an appreciable amount of this toxic substance. A cat was anæsthetized and the carotid artery of one side was connected with a mercurial kymograph for the registration of the arterial blood pressure. The external jugular vein of the opposite side was exposed, and into this five cubic centimeters of fluid which corresponded to twenty or thirty cubic centimeters of the original blood, was injected. After they had noted the effect of such an injection 0.5 cubic centimeters of an 0.5 per cent. solution of atropin was injected subcutaneously into the cat and a few minutes allowed to elapse. "In order to test whether the animal was fully atropinized the vagus of one side was stimulated or 2.5 cubic centimeters of an 0.2 per cent. solution of cholin-hydrochloride was injected into the jugular vein. When inhibition of the heart by vagus stimulation was not obtained, or when cholin-hydrochloride failed to produce its usual fall of arterial pressure (or this was replaced by a rise) the experiment was continued. The second part of the physiological test was then performed and consisted in again injecting the saline solution from the blood suspected to contain cholin. If the injection now produced no fall of arterial pressure, or this fall was replaced by a rise, the identification of cholin by physiological means was completed." In the several cases experimented upon, it was found that there was a decided fall of pressure, and a tracing is appended which shows the respiration, carotid blood pressure, the chronographic record and the period of injection. No cholin was detected in the urine, nor was any effect produced upon respiration. My own observations lead me to believe that it is possible to obtain cholin



1. Respiration; 2. Carotid blood pressure; 3. Chronographic tracing in seconds; 4. Signal line indicating time of injection; 5. Abscissa of the blood pressure.—(Mott and Halliburton.)

*"As the pathology in the convulsive affections approaches nearly an organic basis, in which parenchymatous and interstitial changes play the chief rôle, we must seek their principle of pathogenesis in an initial toxin or autointoxication."—L. Pierce Clark. *The Medical News*, July 18, 1903.

at most times in those cases when there is any reason to believe that there is an extensive granular degeneration of the cortical cells, and there is augmentation before and after the attack itself.

Among the earlier contributions of Hughlings Jackson[11] to the study of epilepsy he made the statement that in the epileptic brain nutrition is carried on on a lower level, and that there is assimilation of nitrogen instead of phosphorus. "There are," he says, "two ways in which nutrition may be imperfect—in quantity and quality. I believe that nerve tissue in discharging lesions is over-nourished in the former sense and worse nourished in the latter. I believe that the highly unstable nervous matter of disease (the discharging lesion) differs in composition, but not in constitution, from the comparatively stable gray matter of health." This certainly has a bearing upon Mott's later discovery of that form of chemical change to which reference has been made.

The clinical study of a large number of cases of epilepsy reveals a striking and more or less uniform change in the circulation which is indicated by a lowering of arterial tension before the attacks and an increase which occurs at the commencement of the tonic stage, and lasts until the period of recovery. With this there is an acceleration of the pulse which is very constant. There seems to be some conflict of opinion between the French writers about the consistency of these phenomena, Féré[12] holding that the arterial tension is increased before and during the epileptic attack, and falls when the crisis is over. Voisin and Petit, on the contrary, take the view which I believe to be correct, that there is an initial lowering of pressure, and they detail eighteen cases in which they found by careful measurement that there was a decrease before the attack, and a decided increase during the stertor and afterward. The rapidity of the pulse in some of these patients was almost doubled, and in all it was accelerated. My personal experience shows that in all old epileptics there is diminished arterial tension in the inter-paroxysmal state with variations which are more or less significant, and I have learned to look upon a soft, rapid pulse with considerable apprehension, for in many subjects its presence often precedes the development of an attack or series of attacks. In a recent case which was carefully watched where the tension was decidedly diminished, the attacks occurred with notable frequency so long as the pulse rate was 100 or more, but when digitalis was administered there was resulting augmentation of tension and lowering of the pulse rate to 80, and the patient went several weeks without any paroxysm. We should therefore connect the state of the circulation not only with continued strain and resulting weakness of the vascular walls, but with some existing toxic influence, and be prepared to use appropriate treatment.

Urine.—In the epileptic patient the condition of the urine certainly bears out the supposition that a general toxemia may exist, and Delore[13] has found in eclampsia that the urine was decidedly toxic, a condition observed by Voisin, Herter and Smith, and myself. The hypertoxicity of the urine is not only found after the attack, but is occasionally a warning of its imminence. The writer has for several years systematically examined the urine of numerous patients, and has found especially in those where the attacks were connected with gastrointestinal disturbance that at periods corresponding both with the beginning and subsidence of the epileptic state, there was a greatly increased amount of indican, indicating that form of intestinal disturbance in which there is a disproportion in the ratio of the preformed and aromatic sulphates. Herter[14] says: "Normally the amount of indican in the urine is small, but in disease it may become greatly increased. The increase is most striking in mechanical obstruction of the gut, but a great increase is often observed in catarrhal enteritis, and in errors of diet consisting of the excessive use of proteid food. We cannot state whether the absorption of indol gives rise to specific symptoms. Sometimes the pathologic increase coincides with the appearance of urticaria, sometimes with depression and headache and sometimes with *grand mal* seizures of epilepsy."

Blood.—Examination of the blood in epilepsy has often been made, and more particularly by the Italians. It cannot be denied that here again the condition of this fluid is distinctly suggestive of a toxemic state, for its tendency to coagulate immediately, its dark color, and sluggishness of flow are characteristic, and common to various forms of poisoning and infection.

Hénocque[15] has found that after an epileptic attack the activity in the reduction of oxyhemoglobin was diminished, and there was a diminution in the number of red corpuscles (Voisin).

Although Petit and other observers lay great stress upon the presence of certain bacteria, the writer is convinced that these have not so much to do with the pathogeny of the disease as the generation of cholin to which reference has before been made, and it is probable that the convulsions are actually due to the chemical processes that take place incident to the slow splitting up of nervous tissue incident to pathological changes. Mott and Halliburton in their search for cholin mixed the blood with six or eight times its volume of absolute alcohol and filtered and evaporated it to dryness at 40 degrees C., the residue being treated with absolute alcohol. After repeated evaporations to dryness, the residue was divided into two parts (A and B), one of which was used for chemical examination and the other for the physiological test. The subsequent process is detailed by them as follows: "To Part A, platinum chloride dissolved in alcohol was added, and the precipitate that formed was allowed to settle, and washed by decantation with absolute alcohol. It was then dissolved in 15 per cent. alcohol. It did not all dissolve, so the platinum chloride must have precipitated substances other than cholin. The solution was freed from the insoluble residue by filtration, and then evaporated in a watch glass to dryness at 40 C. Microscopical examination of the watch glass with a low power showed whether or not the octahedral crystals were present, and a rough quantitative estimation of the cholin was made by noting whether or not the crystals were abundant." Part B was evaporated to dryness and dissolved in physiological saline solution. The result was a neutral fluid slightly opalescent from contained lecithin.

Therapeutic Suggestions.—It has been my custom to determine if possible the existence of removable causes and to follow the ordinary hygienic rules for the management of these patients which are familiar enough to most of us, and need hardly be detailed. They consist in the use of hydrotherapy, carbonic-acid baths, friction, passive exercise, as well as walking and gymnastics, and other means that favor the elimination of waste or toxic products, proper mental occupation and avoidance of stress and strain. The influence of exciting causes that suddenly and profoundly change the cerebral blood pressure should not be minimized, and this must

be familiar to those who have watched the occurrence of attacks where organic disease has been localized. There is always a vascular instability which has been so well described by Fothergill[16]—a likelihood in ordinary anæmic brains of flushings and local congestions to take place, especially about a focus of disease. Under these circumstances there must in all probability be the chemical change due to excited disorganization, and ultimately cholin formation. The regulation of the diet is perhaps a matter of the greatest importance, and idiosyncrasies of the individual, for often enough it is exceedingly difficult even if he is willing to lay down hard and fast rules,* yet we should be alert to discover bad habits of long standing. The writer has recently treated a man who took daily the concentrated decoction from three pounds of coffee and had done this for many years. It is unnecessary to say that no treatment did any good whatever until this habit had been broken off. In this connection a word of warning is in order in regard to the use of coffee which so often interferes with general metabolism. I have no reason to change my opinion, advanced nearly thirty years ago, and which has been shared by some others, that an excessive nitrogenous diet is apt to aggravate the disease, and therefore advise that the quantity of animal proteids especially should be reduced to the minimum. Merson, adopting the idea of Hughlings Jackson that it is the nitrogen that leads to explosiveness and instability, conducted a series of experiments at the West Riding Asylum which showed that a meat diet not only produced a dull, languid condition with an increased temperature, but that the attacks were more frequent. On the contrary, the mental condition of the epileptic was vastly improved when he was confined to a farinaceous diet, and the frequency and severity of the fits was reduced. It is usually no hardship for patients to do without their meat, and there are numerous instances in which persons have gone for years with little or none without discomfort. Small and repeated meals from which are eliminated all articles likely to produce indigestion are preferable to others of a more hearty nature and separated by long periods. Every form of indigestion undoubtedly plays a part in the autotoxemia underlying certain epilepsies, so that it is impossible to fix an arbitrary diet for all. Fats and cod liver oil, which enjoy the approval of neurologists generally, may at certain times be active agents of mischief, when their imperfect assimilation leads to the excretion of abnormal amounts of ammonium in the urine. The ingested carbohydrates may also be factors of intestinal indigestion, undergoing fermentation and usually gas. Indeed, the connection of extreme flatulence is often a feature of an epileptiform attack. It will be seen, therefore, that the rational connection of gastrointestinal troubles, with appropriate remedies, is of far more importance than the mere giving of antispasmodic and the old-fashioned alteratives.

When the tendency to gastrointestinal torpidity exists, the use of hot water before eating, and perhaps the administration of *small doses* of nux vomica or strychnine at the same time will help the patient. When, however, there is reason to believe that the disinfecting action of the bile is diminished, it may be well, in a routine way, to give small repeated doses of calomel or to use one of the familiar intestinal antiseptics of synethic formation, coated with keratin, so that its action is limited to the lower digestive apparatus.

The efficacy of boracic acid in many cases is, after all, undoubtedly due to its value as an intestinal antiseptic, and it may be used in comparatively large quantities despite the unfounded prejudice which exists in regard to it. If bromides are prescribed at all it is better to employ them in quantities where they will have but a mild sedative effect, relying upon other agents to improve the circulation and establish the equilibrium of arterial tension, which should be preserved by careful watching and variation in dosage. The administration of drugs of a depressing nature should be attended by the greatest caution and moderation. If the bromides be given the dosage should be light and the salt be well diluted before the expected attack, if there is any regularity in the recurrence. If not, repeated doses, combined with some cardiac or vascular stimulant, is advisable. In some cases chloral, or, better still, veronal, may be used, but the latter should invariably be dissolved in hot water. The popular idea that bromides should be given to the point of producing anæsthesia of the fauces, or that a crop of acne should appear to signal saturation is, I am convinced, a mistake. With this degree of bromic toxicity there is necessarily a depraved condition, with a vascular hypotonus that can only invite attacks and an interference with the ordinary processes of digestion. In some cases the withdrawal of a certain amount of blood, with coincident intravenus or subdermal injection of saline solution, is attended by prompt results of a gratifying character; especially is this the case in those subjects where there is a series of repeated attacks, or when the status epilepticus exists. In one patient the loss of blood during a severe operation was undoubtedly attended by a lessening in the number and violence of subsequent paroxysms. Sometimes the injection of the saline solution of Leclerc, where the fits are heavy or frequent, will be of signal service. While the length of this article prevents me from presenting any tabulated statistics, it may be stated that my opportunities for observation have been sufficient to lead to the conclusion that the general unfavorable opinion which is held in regard to the prognosis of epilepsy of all kinds is fully justified under the old method of treatment; but my results have been so encouraging since I have treated my cases upon the lines indicated in this article that I believe many apparently hopeless epileptics can be greatly benefited if not cured.

To summarize the treatment:

1. We should, besides every measure that will favor elimination, regulate the dietary so that the idiosyncrasies of the individual shall be taken into account, but nitrogenous food shall be interdicted as far as possible. No large quantity of food shall be taken at any one time.

2. If intestinal autotoxis exists, cholagogues and appropriate ferments, as well as antiseptics, shall be prescribed.

3. Everything should be done to prevent the lighting up of gross intracerebral pathological processes, and the resulting formation of cholin. The equilibrium of the arterial pressure should be everywhere maintained.

4. The bromide should be given only in doses sufficient to diminish the activity of the cortical motor cells.

TACHYCARDIA AND ITS RELATION TO INJURIES.

By U. F. MARTIN, M.D.,
NEW YORK.

Among the medical sequelæ of injury or shock to the body surface, especially about the chest and neck, which are interesting to the surgeon as well as the physician, are certain derangements in the heart action. It is not the purpose of this paper to treat of injuries transmitted directly to the heart, or of indirect laceration of the cardiac tissue, e.g., rupture of the heart, but more especially to consider those disturbances of heart action classed under the general term of cardiac neuroses and more especially as tachycardia. Considerable difficulty has been experienced in getting data of this kind, although this symptom must be more common than this paper would lead me to think. The relation of myocarditis following trauma to cardiac neurosis is so close in some cases that it has been thought advisable to include a few notes concerning that condition of which cardiac neuroses may be only a precursor. A list of five cases cited by Pleasant in the Johns Hopkins Bulletin for May, 1903, in an article on cardiac traumatism, under the subhead of Traumatic Myocarditis, has therefore been included. The causal relation of injury to the myocardium seemed proved in more than one case. It would be interesting, therefore, to have cases of persistent tachycardia watched over a period of years.

Etiology.—The accidents which have been instrumental in bringing on this condition of rapid heart have been varied in character: severe blows in the left axilla, crushing of the chest against a wall, severe contusions of the chest, precardial contusions, compression by tight bands about chest and neck and blows over the cervical region. All of these have been severe enough to be accompanied by some degree of shock, and this in itself holds some causal relation to the symptoms which followed.

Such disturbances are due to changes within the heart in either its muscle fibers or ganglia; the nerves leading to the heart; the centers in the medulla or to a derangement of the nervous system as a whole such as is seen in neurasthenia and hysteria. Inasmuch as symptoms of pain and general neurasthenia often remain for a long time following accidents, it seems open to belief that a rapid action of the heart may be the only symptom of that disturbed nervous state. Of course the fact of a so-called physiological rapid heart in some individuals must not be overlooked, a pulse of 120 having been maintained for years, and there are many individuals in whom the pulse is never below 100.

In deciding as to what class a case of tachycardia belongs, and to understand the pathological state, a knowledge of the conditions which produce an increased action of the heart is imperative. It will, therefore, not be amiss perhaps to state as fully as possible the etiological factors in the production of a rapid heart, for in any case there may be complicating factors, e.g., fever, alcohol, cardiac strain, etc., which are to some extent responsible for increased heart action.

Acting upon the heart directly we find: pyrexia; poisons of the type of alcohol, belladonna, and tobacco; toxins, as of influenza, diphtheria, tuberculosis, and rheumatoid arthritis (the above also acting probably upon the centers in the medulla); physical exertion; cardiac strain as seen in the irritable heart of soldiers; cardiac inflammation as seen in endocarditis, myocarditis and pericarditis.

Acting upon the nerves leading to the heart: (*a*) upon the pneumogastric; compression at the origin from the medulla by thickening of the meninges; growths from bone or aneurism of vertebral artery; punctured or gunshot wounds; acute neuritis following diphtheria, rheumatism or a part of a general neuritis. (*b*) Upon the sympathetic system; compression of nerves or ganglia in cervical region by tumors or bone; irritation or overstimulation in shock.

Acting within the central nervous system: (*a*) Centers in the medulla; mental emotion; organic secretion, e.g., thyroid (W. H. Thompson in his work on "Graves' Disease" is inclined to regard poison generated within the intestinal tract and not increased thyroid secretion as responsible for tachycardia); hemorrhage into the medulla; local softening; slow degeneration of the nerve center. (*b*) Spinal cord; reflex influence, e.g., renal mobility; locomtor ataxia in some cases; concussion of the lower cervical spine.

Acting by derangement of more or less of the whole nervous mechanism, the so-called functional neuroses.

Physiology.—A very brief account of the physiology of heart action may be helpful in appreciating how simple a matter it is for local irritation to cause a disturbance in the normal rate of heart action. The wonder on considering the delicacy of the machinery is not that the heart should be disturbed but that it should escape demoralization with so many of the etiological factors present in many cases, where nothing but the most temporary changes take place.

"Cardiac movements," according to Gibson,[2] "were originally considered by Haller to be automatic and due to an inherent power of contraction belonging to the heart itself: this view was also held by Senæ, although he modified it in regard to the external sources of interference. When Remak discovered the ganglion at the junction of the sinus and of the auricle, Bidder those between the auricle and the ventricle, and Ludwig those between the

two ventricles, other views prevailed, and Rosenthal formulated the theory that the heart's beat was due to an automatic action on the part of the intrinsic ganglia of the heart and not to the muscle itself. With the progress of time these views were modified. The observations of Eckhard and Foster and Dew Smith upon the various effects produced by experiments on the ganglion fore apex and the further investigation of Bowditch and Merunowicz on the same part with nutrient fluids altered our concepts. The result of these observations was the theory that continuous impulses flowed from the ganglia in the sinus and produced rhythmic action of the heart. Gaskell's experiment showed that each part of the heart has a rhythm of its own and that the special rhythm of each part is due to a morphological difference in structure. Engelman found the ganglion fore veins to be the starting-point of the cardiac movement, and we have, therefore, come back once more to the conception that the movements of the heart are due to its own inherent automatic peculiarities. But we know that these movements of the heart are under the domination of the nervous system from outside. These very ganglia that have been referred to are now known to be simply the outlying or peripheral ganglia of the efferent cardiac fibers of the vagus nerve. They can interfere with the cardiac action in various ways, but never originate it."

Hoppe[3] in his article states that Kroneker's center in the intermuscular septum of the heart was regarded by him as controlling the vasomotor nerve of the coronary arteries. This he thought seemed to indicate that the cause of the irregularity in nervous patients might be due to some vasomotor disturbance of the coronary circulation. The most frequent cause of arrhythmia is thought to be a diseased condition of the coronary artery or myocarditis. Less frequent it occurs as a functional derangement. Marked arrhythmia to the point of intermittency is considered always pathological. The nervous ganglia and nerves of the heart are thought to be purely sensory, and therefore we have pain in addition to other disturbances of sensation. The site of this pain and the reason for its apparent superficial distribution is well explained and illustrated in Gibson's lectures.

Pathology.—Of the pathological states secondary to accidents found directly within the heart and acting as irritants in producing tachycardia, the chief are pericarditis, endocarditis, and myocarditis. And this is with or without any direct injury to the muscle. They occur as sequelæ to blows upon the chest not necessarily over the cardiac region. Of these three pathological conditions myocarditis seems to be most important in the consideration of persistent tachycardia. Pleasant[1] has shown that following accidents there may occur hemorrhage into the heart muscle, contusion, or laceration, or even rupture. The muscle fibers thus destroyed are replaced in the process of repair almost entirely by connective tissue. He writes, "Unless the extent of the injury is great or there is subsequent infection of the contused area, the development of progressive myocardial disease seems unlikely in the case of a previously sound heart. Yet this sometimes does occur. If, however, we are dealing with a heart already the seat of myocardial disease, or one in which the reserve resistance is lowered by pre-existing hypertrophy, the liability to serious myocardial changes following injury is increased. That so few cases of traumatic myocarditis are reported is probably to be explained in the following way: (*a*) In severe lacerations of the heart muscle death usually results; (*b*) In injuries of moderate severity in a normal heart, repair without ill effects probably occurs in the majority of cases, while, if myocardial changes do take place, they are in association with serious endocardial or pericardial disease, and are obscured for a time by them; (*c*) If, however, we are dealing with a previously diseased heart, even if the relation between trauma and myocarditis seems close, we feel that we should be cautious in necessarily assuming a causal relation." At the conclusion of his article he thus sums up: "From an examination of the foregoing cases, and a study of autopsy reports it can scarcely be doubted that myocarditis occasionally develops as the result of contusions of the chest. From the scarcity of reported cases, myocarditis of traumatic origin cannot be common, although the traumatic origin of some cases is probably overlooked. As in other traumatic affections of the heart, the evidences of external injury probably bear but little relation to the severity of the cardiac injury. Myocarditis may thus develop in a heart previously sound, but the susceptibility of diseased heart muscle must certainly be greater. Disturbances in the nutrition of the heart by interference with the blood supply, or by actual destruction of the muscle-substance are probably the usual form of injury. In the case here reported (Case I.) there was an infarct of the myocardium. The left ventricle is probably the one most frequently injured. Symptoms may develop immediately after or come on gradually, after the injury. Traumatic endocarditis may be associated with traumatic inflammation of the pericardium and endocardium. That serious myocarditis can develop as the result of the direct extension of traumatic pericarditis as asserted by Bamberger and Friedrich seems quite probable. In other respects myocarditis of traumatic origin does not seem to differ from the non-traumatic forms. . . . It seems established that not only may pre-existing disease of the heart be aggravated by trauma, but that in a heart previously sound, pericarditis, endocarditis, myocarditis may develop as the result of cardiac injury produced by contusions about the thorax, often without any external evidence of trauma."

Nature by position of the pneumogastric and cervical sympathetic nerves has protected them from some forms of damage, although the extensive course of the former renders it liable to suffer from many causes. Acute neuritus of the vagus from cold or rheumatism, according to Starr,[4] is not known to occur, but it may add the fatal touch to a general multiple neuritis or be affected by the toxins of diphtheria. At its origin from the medulla pressure by thickening of the meninges (and this is the usual site of syphilitic affections), by growths of bones or aneurisms of vertebral artery may produce symptoms referrable to the vagus nerve. Clinically, injury to one vagus nerve, by inclusion in ligature about the carotid vessels or division in stab wounds has not seemed to produce much effect upon heart action, although experiments on animals would

seem to indicate that division of the left vagus nerve should be attended by a very rapid heart and by a slowing of respiration. (Starr.) Wounds of the vagus nerve, without accompanying injury to the great vessels, must be of very rare occurrence if it ever occurs. The only possible method would be in the course of an operation after the artery and vein had been separated posteriorly from the common sheath. An occasional paralysis of the vagus nerve has occurred as a complication of locomotor ataxia.

Not much is to be found concerning the pathological state of the sympathetic nerves following injury and its relation to the increased rapidity of the heart. Tillmanns[5] makes the statement that there may be irritation of the sympathetics by one or the other of the fragments in a fractured clavicle. Boise[6] mentions as his belief that the tetanoid condition of the heart and peripheral arteries in shock is due to an irritation of the entire sympathetic system. This would, however, disappear in the majority of cases with the cessation of the symptoms of shock. However, shock may hold a very important position among the factors which go toward upsetting the nervous mechanism as a whole and the production of that state of irritability which seems to be present in every case of so-called cardiac neurosis. Until we know why the normal impulse traveling over the vagus nerve should hold the heart's action down to 72 per minute or thereabouts, we are hardly likely to do more than name the condition in which there is a disturbance of that control. The fact that tachycardia may occur as a normal (?) state throughout life, demonstrates the difficulty in discovering the anatomical, physiological, pathological, or chemical reasons for such a condition. The relation of the pneumogastric nerve and the sympathetic system is thus described by Starr,[4] and explains in a way why shock may be the responsible agent for upsetting the normal state of heart action and heart control. "The connection of the sympathetic system with the brain is made by the great vagus or pneumogastric nerve. The action of the sympathetic system in regulating the vegetative functions and the acts of the heart, bloodvessels and lungs is usually automatic and unconscious; but this activity may be reflected upon consciousness in an indefinite manner, and cause changes in the emotional state and in the general feelings of comfort. Head, who has made a careful study of this subject, affirms that exaltation or depression of spirits, hallucinations, a state of suspicion, and a change of character may be induced by the reflected pains of visceral disease. He ascribes many of the symptoms which we term hysterical to such sources. It is also a fact that unusual states of consciousness, expectant attention and condition of the mind and brain induced by hypnotic suggestion, may in turn produce physical changes in the vascular and vegetative organs. These can be explained only by admitting a control by the brain of these organs through sympathetic channels, but in an unconscious and involuntary manner. Very little is known concerning the diseases of the sympathetic system, and nothing is known of its pathology."

The nucleus of the tenth nerve undergoes degeneration in the course of bulbar paralysis, and may also be the site of hemorrhage, or softening, but pathologically it is never found apart from similar involvement of the ninth nerve. The close proximity of the nuclei of these two nerves beneath the floor of the fourth ventricle provides a reason for their mutual involvement in any disease affecting that part of the medulla.

"Krehl raises the question," to quote from Hoppe,[3] "whether nervous affections can produce changes in the size of the heart. If so, how often and to what extent, and can it produce hypertrophy or dilatation? We might answer at once that when hypertrophy and dilatation are present there is an organic heart lesion, a diseased condition of the muscle itself. At present, however, there can be no certainty upon this subject, principally because autopsies on nervous subjects are exceedingly rare. Krehl says he has seen dilatation of the heart especially in masturbators, and that with a cessation of the habit the dilatation has disappeared. He has also seen dilatation occur in ordinary neurasthenic paroxysm and disappear with the cessation of the attack. Theoretically the explanation is very plausible. It is well known that an irritation of the vagus nerve has marked influence on the tone of the heart muscle. Why should not psychic influence have the same effect, the dilatation being the result of diminished tone. Krehl is not so positive about the recurrence of hypertrophy; he thinks that he has seen it, but does not wish to place himself on record, because of the difficulty of diagnosing small degrees of hypertrophy. Before the diagnosis of dilatation or hypertrophy can be made in neuroses of the heart, we must carefully exclude all organic lesions, and must likewise bear in mind that we may have at the same time both an organic lesion and a neurosis. It is well to remember, however, that we may have as a result of simple neuroses of the heart undoubted dilatation and perhaps hypertrophy."

Such disturbances of the heart action as can be classed under the term of neuroses occur following concussion in which there may or may not be actual thoracic injury. It may follow mere mental shock. The symptoms of increased rapidity of the heart action, sometimes even irregularity, come on immediately after the shock or at varying intervals, and are often associated with symptoms of hysteria or neurasthenia. This condition must be differentiated from traumatic myocarditis. Pleasant[1] says, "The condition is a purely functional one as in the case of other traumatic neuroses, and is not due to any special injury of the nervous mechanism of the heart." Hoppe[3] thinks that "the neuroses of the heart are, as a rule, found in those forms of neurasthenia in which the vasomotor disturbances are common. It is not difficult to understand that if the arteries and veins surrounding the cardiac plexus are in the same state of passive distention and sluggish activity, how readily all the neuroses of the heart can be explained on the ground of a deficient nutrition, producing a changed activity of the cardiac ganglia."

Diagnosis.—The diagnosis of tachycardia as a simple neurosis from myocarditis or paralysis of the vagus nerve or affection of the nuclei is not a matter of ease in all cases. Those which in the early part of the history might be classed as a neurosis later develop symptoms of myocarditis. Some authors claim that the intermittence of myocarditis occurs

with great irregularity, that the arrythmia of nervous origin sometimes disappears under excitement, while bodily exercises invariably increase the irregularity in myocarditis. Myocarditis, as a rule, is associated either with hypertrophy or dilatation, whereas it is the exception in the nervous derangement.

The diagnosis of vagus paralysis can be made when the recurrent branches of the nerve are affected and disturbances in respiration and in the voice develop, or when there is a distinct anæsthesia of the palate or paralysis of the tongue. "Rapidity of the heart," Starr[4] says, "is not a sufficient sign to warrant a diagnosis, and there are no lung, gastric, or visceral symptoms that are characteristic of the disease, the majority of the statements made in books being purely theoretical and not based upon clinical facts or pathological findings." Tillmanns[5] says that the so-called cardiac asthma characterized by a very much accelerated pulse, rapid respirations, and cyanosis, is caused by irritation of the terminal fibers of the pneumogastric in the lungs and paralysis of those in the heart.

The diagnosis of tachycardia from irritation of the sympathetic nerves is made from the association of rapid heart action with dilatation of one or the other pupil, according to the side irritated. Seeligmüller says it is present to some degree in all fractures of the clavicle. Oppenheim is the authority for the additional symptoms of wide separation of the eyeballs, pallor and reduction of temperature of the face. "Fraentzel says that tachycardia due to irritation of the sympathetic can be cut short by morphia, and that produced by vagus affections by pressure on the vagus." (Hoppe.)

In bulbar paralysis, the nuclei of the nerve are affected and paralysis of the æsophagus and of the pharynx and larnyx are the result. It is not possible to distinguish between symptoms due to the lesions of the ninth and tenth nerves. When the vagus nucleus is thus disturbed it no longer exercises the normal control over breathing and heart action, hence, Cheyne Stokes' respiration and intermittent or very rapid heart action are supposed to be due to this disturbance.

The symptoms of pure cardiac neuroses as gathered from the cases cited, are few and must be supplemented by observation over a long period of time before a positive conclusion can be arrived at. Subjectively there may or may not be consciousness of heart action. The heart is irritable, however, and can be easily forced up twenty or thirty beats. Its action is often over 100 per minute and remains so for some months after the accident, gradually falling to normal or thereabouts. In some cases it is associated with the symptoms of general neurasthenia or hysteria, but this is not always so as in the cases here reported. The heart, according to Krehl, may be dilated, but again may not show any increase in the area of cardiac dulness. The prognosis must be a guarded one, as a few years may show the development of a typical myocarditis.

Cases.—The cases here tabulated are grouped according to the general scheme followed throughout this article: those due to changes within the heart muscle; those due to disturbances in the nerves; those due to lesions in the nuclei; and lastly pure neuroses. I have been unable to find any case to be grouped under Class III. as following injury; and in Class II. there is one straightforward case, and Gibson's case, which seems to be a possible example of irritation of the sympathetic. Of Class IV. three fairly typical cases are cited.

Cases referable to disturbances within the heart.[1]

1. *Pleasant's Case.*—The patient, 55 years old, known to have had an enlarged heart a year and a half before injury, but had not previously shown acute symptoms of a diseased myocardium. Two days before admission he had been struck a severe blow in the left axilla with a piece of scantling, as it was being pushed through a partition by a fellow workman. Immediately following the injury gallop rhythm, rapid pulse, and other signs of defective heart action were noted. These symptoms continued for four weeks, when he died. Autopsy showed a recent infarct of the myocardium in addition to a fresh adherent pericardium. The whole picture microscopically was that of a recent necrosis of the myocardium with commencing connective tissue formation.

2. *Mendelssohn's Case.*—Strong and healthy man, 20 years of age. Previous examination of heart negative. He was first examined three weeks after his chest had been crushed against a wall by a vicious horse. He was rendered breathless by the injury, but did not become unconscious. There was considerable pain about the chest, with weakness and shortness of breath. On examination three weeks after injury he was found to be short of breath and cyanotic. Pulse small, rapid and irregular. Heart distinctly enlarged, especially to the right. There was no murmur. His condition gradually grew worse and œdema developed, which yielded to digitalis. Eight months after the injury his condition was reported as serious with marked symptoms of myocarditis.

3. *Stern's Case I.*—Man, 19 years old, sustained a severe contusion of the chest without evidence of external injury. Examination of the heart after the injury, absolutely normal. Two days after the accident traumatic pneumonia and pleurisy developed. With the clearing up of the pulmonary condition, rapid pulse and cyanosis persisted, but there were no murmurs and the heart dulness was not increased. For several months attempts to work were followed by shortness of breath. An examination eleven months after injury showed increased heart dulness, persistent small weak pulse, but no heart murmur. Three years later typical signs of myocarditis were present, marked cyanosis, dyspnœa, small irregular pulse, and pulsation of vessels of the neck. There was great increase in the heart dulness, especially to the right, and at the apex and tricuspid area a soft systolic murmur.

4. *Stern's Case II.*—This second case is somewhat similar to the last, but the symptoms of myocarditis did not develop as rapidly after injury, so that a causal relation is not as certain as in the last case. As in the last case, the signs of myocarditis were typical. There were also associated nervous disturbances of the heart action.

5. *Riegel's Case.*—Here there seemed to be a little doubt of the relation between a severe precardial contusion and cardiac symptoms which set in immediately afterwards, in the case of a man, 44 years old, who was kicked by a horse. The condition gradually

became worse, symptoms of myocarditis and mitral stenosis developing and resulting in death four years later. At autopsy, in addition to mitral stenosis, there was extensive fibro myocarditis of the left ventricle, especially in the anterior wall near the apex.

Cases due to disturbances of the nerves.

6. *Hirsch's*[6] *Case.*—He reports a mixed traumatic injury of the hypoglossal, vagus and sympathetic nerves, the patient being a laborer who accidentally shot himself, the bullet passing through the roof of the mouth and lodging at the left of the fourth cervical vertebra, where it was afterwards found in the sterno cleido mastoid muscle and removed. As a consequence of the injury there were paralysis of the left velum palati, paralysis of the left vocal cord with loss of voice, paralysis of one side of the tongue. There was pronounced secretion of saliva, which accumulated under the left side of the tongue. The left pupil was diminished in size, with slow reaction to artificial stimulation. There was no loss of taste. Paresis of the muscles of the left half of the thorax was found; an increase in the rapidity of the heart's action took place, the count averaging 108; but there was at times a decided tachycardia.

7. *Gibson's Case.*—A patient who was first seen under the care of Dr. Elder in the Lutheran Hospital and afterwards by Dr. Gibson in the Royal Infirmary. He had, so far as could be made out, a concussion of the lower cervical and upper dorsal region, and there was such a state of irritability when he walked a few steps that he had a tremulous acceleration of the rate of the heart.

Cases of pure cardiac neuroses following accidents.

8. *Knight's*[7] *Case.*—A young man thrown violently while getting into a car, striking the chest over the region of the heart. Rapid action of the heart ensued for some time after. According to the testimony of his friends, whenever he was examined there was rapid action of the heart. On examination there was found a slight systolic murmur over the pulmonic area.

9. *Mulhall's Case.*—Miss Carrie W., school teacher, 26 years of age. Heart examined twice previous to accident, and at both times perfectly normal. In a collision of trolley cars she was thrown forward and sustained several superficial incised wounds of the face. On examination she seemed anxious and frightened, not, as she explained, because of the slight cuts, but because of a sensation in the region of the heart which she had never before experienced. It was at times that of a fluttering bird; again a sense of weight or constriction, and was accompanied by sobbing respiration, but no true dyspnœa. She was of a highly emotional temperament. There was in this case no contusion of the chest, nor did she remember any concussion of the chest wall. No thrill or palpitation, the impulse was feeble and the apex beat not displaced. Pulse was small, feeble, irregular, and, after patient had rested fifteen minutes, still 90 to the minute. In the mitral area the first sound was feeble and accompanied with a loud murmur. It bore characteristics of a hæmic murmur, but was of much greater intensity. Rest and treatment with Tinct. Strophantus allowed her to partially resume work in a week. At the end of three months there were no subjective symptoms, the murmur was less intense. At the end of fifteen months there were no abnormal physical signs or symptoms. In discussing the case, Dr. Mulhall said, "My opinion was that not only was there a general traumatic neurasthenia, incident to railway collision without discoverable marks of violence, but that this unstable nervous condition might be confined to one organ as, for example, the heart. The murmur in this case can hardly be explained on any other hypothesis than that there existed dilatation of the left ventricle and consequent non-approximation of the mitral segments, the result of a functional paralysis of certain cardial motor nerves."

10. *Author's Case.*—Henry C., 21 years of age, brass worker. While at work on March 19, his jacket was caught in the back by a rapidly revolving wheel and the buttons of the coat torn off except the upper one, which held. In this way the coat tightly gripped him about the neck and axilla, and, being used as a sling, he was hurled around until the throwing out of a cog stopped the machinery. When cut down, his face and neck were seen to be black-blue in color, the conjunctiva intensely congested, and presenting an appearance well depicted in the illustration to be found in the Annals of Surgery[8] for April, 1904. The man did not lose consciousness at all during the accident. Examination on admission to the service of Dr. J. W. Wright at the Bridgeport Hospital showed both feet crushed with a compound fracture of the lower end of both bones in each leg. In addition to the discoloration of face and neck there were a few scalp wounds, not deep in character. He had also sustained a fracture of the eighth and ninth ribs of the right side, at the angle. As soon as the man had rallied some from the immediate shock, he was taken to the operating room, and as there was absolutely no pulsation in the arteries of either foot both legs were amputated at the lower third. The fractured ribs were treated by strapping. The patient was only lightly anæsthetized by chloroform and ether, but during the operation his pulse varied from 144 to 175. He was delirious, off and on, for over a week, and his pulse remained 150 without let up. For a few days he complained of difficulty in breathing and severe pain over the site of fracture. The respirations were thirty. For the first week his temperature was around 104° F., falling by lysis to 99° F., and then irregularly about 101° F.

The second week showed P. 120-148; R. 22-28.

The third week showed P. 124-238; R. 20-24.

The fourth week showed P. 108-138; R. 20-24.

The fifth week showed P. 112-120; R. 20-24.

The sixth week a secondary operation upon the flaps was performed and with anæsthesia his pulse rose from 130 to 180 and after operation remained about 150.

The seventh week showed P. 116-140; R. 24.

On discharge, pulse was 112; R. 24.

Examination of the heart at different times while in the hospital failed to show any murmurs or any abnormal signs except the rapidity and a slightly accentuated aortic second sound. Examination at his home the week following his discharge from the hospital showed the heart action, while sitting in a chair, to be 115, of good quality and without irregularity. No increase in cardiac dulness was made out, the apex being located in the fifth space within

the nipple line. After exercise with the arms the heart was not observed to increase its rate out of proportion. The patient claimed, however, that any sudden start would make him conscious of palpitation. He seemed to think that this tendency he had always had, and that perhaps his heart had been rapid before the accident. His family physician, however, assured me that just preceding his present illness he had examined him, and while he had not the actual count was sure that it was not higher than 80.

The persistence of the increased rate of heart action and its somewhat slow improvement eight weeks after injury with no signs of valvular lesion, or cardiac enlargement, leads me to place this case under the head of pure cardiac neuroses following injury to the neck and chest. Just what factor is responsible for upsetting the control of the heart action is not plain. Gibson writes, "Tachycardia depends for the most part upon a reduction of the diastolic phase. There can be but little doubt that this increased frequency in tachycardia is probably produced as was suggested by Mackenzie and shown by Wenckebach and Cushing, by a stimulus which comes to the sinus or auricle before its right time; that is to say that there is either a condition of irritability or of diminution of control which allows the normal stimulation of the heart to occur too soon.

TWO CASES OF HENOCH'S PURPURA;

WITH REMARKS UPON THE GASTROINTESTINAL LESION.

By OLIVER C. SMITH M.D.,
HARTFORD, CONN.

Case I.—Earl Reckliffe, aged 9 years, American. Family history negative; has had measles, diphtheria and malaria, all without sequelæ.

On April 29, 1903, the patient was struck on the abdomen while playing at school. No immediate symptoms followed. Two days later purpuric spots appeared on the legs and abdomen. Five days later the patient became nauseated, and the stomach rejected nourishment. On the same day convulsions occurred, followed by severe abdominal pains. The urine now became decidedly albuminous, and contained blood, the purpura becoming general. The above history was furnished by Dr. E. O. Elmer, the family physician, to whom the credit of a correct diagnosis is due.

The patient was admitted to the Hartford Hospital, May 15, two weeks following the onset of symptoms. At this time he presented the following appearance and conditions. Body pale; face and extremities œdematous; legs flexed on thighs, and thighs on abdomen; fading purpuric spots over the body. Examination of chest was negative. The abdomen was very rigid and tender throughout, but not distended; there was no localization of the pain; there was slight dulness in the flanks and a suggestion of fluctuation in the abdominal cavity. The blood count gave 14,000 leucocytes. Examination of the urine showed 20 per cent. albumin by volume, no blood at this time and no casts. Temperature 101.2°, pulse 126, respiration 30. There was persistent vomiting with apparent intestinal obstruction. The following day the abdomen was opened by low median incision. A small amount (from 100 to 200 c. c.) of turbid fluid escaped. The small intestines were collapsed, showing petechial and ecchymotic spots throughout their entire length. The large intestines were also collapsed, presenting fewer ecchymoses. The peritoneal cavity was flushed with salt solution. The intestines were lifted up and douched, and the abdomen was closed with as much normal saline solution as it would hold.

The following day the pain in the abdomen continued, and the patient was nourished by the rectum with albumin water. On May 18, two days after the laparotomy, there was less abdominal tenderness; the bowels resumed their peristalic action, and a movement occurred. On May 20 the patient was given beef juice by the mouth, which was retained. The gastrointestinal symptoms gradually abated from then on.

On June 10, the renal conditions became grave; the albumin increased to 30 per cent.; the patient became more œdematous; convulsions reappeared and the child gradually became semi-comatose. As a last resort decapsulation of both kidneys was performed, but without apparent relief.

The patient lived four days after this, being comatose most of the time.

Case II.—Dominick Santoll, aged 16 years, Italian laborer, entered Hartford Hospital June 17, 1903. The man spoke no English, and a history was hard to obtain. An indefinite history of injury to abdomen by a falling barrel led us to believe the symptoms were due to trauma. The patient had been feeling bad for two weeks, and for the past three days had become much worse, suffering from severe pain in the abdomen; he had vomited and had watery stools. The maximum amount of pain was in the region of the umbilicus.

At the time of entry the patient was poorly nourished and developed. The facies was that of one acutely ill. Examination of the heart and lungs was negative. Examination of the abdomen revealed muscle spasm on both sides; there was no dulness. Temperature 97.4°, pulse 80, respiration 28. There were purpuric spots over the abdomen and also the extensor surfaces of the right elbow, thigh, both lower legs, and left thumb. The movement of the right elbow was somewhat restricted by pain in joint. Leucocytosis 14,000. Urine albuminous. Without development of high temperature or other evidences of inflammatory trouble, the patient continued to vomit. No action of the intestines could be induced.

The vomitus contained blood. An exploratory laparotomy was deemed advisable, and was done through a low median incision. The intestines were found collapsed, and the visceral peritoneum studded with small ecchymotic spots. Many feet of the intestines were perfectly flat, except at the side of the mesenteric attachment, where a continuous hard pencil-sized roll could be felt. This appearance was proven to be due to lumbricoid worms which lay on the mesenteric side of the bowels.

The intestines were drawn up and douched with warm normal salt solution; the abdomen was filled with the same and closed.

The following day the patient was doing well; vomiting ceased, but he was fed by the rectum. Two days later the bowels moved in response to an enema. On June 24, the wound had healed by primary union, the patient now being fed by the mouth. He continued to improve, but had occasional slight rises of temperature without apparent cause. The purpuric spots gradually faded. He was discharged cured, July 15, four weeks following the laparotomy.

In both of these cases we were led at first to believe that the patients were suffering from the effects of abdominal trauma, and the ecchymotic spots over the abdomen lent color to this theory, but in the light of later developments and more complete histories, it is evident that neither was traumatic, but that both were cases of Henoch's purpura with marked gastrointestinal symptoms.

The first report of a case of this unusual form of purpura was made by Robert Wilan in 1808. Four cases were reported by Henoch in 1874, and in a recent article on the "Hemorrhagic Diasthesis," which has been translated from the German for me by Dr. Paul H. Waterman, of Bellevue Hospital, four more cases are added to the first series. In 1876, a number of cases were reported by Couty. Osler published a series of eleven cases in the *American Journal of the Medical Sciences,* in 1895, a second series of seven cases in the Jacobi "Festschrift" and the *British Journal of Dermatology* in 1900, and a third series of eleven cases in the January number of the *American Journal of Medical Sciences.*

These authorities agree in their description of the clinical picture, symptoms and progress of this disease, that in addition to the pain and swelling of the joints of purpura rheumatica, and the petechiæ and ecchymoses of the skin, there occurs vomiting, intestinal hemorrhages, colic, albuminuria and hæmaturia. There may be convulsions and general œdema. Death may occur from either the renal condition, or lesions in the gastrointestinal canal.

It is distinctly a disease of young life, and is about evenly divided between males and females. Osler says the seriousness of this condition is attested in the occurrence of seven deaths of his twenty-nine cases, or a mortality of twenty-four per cent. He further says one of the most constant features in this group, occurring in twenty-five cases, is the recurring attacks of colic, sometimes with vomiting, and sometimes with diarrhœa, occasionally with the passage of blood. The colic in Osler's cases he reports as severe, the attacks persisting for one or more hours and requiring morphine for relief. In fourteen of the twenty-nine cases there existed an acute nephritis, with albumin and casts. He says that "as a rule this comes on at the height of the skin lesion, or it may follow within one or several weeks later."

In the January, 1904, number of the *British Journal of Children's Diseases,* Mr. Harold Barrows reports a case of a boy aged eleven years, who developed intestinal intussusception. He had been feeling bad for ten days when the abdominal symptoms suddenly became violent. Ecchymoses were found on the intestine as in the case which I have reported, but the purpura of the skin was not observed until the day following the operation.

In the same journal, Dr. G. A. Sutherland reports two cases, both in children suffering from purpura, in whom laparotomy was performed. The first case was that of a boy of five years, who was seized with sudden vomiting and pain in the abdomen. The symptoms abated after four days, and recurred after a two days' remission. The abdominal symptoms then became very grave; there were severe colic, distention, blood-stained stools, and apparent obstruction. The abdomen was opened with the anticipation of finding an intussusception, but instead they found a portion of the small bowel, dark in color from extravasated blood, and with thickened walls. The article says the boy reacted well, but it does not state how soon the colic and vomiting abated, and normal peristalsis resumed. The skin eruption and albuminuria did not appear until after the operation.

In Dr. Sutherland's second case, a girl of seven who had been suffering for some time with abdominal pain, vomiting of blood, melæna, albuminuria, and hæmaturia, gradually recovered from this attack, and three months later was seized with a recurrence, and died in convulsions. Autopsy showed general peritonitis and intussusception of the cæcum and part of the ileum into the colon. Dr. Sutherland concludes, and Professor Osler agrees with him, "that the fatal attack was induced by hemorrhages into the wall of the colon, leading to paralysis of the effected part, and to increased muscular contraction with colic in the adjoining part of the bowel. As a result of these strong muscular contractions the sound part of the intestine became invaginated into the paralyzed and hemorrhagic portion.

Silberman reported a case in 1890, which is quoted in Osler's article in the *American Journal of the Medical Sciences,* in 1895. The patient, a child of ten years, suffered from purpura rheumatica, in December, 1887. Colic and hemorrhages from the stomach and kidneys were present. The attack subsided in a few days, to recur with increased intensity on the 20th of January. Peritonitis developed, of which the child died. Autopsy revealed a perforation at the fundus of the stomach. The mucosa of the intestines was swollen and congested. There were necrotic foci in the stomach and intestines, and thrombi were found in some of the blood vessels.

In Dr. Osler's article in the May number of the *American Journal of the Medical Sciences,* he cites a case of a girl of seventeen, who suffered with recurring attacks of abdominal pain, accompanied by slightly swollen and tender joints. There was obstinate constipation and persistent vomiting, but with no skin eruption. Following an unusually severe attack, an exploratory laparotomy was performed, but further than to state that the stomach, gall blad-

der and intestines appeared normal, the findings at the exploration are not given. In calling attention to this case, Dr. Osler remarks upon the likelihood of mistaking these visceral crises which are associated with this form of purpura, for various grave abdominal lesions, such as appendicitis, intussusception or obstruction from some other cause.

It would seem to me that with the history of two fatal cases from intussusception, and one from perforation of the stomach, which have occurred in this condition, as result of the pathological changes in the intestinal and stomach walls, an exploratory laparotomy in cases presenting grave abdominal symptoms, even though there does exist purpura at the time, would be not only permissible, but decidedly indicated, and the chief point I wish to make is that this disease, known at present as Henoch's purpura, is not to be regarded as entirely a medical disease, but that the intra-abdominal conditions sometimes call for exploration, and for further operative procedures when lesions are discovered.

The most important fact, to my mind, in the two cases which I have reported, is that filling the abdomen with salt solution was followed within a few hours by a resumption of intestinal peristalsis, and a cessation of the vomiting, which had become alarming in both cases. The intestines were emptied and collapsed, and whatever peristalsis there was, prior to opening the abdomen, was in the reverse direction, as the vomitus proved.

It is not difficult to understand that the absorption of so much saline solution into the intestine by process of endosmosis stimulated normal peristalsis, and intercepted the train of morbid developments.

I wish to acknowledge my indebtedness to Dr. Walter R. Steiner, pathologist at the Hartford Hospital, and Dr. H. F. Stoll, resident physician, for their valuable assistance in securing references to the literature of the subject. To Dr. Stoll is due the credit of a correct diagnosis in the second case.

44 High Street.

A FEW REMARKS ON INFANT FEEDING; WITH A SIMPLE AND SAFE METHOD FOR THE GENERAL PRACTITIONER.

By FRANCIS H. GLAZEBROOK, M.D.,

MORRISTOWN, N. J.

ATTENDING PHYSICIAN TO THE "SPEEDWELL SOCIETY" OF NEW YORK AND ASSISTANT VISITING PHYSICIAN TO MORRISTOWN MEMORIAL HOSPITAL.

Infant feeding is one of the most important subjects with which the general practitioner has to deal, and the one which he is most apt to overlook and give entirely too little attention. Every physician should be well informed on this subject, and at least be able to recognize symptoms which point to faulty feeding, and know what to do when they appear, otherwise, in a very short time, irreparable harm is done and another life sacrificed unnecessarily. According to reliable statistics, "of all children born one-third die within three months." The rate of mortality for the third year of life exceeds any other year up to the eightieth, and over 80 per cent. of the deaths in this first year are the direct result of ignorant or improper feeding, 50 per cent. of which occur during the first month.

These statements are startling, but the figures are facts,—and it is up to the general practitioner to reduce this alarming mortality. There are few subjects upon which more time has been spent than upon artificial or substitute infant feeding. It has been almost the life work of many famous physicians, and every worker among children in the world has experimented more or less along this line, trying to find the best and safest substitute for mother's milk, with the result that there have been innumerable theories and methods advanced which are, as a rule, most confusing and difficult to follow, yet our technique has been vastly improved by these efforts, and though we are still confronted by many of the same evils which confronted our predecessors, we are much better equipped to deal with this subject.

It is upon the family doctor that everything depends, for the specialist is seldom called until he is in trouble. His responsibility begins as soon as the baby is born. An important and often neglected part of every confinement is to at once investigate the condition of the mother's breast, and ascertain how the baby is to be fed. If, for any reason, the mother is prevented from nursing her child, see to it that a proper food is prescribed, and watch with greatest care the early weeks of such feeding. It is by no means an uncommon occurrence for this important matter to be left entirely to an inexperienced woman, or nurse, and the greatest harm is done when a wrong start is made. The alimentary tract of an infant can be damaged beyond repair in a very few days, and before you know it you have a severe pathological condition to deal with, which complicates matters seriously. There is but one perfect food for the newborn infant, namely, mother's milk. Every child should get the first secretion of the mother's breast, or the colostrum. This plays a most important part in the development of the digestive apparatus, and fortunately it is not often necessary for us to wean at birth, for it is a difficult matter, even for the expert, to find a satisfactory substitute for this most necessary part of lactation. This, I think, helps to explain the high mortality during the first month of life in bottle-fed infants, especially among the poorer classes and those ignorant of the importance of this subject.

Proteid is the nitrogenous constituent of milk. Proteid is necessary, therefore, for growth and development. The proteid of mother's milk is albumin and casein. Albumin is easily absorbable and is not coagulated by the gastric juice, while casein is not digestible for the infant, and is coagulated into tough curds by the gastric juice. Cow's milk also contains proteid in these two forms, but the percentage of albumin in mother's milk is about 1.25 per cent., as against 0.50 per cent. in the cow's milk, while the casein in mother's milk is about 0.50 per cent., to almost 3 per cent. in cow's milk, or, mother's milk contains about 4 per cent. fat, 7 per cent. sugar, 1.75 per cent. proteid, most of the proteid being easily absorbable albumin; cow's milk about 4 per cent. fat, 4 per cent. sugar, 4 per cent. proteid, most of the proteid being indigestible casein.

I will call your attention for a moment to the formula of colostrum, which is 5.50 per cent. proteid, 2.50 per cent. fat, 4 per cent. sugar. Now, colostrum, as mother's milk, contains little or no casein (the insoluble proteid), but has a high per cent. of albumin, higher than at any other time

*Read before the Morris District Medical Society, June 8, 1904.

during lactation, which is readily absorbed by the young infant, and is essential for proper development at this stage of life.

It must be remembered that during the early days of life, digestion is really an absorption, but in about two weeks colostrum has gradually changed to milk, which contains less easily absorbed proteid, and true digestion begins; so, as the child grows older, and its power to digest casein increases, the more easily can we substitute a suitable food, if it becomes necessary.

Dr. Chapin, in a recent article, calls the attention of the profession to the functions of maternal milk in developing the stomach. He says: "During the colostrum period there is little secretion in the stomach, and colostrum is especially fitted for intestinal digestion. In the change from colostrum to milk, the mother alters the character of the proteid supplied, and the infant's digestive secretions change at the same time for a specific purpose. In artificial feeding, it is essential to supply as much fat and carbohydrates as are found in breast milk, to serve as fuel for the body, and as much proteid and mineral matter to build up a strong body, or anæmia, rickets, or malnutrition will follow. But it is also essential that a portion of the proteid shall be of a form that will develop the stomach, as the lack of such food will profoundly affect the general nutrition."

The temptations to wean are becoming greater every day. In all classes we find women so busy with social affairs and other equally important occupations that she is only too willing to accept anything as an excuse to wean her baby. The anxious young mother, because her baby has a few green stools, or an attack of colic, thinks her milk is not rich enough, or that she is not strong enough to successfully nurse her baby, and so without knowing the harm she may be doing and the risk she is running, puts it on some food which some kind friend has recommended, without (and sometimes with) the knowledge of her physician, when with a little attention to her own diet the disorder could have been corrected in a few days, and the dangers and trouble of bottle feeding avoided. As the number of artificially fed babies is increasing, so the responsibility of the family doctor is increasing, and he should, first, insist upon the mother nursing her baby as long as is wise; second, prepare himself to meet this necessary evil in as safe and as simple a way as possible.

I claim no originality for the method of feeding which follows. I have had the opportunity of directly caring for, and experimenting with, over one hundred and fifty bottle babies of the Speedwell Society of New York City during the last twenty months, sent here from the various hospitals and tenement districts of New York City, most, if not all, of them coming with a diagnosis of malnutrition or gastro-enteritis, victims of improper or ignorant feeding. I am greatly indebted to Dr. Henry D. Chapin, the medical director of this society, for his great help to me. I have been guided almost entirely by his method, which, I believe, will soon be, if it has not already been, universally accepted as the best method of artificial infant feeding. The object of this paper is to freshen your minds and call to your attention the importance of this subject, presenting to you some phases of bottle feeding in a simple manner, so that they can be more practicable, without learning complex methods and consulting formulæ.

All writers on this subject agree that modified cow's milk is the best substitute for mother's milk, though there are differences as to how it should be done. It is of great importance to have a clean, pure milk. There should be nothing present foreign to milk. Great care should be exercised, therefore, in recommending and choosing the milkman. You should know that the cows are clean and well kept, and the milking should be done by clean hands, and especial attention paid to the udders of the cow, for there is great danger from the bacteria which are found on these. The bottle method of keeping and delivering milk is the best. After bottling, it must be kept on ice or in cool water, temperature 60° F. or less. Quart bottles being used, the milk should be allowed to stand until the cream has separated (centrifugal cream should not be used). A good average milk thus prepared contains in the top nine ounces, about 12 per cent. fat, 4 per cent. proteid, 4 per cent. sugar. The top sixteen ounces contains about 8 per cent. fat, 4 per cent. proteid, 4 per cent. sugar. Or the top nine ounces contains about three times as much fat as proteid, and the top sixteen ounces about twice as much fat as proteid. This relation of fat to proteid in these amounts is constant, no matter whether the milk is richer or poorer. Dr. Chapin has found, therefore, that the top nine ounces of a quart is best adapted to the young infant, or those under three and one-half months, while the top sixteen ounces is best for older infants, using any part of either, according to the strength required. The Chapin dipper, with which you are all familiar, holds just one ounce, and will go into the neck of the ordinary quart bottle, simplifying the preparation of the food greatly. As the sugar is reduced by dilution, it is necessary to add a little, best in the form of sugar of milk; a good rule is to add about one-twenty-fifth of the amount of food prepared, or one ounce of sugar to every twenty-five ounces of food. Of great importance in modifying milk is the diluent used, as mentioned before. About 1-6 per cent. of the proteid of cow's milk is soluble, and capable of being easily digested. "When milk is diluted," says Dr. Chapin, "the quantity of this easily absorbed proteid becomes so small that the infant actually gets a proteid which is not digestible, and forms curds in the stomach, making a good culture medium for the bacteria which may be present. Diluting with water does not prevent the formation of these curds, but diluting with pre-digested cereals breaks up these curds and, furthermore, adds a readily absorbed nutriment." The cereal, after being prepared, should be dextrinized with one of the diastase preparations, made at home from malted barley grains, or it may be more convenient to use one of the commercial preparations. They should be used as follows: After your barley or other gruel has been made, allow it to cool, so as to taste, then add one teaspoonful of cereo for every quart of gruel, stir until the gruel becomes thin and watery. With your gruel for dilution prepared as above, and remembering that the top nine ounces of an average milk contains about 12 per cent. fat, 4 per cent. proteid, and 4 per cent. sugar, and the top sixteen ounces 8 per cent. fat, 4 per cent. proteid, and 4 per cent sugar, and that food prepared from the former is better for children under three months, and the latter over three months, any per cent. of fat, proteid and sugar can be obtained in a very simple manner, and you have an easily digested and a nourishing food.

Example I.—For a child under three months, take off the top nine ounces of a quart of milk which has stood a few hours, or until the cream can be seen on top. Of this take six ounces. Add sugar of milk one and one-half ounces, and barley gruel twenty-four ounces. We have diluted six ounces of

milk, containing 12 per cent. fat, and 4 per cent. proteid, with twenty-four ounces of barley water, a dilution of five, or 12 per cent. and 4 per cent. divided by five equals fat 2.4 per cent, sugar 6 per cent., and proteid 0.8 per cent. By using more or less of the nine-ounce milk we can make the food any strength we please, viz.:—

A. 5 oz. top, 9 oz. + 24 oz. gruel + 1½ oz. milk S. = F. 2.1%, S. 6%, P. 7% (Dil. 5.8%).
B. 6 oz. top, 9 oz. + 24 oz. gruel + 1½ oz. milk S. = F. 2.4%, S. 6%, P. 8% (Dil. 5%).
C. 7 oz. top, 9 oz. + 24 oz. gruel + 1½ oz. milk S. = F. 2.7%, S. 6%, P. 9% (Dil. 4%).
D. 8 oz. top, 9 oz. + 24 oz. gruel + 1½ oz. milk S. = F. 3%, S. 6%, P. 1% (Dil. 4%).
E. 9 oz. top, 9 oz. + 24 oz. gruel + 1½ oz. milk S. = F. 3.33%, S. 6%, P. 1.1% (Dil. 3.66%).

Example II.—For an older child, take the top sixteen ounces of a quart of milk; of this take ten ounces, add milk sugar and twenty-four ounces of barley water as before. Now we have ten ounces of milk containing 8 per cent. fat and 4 per cent. proteid, diluted with twenty-four ounces of gruel, a dilution of 3.4, or 8 per cent. fat and 4 per cent. proteid divided by 3.4 equals 2.35 per cent. fat, 6 per cent. sugar, and 1.2 per cent, proteid. (By adding one ounce of sugar to every twenty-five ounces of food, the sugar is always 6 per cent., which is a good average amount.) So, as before, by using more or less of the top sixteen ounces of milk, we can get any percentage of fat and proteid desirable, viz:—

A. 10 oz. top, 16 oz. + 24 oz. gruel + 1½ oz. milk sugar = F. 2.35%, S. 6%, P. 1.2% (Dil. 3.4%).
B. 11 oz. top, 16 oz. + 24 oz. gruel + 1½ oz. milk sugar = F. 2.5%, S. 6%, P. 1.25% (Dil. 3.2%).
C. 12 oz. top, 16 oz. + 24 oz. gruel + 1½ oz. milk sugar = F. 2.66%, S. 6%, P. 1.33% (Dil. 3%).
D. 13 oz. top, 16 oz. + 24 oz. gruel + 1½ oz. milk sugar = F. 2.9%, S. 6%, P. 1.4% (Dil. 2.9%).
E. 14 oz. top, 16 oz. + 24 oz. gruel + 1½ oz. milk sugar = F. 3%, S. 6%, P. 1.5% (Dil. 2.6%).

In figuring out a formula of modified cow's milk for a case, you should always begin with one considerably weaker than that of a breast fed baby at the same age.

Now, you see from these tables that, as I mentioned before, the percentage of fat in formulas under No. 1, or from the top nine ounces, is three times the percentage of the proteid, and in those under No. 2, from the top sixteen ounces, twice; and this relation is constant, whether the milk be richer or poorer. For example, take a poorer milk, one containing in the top nine ounces 10 per cent. fat instead of 12 per cent. Our formula for the top nine ounces of this milk would read about 10 per per cent. fat, 4 per cent. sugar, 3.5 per cent. proteid. So, by taking five, six, seven, or more ounces of the top nine ounces of milk of this strength, we have formulas reading:—

A. 5 oz. top, 9 oz. of (10% F.) milk + 24 oz. barley gruel + 1½ milk sugar = 1.72% F., 6% S., .57% P. (Dil. 5.8.)
B. 6 oz. top, 9 oz. of (10% F.) milk + 24 oz. barley gruel + 1½ milk sugar = 2%F., 6% S., .67% P. (Dil. 5.)
C. 7 oz. top, 9 oz. of (10% F.) milk + 24 oz. barley gruel + 1½ milk sugar = 2.3% F., 6% S., .77% P. (Dil. 4.4.)

It can be seen now that the relation of fat to proteid is three to one, or the same as in the formulas prepared from the 12 per cent. milk, the only difference being that these are a little weaker. (B) here being equal to (A) in the other. The same is true of the top sixteen ounces, only the relation is two to one. So, by this method, no matter whether you have a rich or poor milk, your relations are always the same; and this is the important point, all you have to remember is the top nine ounces for young babies, the top sixteen ounces for older, increasing or diminishing the amount used according to the effect.

It is convenient to prepare the whole amount of food for twenty-four hours at once, so if you have not enough to last this length of time, double all the ingredients. In choosing a formula for a given case, it is best to begin with a weak one and gradually increase it, being guided by the effect it has on the child. If the child does not seem to get enough, it is best to increase the quantity a little, then increase the strength. If there is vomiting more than ordinarily occurs in a normal breast-fed baby, immediately after the nursing, your baby is getting too much food, so reduce the quantity. If the vomiting occurs half an hour or so after feeding, and is sour and curdled, stop your milk for twenty-four hours, feeding the gruel alone, and begin again with a food containing a lower percentage of fat. By watching these conditions of the stomach carefully and acting promptly, there is seldom any disturbance in the bowels, providing your milk is pure and sweet. If, however, you should get thin, watery, green stools, your food contains too much sugar. If there are curds, and colic is present, your food is not diluted enough; to correct, use an ounce or two less milk, in other words, a weaker formula. Severe diarrhœa with vomiting indicates harmful changes in the food and a catarrhal condition of the bowels, the former being due to bacteria, the latter to the actions of bacteria or persistent feeding with a food containing too much insoluble proteid, or fat and proteid out of correct relations.

Before closing, I want to say a word about an infant food which is largely used by mothers, and by many physicians, and though condemned by a large majority of specialists, certainly is deserving of a place among infant foods. I am speaking of condensed milk. In certain cases, especially in those in which the infant, owing to careless or ignorant feeding, does not seem to tolerate fresh cow's milk in any form, condensed milk often works like a charm. I have used it in a great many cases which have been given up as hopeless, and improvement is almost immediate. The child gains in weight and strength and the bowels rapidly become natural, and when well there is seldom any trouble in changing to fresh milk again, on which the child thrives as if it had never had any trouble. This is explained by the fact that the vacuum process of condensing milk seems to make the curd more assimilable to certain infants, or it becomes more friable. The difficulty in prescribing condensed milk is to get the percentage of fat and proteid in correct relation to each other. The percentage of fat is much too low; this can be overcome by adding top milk or cream to the condensed milk. An easy rule to remember is to add as much cream or top milk as condensed milk.

I claim for this method of substitute feeding, that by carefully watching every case at the beginning, any infant over one month can be weaned without experiencing any difficulty, and the physician has little to tax his memory. To sum up:

(1) A pure, sweet, quart bottle of milk on which the cream has risen.

(2) Top nine ounces for young babies, top sixteen ounces for older.

(3) Twenty-four ounces of predigested gruel.

(4) One and one-half ounces of milk sugar.

(5) Begin with weak mixtures, increasing according to the demand. In infants under one month this does not apply; in other words, during the colostrum period of lactation, before true digestion

is established; here we need a lower per cent. of fat and a very high per cent. of proteid. I should recommend for these cases food prepared from the top two ounces of a quart, which contains about 20 per cent. of fat, diluting with eight times as much predigested gruel for the first two weeks, and six times as much for the last two. The formulas for such food, prepared from an average milk, are:—

(A) 2.75 per cent. fat, 0.50 per cent. proteid.

(B) 3.66 per cent. fat, 0.66 per cent. proteid.

Don't add any sugar the first two weeks, as colostrum contains only 4 per cent. sugar. The per cent. of proteid here is far from corresponding to the amount of proteid in colostrum. It is, as said before, impossible to modify cow's milk in such a way as to obtain as high a per cent. of soluble proteid (or albumin) as is found in colostrum; therefore, the only thing to do is to reduce the insoluble proteid (casein) of cow's milk to a figure corresponding to the same in mother's milk.

106 South Street.

PHYSICAL EXAMINATION, THERAPEUTICS, AND RESULTS OF MODERN MEDICINE. A Plea for More Accurate Physical Diagnosis.*

By WARREN SCHOONOVER, Jr., M.D.,
NEW YORK.

NSTRUCTOR IN MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING PHYSICIAN TO THE NORTH EASTERN DISPENSARY, DISEASES OF THE HEART AND LUNGS.

The competition thrust upon us by grandmas, nostrum agents, prescribing druggists, patent medicine makers, quack physicians, the patient himself, and, in short, everyone, should make us alive to the thought that something is radically wrong with the laity's opinion of our skill, and this itself leads to the depression of our finances. I had almost forgotten to mention what thrives in the large cities, the ten, twenty-five and fifty-cent doctor. With all these we must compete, not forgetting the hospitals, clinics, and free dispensaries, which are numerous and attract crowds, notwithstanding the efforts to keep out all but the worthy poor, which are, in the main, futile.

Now what makes all this obtain? We will say, careless examinations of patients by the physician, not that any of us would intentionally be guilty of any such breach of contract with our clients—but cursory examinations make poor diagnosis and prognosis and furnish a bad standard on which to exhibit any therapeutic measures for the relief or cure of disease. This is the reason why people wander from hospital to hospital, clinic to clinic, dispensary to dispensary, and physician to physician, seeking in vain for aid for their ills, and it is the prime cause for the physicians losing patients and fees.

We will instance what is meant by careless examination—the patient goes to see a physician, giving a history of the case, and the physician inquires into the condition of the bowels, sees the tongue, takes the pulse and temperature, inquires about the sleep, and takes the fee, and if luck attends the medical man the patient, perhaps, gets well. This, to a great extent, has been heard from patients whom we all see, and we see the great field for patent medicines which, when taken by the dozens of bottles, are supposed to work marvelous cures. Maybe through improper teaching, unknown normal characteristics and signs the physician is to prescribe in exactly the above way, and many a patient has run to different medical men with the same result until meeting the expert diagnostican; then, and then only, by proper therapeutic methods, has been relieved or cured.

The cause of cursory examination is the improper teaching of physical diagnosis in our medical schools, more especially in undergraduate colleges, although there are exceptions to this as to every rule. The student is not given ample acquaintance with normal signs and sounds, especially those of the breast and lungs, and this being true, how can he be expected to differentiate from them diseased conditions? An instance of this is afforded in the following: A physician, freshly graduated, came to one of our post-graduate institutions to take a course in general medicine; in course of time he was given a perfectly normal case to examine and the suggestion made to pay particular attention to the heart, the result of his examination gave every pathological cardiac condition possible, except rupture of that organ. Again, I myself have had students tell me that they have felt, seen, and heard, conditions that were positively present, although it was plain to me that they did not—they were too modest to follow the old motto "If at first you don't succeed, try, try again."

All this ought to be changed, and the student should be taught thoroughly the normal physical signs, those of the organs not only of the chest, but also of the abdomen and pelvis, and they should use instruments of precision. The physician, who has been carelessly taught physical diagnosis, should endeavor to teach himself or be taught normal physical diagnosis, and when expertness in that subject has been reached, then, and only then, start in and study and learn pathological physical diagnosis. This, in my opinion, is the way that the physical examination of the patient should be taught in all our medical colleges; but is it so at present?

During our visit with the patient I believe that, following the subjective examination of the case, we should also make a careful objective one, going through a systematic routine of the suspected field: (1) Inspection, (2) palpation, (3) percussion, (4) auscultation, and (5) any other means necessary to afford an exact diagnosis, such as mensuration, urine testing, both microscopical and chemical, the use of the sphymograph, etc., and should not diagnosticate a condition on the subjective examination only plus the five cardinal points of pulse, temperature, bowels, sleep, and tongue.

In inspection, the examiner should not, as we have times without number noticed, stand in front of the patient and inspect only the anterior surface, but he should survey the body from all points noticing every minute sign. And on palpation, nothing is gained by laying on of the hands heavily, as we have seen done.

Percussion seems to be one of the bugbears of the medical man, and the method of percussing from the whole arm, as I have often seen, is to be deplored, for the only rational and resonant tone is produced by striking from the wrist alone. We be-

* Read before the Mt. Vernon Medical Society.

lieve the use of pleximeter and percussion hammer to be far superior in most hands to the system of using one hand as the hammer and the other as a pleximeter.

Auscultation by some having a very acute ear can be practised to a great extent by that organ alone, but even here the use of a first-class stethoscope, phonendoscope, and other instruments of that type with well-adapted ear-pieces, serves the purpose far better for most of us than the human organ of hearing alone.

By means of instruments of exactness the expert can make the diagnosis of pulmonary tuberculosis from one to six months before the *x*-ray has shown the evidences of the disease. Sometimes we get vague histories, incomplete, and maybe no history at all in cases—as when the foreigner seeks our aid and he speaks not our tongue, neither do we his—and in such class of cases we have to depend on physical examination alone as a basis of diagnosis, prognosis, and treatment. The following case is cited: A man, about 45, born in Turkey, no history obtainable. Inspection: Chest emaciated, breathing difficult; chest moves as one piece, barrel-shaped, myodœma. Palpation: Increased vocal fremitus. Percussion: High-pitched and short percussion note. Auscultation: Prolonged inspiration and expiration, high-pitched crepitant râles, rough in character; increased vocal resonance. Taking all these signs, we diagnose his case as one of emphysema, and also make a prognosis.

Now what are the indications for treatment, and how are they best met? Improve breathing by gymnastics and massage; remove mucus by expectorants; to remove thickened tissues use iodides; to build up the body give food; as regards climate, moderate elevation is best. I have cited this case to show how important is physical examination, not only in diagnosis but also in prognosis and treatment.

Now as to therapeutics. Numerous as are our cases and troubles, none is worse than the agent who fills our waste baskets with literature and our offices with samples. Some of these compounds, no doubt are good and are being used and deservedly, but in the long run, diet, exercise, and the use of old and tried remedies of the Pharmacopœia, in short, intelligent therapeutics, with a few grains of common sense are far better for your patients and we know why we attain results. The materia medica of the Pharmacopœia has not been tried and always found wanting, therefore let us not get the craze of wading in the sea of nostrums, but stick to the old manner of writing prescriptions, and thereby knowing what our patients are using, until something infinitely better attains; when it does we may use it. The reason for the popularity of the nostrum is that it is more pleasant to take, pleases the æsthetic eye, the druggist or chemist does the thinking, etc., but we can meet those demands by a little more careful prescribing and addition of aromatics.

In giving directions to patients, be clear, and it seems to me better not only to explain why you are using certain methods, but also instead of telling them to take a medicine so many times a day or at intervals of so many hours, to indicate the exact times it should be taken. If you do so, the patient will aid you very materially. Do not do, as a friend of mine did in explaining to a lady about chlorosis and after a thorough explanation told her, "Madame, you want to get blood," whereupon she exclaimed, as she suddenly left him, "But, doctor, I could never drink that." Another time, a near relative of mine, while attending a clinic for rheumatic conditions, was consulted by an old Irish lady, who was rather dull of comprehension, and she was told after he had prescribed for her and handed her the prescription to rub this on the painful joint thoroughly. About one hour after, upon leaving, he noticed her still there and inquired of her the cause; when she told him that she had rubbed the knee thoroughly with the paper with no result whatever.

These are simply brought forward to show how very important it is to have the patient thoroughly understand what should be done and how to do it, in the line of exhibiting not only medicines, but also all therapeutic aids which may obtain in the particular case, and you yourself should be sure that he thoroughly understands everything that you have explained and told him to do just as well as you know your indications and how to meet them.

Some years back cardiac diseases were a cause of great worry and fright to the laity as well as to the profession, but at present they are handled so successfully by the physician that the patients live on under proper therapeutics until the end of the term of their natural life, without much difficulty from the diseased organ. Sir Andrew Clark had numerous patients with heart disease which lived to green old age without any particular disability. In the practise of an esteemed colleague and teacher was a case of aortic stenosis, which was under the care of his grandfather from 1830 to 1856, his uncle from 1856 to 1882, and himself from 1882 to 1893, when the patient died at the age of 93, having been under the care of the first physician for twenty-six years, the second for twenty-six years, and the third for eleven years; a total period of 63 years.

This has been brought about by careful experimentation and study of those conditions, the indication for and means of combating them, and the same is true in all other departments of medicine at the present day. The percentage of deaths is being brought down in most all diseases, and this because more careful examinations are being made and proper therapeutic treatment instituted, so that at the present writing we find that in pneumonia under the creosote treatment the percentage of deaths is from five to eight. But physicians do not want to see a death rate in all diseases of nil, because if there was no fear of dying, we would be in fear of starving; nevertheless, it is our duty to study out all diseased conditions not only from the preventive side, but also for the purpose of curing every one we possibly can.

My deeply respected colleague was invited to read a paper on typhoid fever at an occasion of this kind, and in it brought forward that he had 2 per cent. of deaths; when in the discussion that followed it came out that in a county of 13,000 people, according to the statements of the different physicians practising there, every man, woman, and child had had typhoid during the year at least three times each and none of them had died.

None of us probably is as lucky in results as that, but in time to come we may be, and it all rests on the basis of exact physical examination and exact therapeutics, and as we gain that goal, fellow-students of medicine, then will our results shine as the stars in the firmament and our profession will move onward to reach the height of an exact science.

I have not dwelt any upon the results of modern medicine, for that had be left to each of us to add his quota and to take an active part in producing better results than we are doing. Then, and only then, will our newspapers, fences, walls, and houses be bare of medical advertisements. In conclusion, knowing that diagnosis, prognosis, and treatment depend mainly on physical diagnosis, let me register a plea for the better teaching and more expert practice of physical examination.

ACUTE APPENDICITIS OCCURRING ON THE EIGHTH DAY OF A TYPHOID FEVER. OPERATION. RECOVERY.

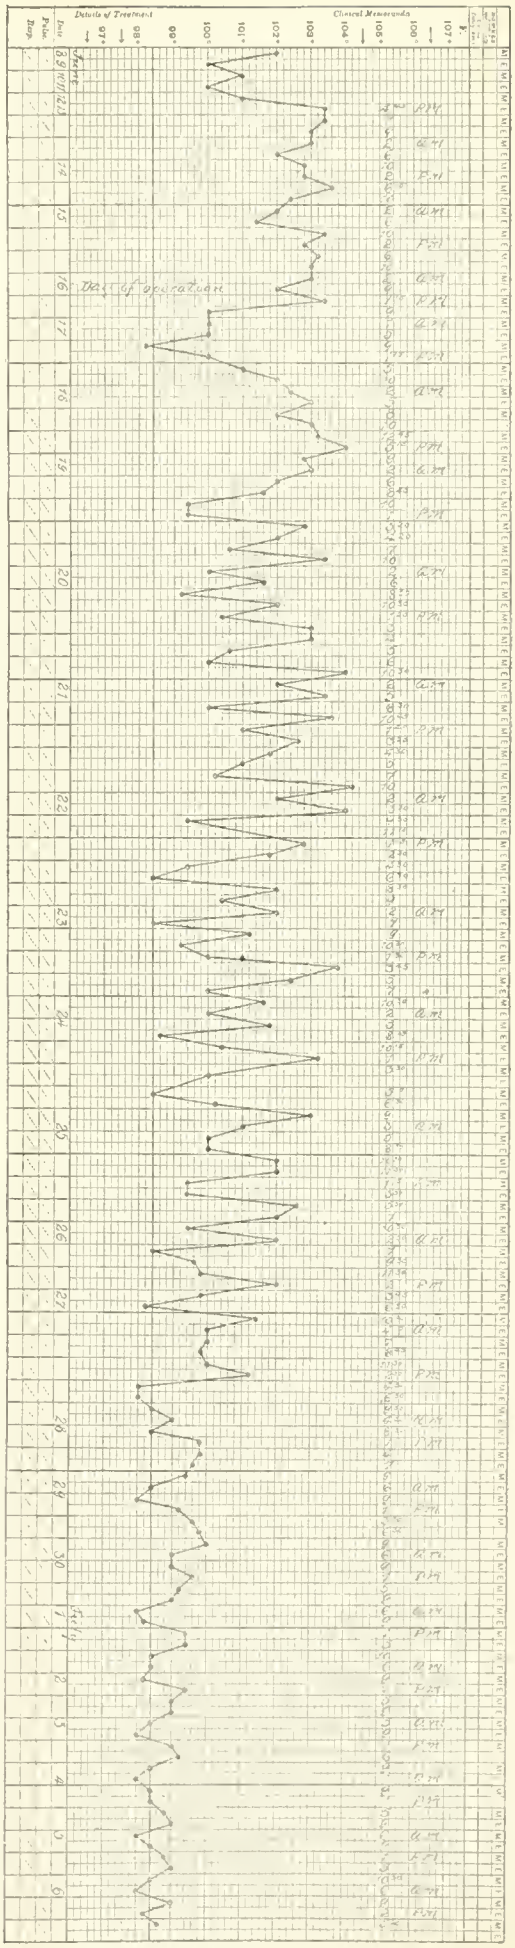
By GEO. HERBERT WILLIAMS, M.D., M.R.C.S., ENG., L.R.C.P., EDIN.

FISHKILL-ON-HUDSON, N. Y.

VISITING SURGEON TO HIGHLAND HOSPITAL, MATTEAWAN, N. Y.

On June 8, 1904, I was called to see Miss D. F., a well-nourished girl. She gave a history of having been sick for four days previously. The patient complained of severe headache and neckache, the pulse was 110, and the temperature 102°. The bowels were constipated, the tongue was coated, and one or two suspicious spots were to be seen on the right side of the abdomen. The patient was given twenty one-tenth grain doses of calomel at fifteen minute intervals, followed in two hours by an aperient. Then two grains of bisulphate of quinine every two hours. A strict milk diet was enjoined. At my morning visit the following day, the temperature had fallen to 100°, several movements of the bowels had been obtained, the pulse was 92. Headache and backache were unrelieved. Quinine was continued. On June 10 the temperature was 101°, the other symptoms were the same.

On June 11, the temperature was 100°, and a few additional spots were found on the abdomen. The patient still complained of severe headache and backache. On June 13, the temperature was 103°. On examining the abdomen, the spots were still evident, and two or three more were present on the lower part of the chest. For the first time the patient complained of pain in the right side of abdomen, and pressure over McBurney's point elicited a good deal of distress. I advised that the patient be removed to Highland Hospital for more careful observation. On her arrival, the temperature had risen to 103.4°. Medicine and diet were continued as before, and an ice-bag was applied over the appendical region. During the next three days the temperature varied between 102° and 103.4°, there was increased pain on pressure over McBurney's point, a slight increase in number of spots. The patient had an anxious and distressed look, but retained her flesh well. The pulse was rapid, but of fairly good volume. On the twelfth day of the fever, at my evening visit, I found the temperature 103.4°, more pain on pressure, and some decided rigidity of the right rectus muscle. I



advised operating. With the assistance of my colleagues, Drs. Doughty and McClintock, the operation was done on the thirteenth day of the fever. After the peritoneum was incised and the cæcum drawn up and out of the wound, the appendix presented itself, standing up in the wound like an inflated rubber finger cot. It was quite congested and enlarged in caliber, and about 4½ inches long. The omentum was sutured and the appendix amputated, the wound being closed in the usual manner. The appendix was carefully examined, and cut up on a director; the mucous coat was soft and broken down, and the outer two inches contained a considerable amount of pus. The operation was done on the afternoon of June 16, and the temperature during the night fell to 100°, and at my morning visit on June 17, at 9 o'clock, it was 98.2°. During that day it rose again, and at 5 o'clock on the morning of June 18 it was again 103°. Going up during the day, it reached 104° at 5 p. m. From this time on, as the chart will show, there was a more or less regular typhoid run of fever, with its usual smyptoms. Quinine was given every four hours, and strychnine sulphate (1-50 gr.) every four hours. Surgically, nothing of interest occurred, the superficial stitches were removed on the seventh day, and a good, strong, healthy wound was found. On the twenty-fifth day the temperature went twice to the normal point, and after that, during convalescence, did not vary much.

I have thought the case worthy of record, as I have never seen or known of the two diseases occurring together, and I think the coincidence must be very rare.

Why the temperature went to subnormal even for a few hours, the day after the operation, I am at a loss to understand, unless is was that the appendix was so large an additional focus of infection, and its removal so relieved the system that the fall occurred for a short time.

The patient left the Hospital on July 20, entirely recovered.

Broncholithiasis.—D. Braden Kyle reports a case of this unusual condition, his patient being a woman of thirty-eight years, who, for the five years before coming under observation, had had a hacking cough with a sensitive spot on the left side of the chest, in the second space slightly to the left of the parasternal line. Coughing came on in paroxysms, during which a lancinating pain was felt in the sore spot. There was no hæmoptysis and no dyspnœa, except at the coughing spells. No tuberculosis could be made out. In one of the attacks a hard, irregularly formed, oblong body, about .5 x .8 cm. in size, and bony in appearance was expelled. The surface was uneven, with four small crests and one deep excavation. The analysis showed its composition to be calcium and magnesium phosphate, combined with a small quantity of calcium carbonate and organic matter, which are the most usual elements found in bronchial concretions. The attacks of cough and the chest tenderness did not occur after the stone was expelled.—*The Laryngoscope.*

Abdominal Myomectomy.—V. Cocq declares that the treatment of uterine fibromata has given rise in the last fifteen years to many diverse opinions. At one time, conservative gynecologists thought that they had found in electrotherapy a powerful aid. But the results of this treatment were not what had been hoped for. Those at the present time who are advocates of the expectant treatment are in the minority. The greater number of gynecologists agree that it is better to operate when the conditions are good than to wait till they are changed, till the patient is anæmic. The treatment of fibromata is essentially surgical, and the necessity for operation is realized more and more. Total or partial hysterectomy has more advocates than have other methods. The benign character of fibromata seems incontestable if one considers the origin, structure, and etiology of the tumor. The writer believes that the indications for myomectomy are very limited. Myomectomy is really indicated only when the fibrous nodules are few in number, small, and when the patient is still far from the menopause. This last condition is rare. Statistics show that fibromata are far less frequent in young subjects. It can be seen that it is only in very rare cases in which conditions are favorable for enucleation of the tumor without extirpation of the uterus, that the operation under consideration would be the method of choice. The operation when undertaken is conducted like an ordinary laparotomy.—*Gazette de Gynécologie.*

Decrease of Population in France.—It appears that it is not alone the question of race suicide that is troubling the sanitarians of France, but also the terrible increase in the death rate. According to *The London Telegraph,* Dr. Lowenthal, who is a member of the commission which is investigating the causes of the shrinkage in census returns is not exaggerating when he says in a recent article that, "alcoholism alone is killing France." Tuberculosis, he continues, which of all diseases is the most easily avoided, is raging in France with more violence than in any other country in the world. Every year it kills more than 150,000 victims, and contaminates more than half a million more. Then typhoid, typhus, dysentery, scarlatina, and other diseases and infectious maladies, which are decreasing in England, Germany, Switzerland, Belgium, Holland, Sweden and Norway, the United States, and even in Italy, are, on the other hand, remaining at a very high average in France, some even displaying a marked tendency to develop. Smallpox, which has nearly disappeared from every civilized land, continues to make thousands of victims in France, and hecatombs in her colonies. Such is the gist of Dr. Lowenthal's article, and it cannot be said that he is inclined to be unduly pessimistic.

Alcoholism in German Schools.—How widespread is the consumption of alcoholic beverages throughout Germany is well shown in a recent paper by Dr. Goldfeld, which is quoted in *Harper's Weekly.* Its subject is the prevalence of alcoholism among the school children of Germany, and the author believes that the situation is serious and should be brought to the attention of the parents by means of addresses at meetings and by the distribution of essays on the evil effects of alcohol. The investigator is medical officer of the public schools of Schöneberg, a suburb of Berlin, and his examination included 967 children, 470 of whom were in a boys' school and 497 in a girls' school. Of these, 496, or 51.3 per cent., were accustomed to drink from one to two glasses of beer daily, while 299, or 30.9 per cent., took spirits more or less frequently. The favorite beverage was malt beer, but all kinds of beer and various kinds of spirits were taken, the sweeter liquors being preferred by the girls. Dr. Goldfeld was informed by the teachers that the children addicted to the use of spirits were especially lazy, absent-minded and inclined to lying. Neither children nor parents heeded Dr. Goldfeld's warning.

Manufacture of Vodka in Russia.—Measures adopted by the paternal forms of government sometimes lead to curious results. According to *London Tit-Bits,* a remarkable scene was witnessed a few years ago, when the tsar of Russia ordered that the private manufacture of vodka (the national drink) should cease, and that the business should be taken over by the state and conducted on temperance lines. The new state monopoly was inaugurated in a remarkable way. Priests attended at all the drinking shops by official command, and conducted special services. The public houses were dedicated to God and prayers offered that under the new régime drunkenness might be abolished and the spiritual welfare of the people improved.

Medical Record.

A Weekly Journal of Medicine and Surgery.

New York, December 3, 1904.

THE SANITARY BACKSLIDING OF CUBA.

There have been for some time persistent rumors of the reappearance of yellow fever in several of the Cuban towns, and three cases have been officially reported within the past month by the U. S. Public Health and Marine Hospital Service. These three cases were not imported from Mexico, but are said to have originated at Punta de Sal in Santiago Province. If this is true—and a despatch from Havana says that Dr. Finlay, chief of the Cuban Board of Health, admits that at least one case originated on the island—it is a matter of grave importance. The disease cannot arise *de novo*, and if one case has originated at Punta de Sal there must have been a previous case, and possibly, even probably, a series of cases. This fact, taken with the known filthy condition of Santiago and other towns in the eastern end of the island, is one to cause concern to this country. According to the report of the U. S. Chargé d'Affaires in Cuba, the streets of Santiago are in such a condition as to be most favorable to the breeding of disease germs, and particularly those of yellow fever. It is stated that there is practically no drainage, and that water is allowed to stand in the streets for days at a time. The press of Havana confirm these reports, one paper, the *Discusión*, stating that it is an undoubted fact that sanitation in nearly all the towns of the island is at such a low level that the public health is in danger. The paper declares that this condition of affairs is a blot on the republic and a shame to the Cuban people.

In consequence of these reports, the State Department at Washington has called the attention of the Cuban Government to the necessity of rigid sanitary control of the situation in the island. This action of our government finds warrant in the sanitary article of the "Platt Amendment," which provides that "the Government of Cuba will execute and as far as necessary extend the plans already devised, or other plans to be mutually agreed upon, for the sanitation of the cities of the island, to the end that a recurrence of epidemic and infectious diseases may be prevented, thereby assuring protection to the people and commerce of Cuba, as well as to the commerce of the Southern ports of the United States and the people residing therein."

Perhaps this reminder from Washington and the near approach of the annual meeting of the Public Health Association in Havana will give the needed jog to the Cuban health authorities, who are thoroughly capable but have to struggle against the unsanitary traditions of Spanish officialdom.

TROPICAL ABSCESS OF THE LIVER.

Abscess of the liver being rare in northern latitudes, the text books contain only meager accounts of it. This leads Dr. E. W. Pinkham to give, in the *Journal of the Association of Military Surgeons* for October, his experience as operating surgeon at the Department Hospital at Iloilo during a year from May, 1900. In that time sixteen cases of liver abscess were seen, mostly accompanying or following amœbic dysentery. This series gave seven recoveries and nine deaths. Eight autopsies revealed conditions not discovered beforehand which rendered death certain. In some cases operation gave a measure of relief to symptoms, but could do no more. Considering the emaciated and weak condition of the patients, the tendency of the dysentery to recur, and of the suppurative process to spread, it may safely be assumed that without surgical procedures all the patients would have died. Not more than six entered hospital with a correct diagnosis, the condition being regarded as appendicitis, malaria, acute pleurisy, acute pneumonia, peritonitis, empyema, convalescence from typhoid fever, and delirium tremens with pain in the side. After the surgeons became more familiar with this common complication of amœbic dysentery and were on the lookout for it, the diagnosis was made more readily. The errors in diagnosis, and the total failure to recognize the disease early, account for the high rate of mortality. In the only two cases where a blood count was possible, no leucocytosis existed, but anæmia was present. In the majority of cases dysentery coexisted. In all the cases without dysentery, recovery took place. In all cases emaciation and debility existed, as the results of the dysentery, the unrecognized abscess, and the climate; and were important factors in determining the fatal issue. In thirty-two autopsies on dysentery cases, liver abscess was found in five. These so-called abscesses are not true abscesses, but rather areas of necrosis, and their contents are liver cells in all stages of degeneration and disintegration, free fat particles, and more or less blood corpuscles and serum. They do not contain pus. Amœbæ were found in eight cases, in some only when scrapings of the abscess wall were examined. In all cases with concomitant dysentery, amœbæ were found in the stools.

In diagnosis the previous history is of the utmost importance. With a history of dysentery of tropical or amœbic type, and an indefinite pain or sensitiveness over the liver on compressing the ribs on the right side, with chills or chilliness, and fever more or less similar in type to that of septic infection, liver abscess may be suspected whether or not the liver is enlarged. If with the above symptoms, dysentery coexists, abscess is almost certain. Aspiration may aid, but it is by no means certain, as many punctures may fail where subsequent operation discloses abscess. Finding the abscess is thus a good deal a matter of luck. It is, however, a good plan, just before operating, to try to locate the abscess by aspiration, as success gives a good guide, and in case of failure no harm is done.

The diagnosis once made, immediate operation is demanded. Whether bulging or not, the abscess should never be evacuated by the trocar and cannula, on account of the danger of infecting the serous cavities. No one can be sure whether adhesions exist or not; most likely they do not. Operation by in-

cision is, therefore, surer and safer. One interesting result brought out by the author's operative experience was the demonstration of the freedom with which one may search through the liver tissue without dangerous hemorrhage. The search should be made with the finger, which seems to slip over the large blood vessels without rupturing them, and not with any sharp instrument. In all cases except the first, the walls of the abscess were curetted carefully with a sharp curette before packing, to remove as much infected tissue as possible.

In two cases with dysentery the colon was entered and irrigated. In Pinkham's opinion this is the best method of treating those obstinate cases of recurrent dysentery which so often baffle medical skill. The most practicable way to accomplish the end is to perform right inguinal colotomy, as recommended by Bolton. It is his belief that a large number of lives might have been saved in the Philippines during the late war had this surgical treatment been adopted. As it was, the antagonism of the great majority of our medical men to the introduction of surgical methods in the treatment of a disease which had hitherto been considered as belonging especially to the province of the physician was too strong to be overcome.

The general cyanosis, regarded by Osler as a symptom of liver abscess, was seen in so many poorly nourished soldiers, suffering from a variety of diseases, especially recurrent dysentery with or without abscess, that it did not seem specially diagnostic of abscess. The swelling at the costal border which he speaks of was present in only a few of Pinkham's cases, generally those of the single abscess type without chills, which almost invariably recovered.

Pernicious Activity in the Consular Service.

Those who are in a position to know tell us that the personnel of the American consular service has greatly improved of late years, and that the "Yankee Consul" is no longer a type of our commercial representatives abroad, even of those vegetating in the fruit ports on the Caribbean Sea. This is well, and as good citizens we are pleased to think that the traveling American need no longer heed the impulse to turn down the first side street when his eye lights on the flag of his country flying over the consulate in some foreign port. At the same time the Secretary of Commerce and Labor would do well not to let the consuls, in their zeal to be doing something, fill their reports with misinformation on matters of health and hygiene. We recently commented on the peculiar report of our consul at Frankfort-on-the-Main concerning the alleged innocence of the oyster in the transmission of typhoid bacilli. This report was published widely under headlines asserting that the oyster could not transmit typhoid fever. Now comes another report, this time from the American consul at Nottingham, of the discovery, by Dr. Stephen Smith, of London, of a means of curing errors of refraction by "manipulation of the eye." The treatment is described as gentle and gradual, a few minutes daily, causing no pain and having no injurious effect of any sort. "Some patients are cured in a week, and in all cases improvement is rapid. Thirty patients who previously had to wear spectacles have so far been treated by Dr. Smith, and with one exception, it is stated, all have discarded glasses and can now read, at either long or short distances, as easily as people who have never needed glasses." The groundlessness of Dr. Smith's claims have been most fully disclosed by the medical press in London. He consented, it was said, to a demonstration of his method under the inspection of competent opthalmologists, but, when the proposal was about to be acted upon, put forward so many conditions and limitations that the investigation, if undertaken, would have been of necessity inconclusive. Yet doubtless many quacks will be prompted by this report of our consul to undertake massage of the eyeballs, and many foolish myopes and presbyopes will submit their eyes to this dangerous manipulation in the hope of thereby being able to discard their glasses. Why an American consul in Nottingham should feel called upon to boom a therapeutic measure advocated by a London oculist, which has never received the approval of any ophthalmologist of note, but has, on the contrary, been condemned by nearly all, we fail to comprehend.

About a quarter of a century ago a British consul in Philadelphia read of an alleged case of trichinosis in Illinois, and hastened to inform his government that the American hog was infected with trichinæ. The hog growers of France and Germany learned of this report and used it to such advantage that laws were passed excluding American swine products from those countries; these laws were effective for many years and resulted in the loss of many millions of dollars to American farmers. This is cited only as an instance of what harm a consul may do by writing about something of which he has no personal knowledge. If our consuls must report on medical matters they should be warned to get their facts from trustworthy sources, and not from the pages of yellow journals.

The Hot Bath in the Treatment of Appendicitis.

Lieutenant Enrico Castelli, writing on the treatment of appendicitis in the August number of the *Journal of the Association of Military Surgeons of the United States*, in the course of his remarks descants on the value of warm balneation in the symptomatic treatment of appendicitis. The warm bath, according to the author, produces a general tonic sedative effect on the nervous system in all states of asthenia; it equilibrates thermogenesis; it decongests the internal organs, and relieves all pains of a colicky type; besides, it has an antitoxic effect, since it increases the reactive processes of metabolism, produces free exudation, also relieves the ischuria paradoxa—a symptom not uncommon in all infectious diseases. In appendicitis, the author prescribes the bath at any period of the attack, and during it the other symptomatic and causal treatments are producing their effect, because it not only does not interfere with their action, but, on the contrary, becomes to them a useful adjunct. The temperature of the water should vary from 81° to 95° F. During the bath small doses of cold champagne are administered. Pain and the general condition of the patient form the only guide to the use and length of balneation, as well as to its repetition as often as may be thought necessary.

Lieutenant Castelli does not claim that the hot bath relieves pain; on the contrary, it may increase the pain to the highest degree, but such a recrudescence must constitute a warning for the physician, showing, as it does, the presence of pus in the region of the appendix. In other words, an increase of pain in such a case is the clinical equivalent of suppuration. As an adjunct to the relief of coprostasis, Castelli administers at the beginning of the attack an enema of about a pint of 5 per cent.

saline solution at a temperature of 65° to 75° F. to be injected at low pressure. This enema is to be repeated every twelve hours, equal parts of sulphate of sodium being added to the chloride of sodium, and thus continuing until the watery discharge becomes colorless.

In Lighter Vein.

The annual burlesque supplement of the *Münchener medizinische Wochenschrift* is always a source of joy to the discerning, and this year's number is just as amusing as its predecessors have been. The ofttimes pedantic ponderousness of the Teutonic scientific communication lends itself admirably to caricature, and that there are not wanting in the Fatherland unregenerate spirits quick to put the thumb of derision to the nose of scorn is attested by the contents of this *Scherznummer*. A pompous dissertation on general anæsthesia elucidates the author's discovery that the active narcotizing principle of ethyl chloride resides in its refrigerating powers, and after numerous costly experiments it was found that champagne formed the most satisfactory vehicle for administration. By spraying the bottles with ethyl chloride the active principle of cold was imparted to the contents and it was found that complete anæsthesia could be pleasantly produced by taking the anæsthetic by the mouth, though the after-effects, consisting in a tendency to somnolence and cephalalgia, were somewhat disagreeable. An admirably executed *x*-ray picture, consisting of an absolutely uniform rectangle of printer's ink, serves as a text for an enthusiastic description of a new type of fracture of a metacarpal bone, and the fonetik orthografists receive recognition in an essay on "Kiuretaszh of the serviks," in which such writers as Hauard Kelli and Pastöhr are quoted.

The most important contribution in point of length is a novelette setting forth the fall from grace and subsequent expiation of Eosinophila, a beautiful but wayward leucocyte, remarkable for the charming delicacy of her nuclear network and the grace of her pseudopodia, who falls in love with a bold, bad epithelial cell in the cornea and thus acquires dangerously socialistic tendencies. An excursion to the pyramids (in the cortical zone) serves only to inflame her rebellious spirit, but she finally dies a glorious death in a pitched battle against the cohorts of the gonococcus, and having been expelled from the urethra in a drop of pus, her dead body may be seen beautifuly stained red and blue in a mausoleum of balsam on a microscopic slide. Quotations from Faust throw a medical sidelight on many passages usually considered innocent of any esoteric meaning, and a newly-discovered fragment of the Odyssey describes in faultless hexameters the reward of Dakryokrates, a worthy Attic opthalmologist. After he had cured the eye of Polyphemus, wounded by the sage Ulysses, Poseidon, in gratitude, commanded the west wind to bear his high-prowed ship to the land of the Ophthalmodonts, a paradise for oculists, where all the inhabitants have thirty-two eyes and only two teeth. In consequence they eat but little, and owing to the sharpness of their vision all but dentists acquire huge wealth. The king of the land had cataract in every eye, his lovely daughter was a sufferer from strabismus to an equal degree, and the subjects were correspondingly afflicted, so that the happy Dakryokrates had his work cut out for him.

Other original articles, society reports, book reviews, and advertisements in abundance hold the mirror up to medical nature, and in good-humored satire point out some of the foibles of our calling.

News of the Week.

Changes in Management of the State Hospitals.—It is stated that Governor-elect Higgins is not in accord with Governor Odell as regards the management of the State hospitals, and it is announced that he will recommend, in his first message to the Legislature, the reestablishment of the local boards of managers for State hospitals for the insane, and transferring from the State Commission in Lunacy to such local boards all the administrative powers and responsibilities which they had when abolished, except those strictly financial. Under the old law the local boards had the right to say how the patients should be fed, how clothed and cared for, and who should feed, clothe, and care for them. He would also make the State Prison Commission an unsalaried board, as contemplated by the Constitution, and a board of philanthropic expert men and women, having full powers of inspection and recommendation. He would make a State reformatory out of the State institution at Napanoch, which would then have its own local board of managers. The institution is now under control of the State prison department. Finally, Mr. Higgins is said to favor increased appropriations for the enlargement of State institutions for idiots and feeble-minded, and securing the removal of all this unfortunate class from the county almshouses.

Fourth Pan-American Medical Congress.—Dr. Rudolph Matas, of New Orleans, secretary of the Section of General Surgery for the United States, writes that a United Fruit Company steamer will leave New Orleans for Colon on Wednesday, December 28, 1904, at 10 A.M. (instead of Friday, December 30, as previously announced) which will reach Colon (Panama) on Monday, January 2, 1905, the opening day of the Congress. Those who intend to go this way are requested to write to Dr. R. Matas, No. 2,255 St. Charles avenue, New Orleans, La., not later than December 22, 1904. The routes to Panama are gradually narrowing down to a select few as more advantageous rates are offered. Those who go only to the Pan-American Medical Congress will probably go and return by the way of New York or New Orleans. From the former starting point $100 will be charged for the round trip; from the latter $50. The Di Giorgio S.S. Line, of Baltimore, Md., offers a special ship for the exclusive use of the party, including meals and berth at sea and in ports, to Colon, Havana, and return, visiting Kingston and Port Antonio, Jamaica, for $130, providing fifty persons take passage. The Athos will leave Baltimore December 27, arriving at Colon January 2 or 3; leave Colon January 7, and arrive in Havana January 9; leave Havana for Jamaica January 14, and arrive at Baltimore January 18. The members of the party can live on board when in port if they desire, thus saving hotel expenses. Lunch and dinner will be served on deck when in smooth waters. Physicians can bring members of their families and friends at the same rates. All arrangements must be closed ten days before sailing date. The number of passengers is limited to seventy. Applications for reservation of staterooms, berths, etc., should be made to Ralph F. Nolley, 103 Park avenue, Baltimore, Md.

A Filtration Plant for Manhattan and The Bronx.—Work on the Jerome Park reservoir has been suspended by the Aqueduct Commission pending a consideration of the advisability of building a filtration plant. Plans and estimates for the plant are now being prepared by Chief Engineer J. Waldo Smith. The cost has not yet been figured out, but a similar system of filtration beds for the cleansing of

the inflow to the Philadelphia reservoirs cost about $22,000,000.

No Canteen Legislation.—Mr. Hull, chairman of the House Committee on Military Affairs, is reported as stating that there will be no legislation in Congress this session looking to the reëstablishment of the army canteen. He thinks the present system has not been running long enough to permit of a decision for or against its practicability.

German Tuberculosis Commission.—The imperial commission appointed to investigate the relations between human and bovine tuberculosis met on November 25. Dr. Weber, one of the members of the commission, reported that the investigations made showed that human and bovine bacilli were absolutely distinct biologically, and that one never develops or changes into the other. Several cases of mixed infection with both organisms in man were reported and the commission urges the exercise of all possible precautions to prevent infection with the bovine bacillus.

The Inauguration of Dr. Charles W. Dabney as president of the Cincinnati University was celebrated on Tuesday and Wednesday of last week. On Tuesday evening Dr. Dabney was given a public reception at the University buildings. The inauguration ceremony took place at Music Hall Wednesday morning and was preceded by a parade of the student's alumni and faculty of all departments with visiting officers of other universities, numbering in all 2,000 persons. President Jones, of the University Board, presided and introduced Dr. Dabney. Judge Thompson, of the United States Court, administered the oath of office. Addresses of welcome were then made by Mayor Fleischman of Cincinnati, Governor Herrick, and Dean Joseph Edward Harry, on behalf of the faculty. Drs. Wm. L. Dudley, of the Medical Department, Vanderbilt University, and Wm. O. Thompson, president of Ohio State University, made congratulatory speeches. Dr. Dabney then delivered his inaugural address. Other addresses were delivered by Dr. Wm. H. Welch of Baltimore, Judge Rufus B. Smith of Cincinnati, President H. F. Pritchett, and the presidents of Cornell and the College of the City of New York. In the evening a large banquet was given, with addresses by many prominent men.

Civil Service Examinations for Physicians.—The fight of the medical profession against the establishment of civil service examinations for physicians seeking appointment on the Cook County Hospital staff, Chicago, came to a partial climax November 25, when the County Board decided to rescind its action of October 31, placing the medical staff under the control of an examining board. The president of the Board, Mr. Foreman, vetoed the rescinding vote, but whether the veto will be effective is a question which may call for a judicial decision. Those who fought against the plan for placing the members of the County Hospital staff under civil service alleged as their chief argument that the examining board, as appointed, was dominated by Rush Medical College, which is affiliated with the University of Chicago, and that applicants for positions on the staff, graduates of other colleges, might be discriminated against.

Cincinnati Society for Medical Research.—At a meeting of this society, held at the Cincinnati Hospital November 17, the following papers were read: Dr. J. H. Schroeder spoke of a new method of his for locating the greater curvature of the stomach. He had the patient swallow the stomach-tube, into the end of which an electromagnet was fastened, and then located the magnet in the greater curvature by means of a magnetic needle in front of the abdominal wall. Dr. A. Faller read a paper on the Widal reaction, and reported twelve cases with a positive reaction when typhoid fever was absent. Dr. M. L. Heidingsfeld demonstrated lantern slides from a case of porokeratosis. He said that after careful study he considered this a symptom of several diseases, and not a distinct disease in itself.

Cincinnati Academy of Medicine.—At a meeting of the Academy, November 7, Dr. C. R. Holmes, of the new City Hospital Commission, read a paper on Hospital Construction, with special reference to the needs of Cincinnati. He favored the pavilion plan of hospital and showed photographs of many hospitals built on this plan at home and abroad, notably Eppendorf Hospital, at Hamburg. He also spoke of the advantages of having the hospital located outside of the city, or at least outside of the crowded part of the city. The new site purchased by the committee is near the geographical center of Cincinnati, but out of the crowded portion and on an eminence overlooking the business portion of the city.

National Association for the Study of Epilepsy.—At the fourth annual meeting of this society, held in Boston, November 22, the following officers were elected for the coming year: *President,* Dr. W. P. Spratling, of Sonyea, N. Y.; *Vice-Presidents,* Hon. W. P. Letchworth, LL.D., of Portage, N. Y., and Dr. Max Mailhouse, of New Haven, Conn; *Secretary and Treasurer,* Dr. Everett Flood, of Palmer, Mass.; *Chairman of the Executive Committee,* Dr. Wm. N. Bullard, of Boston. The next meeting will be held in New York City in November, 1905.

A Convalescents' Home for England.—An English newspaper says Andrew Carnegie has purchased, or is about to purchase, for $3,750,000, Lea Park, the late Whitaker Wright's estate in Surrey, with the object of establishing a national convalescent home. If this report is true it would seem to indicate a change of heart in the donor, who has hitherto been supposed not to favor the giving of money for hospital purposes, his large gifts being chiefly to promote educational objects, if one may so characterize free libraries.

Ohio State Laboratory.—The Ohio State Board of Health will soon throw open its laboratory, chemical and bacteriological, at Columbus, to all the certified physicians of the State. Now only samples submitted through the health boards are accepted and worked out by the department. There is some apprehension that the laboratory may be overwhelmed with work, but if such proves to be the case, the Legislature will probably provide means for a larger force.

The Prevention of Smallpox.—Dr. Benjamin Lee, secretary of the Pennsylvania State Board of Health, points out in his annual report, just submitted, that during the year ended November 1, there were reported in the State 5,172 cases of smallpox, with 521 deaths, which is in marked contrast with the experience of the German army, in which, since vaccination and revaccination were made compulsory, thirty years ago, there has not been a single death from smallpox. In the city of Philadelphia, as a result of an active vaccination crusade, the number of cases of smallpox has been reduced from 396 in December, 1903, to 26 in June, 1904, and in Pittsburg from 537 cases in October, 1903, to 15 in March, 1904. At the present time there are only 42 cases throughout the entire State.

Attempt to Victimize a Physician.—A Brooklyn physician received a call last week from a well dressed young man who said he had come to await

his father who had met with an accident and would arrive in a few minutes. He was shown into a waiting-room while the doctor attended to another patient, but when the latter had departed the young man could not be found, until the doctor with his servants searched the house and discovered him in a bedroom on the second floor. After he had been taken in custody it was discovered that he had first made an ineffectual attempt to play the same trick in the office of a near-by dentist. The police reports show that twenty-four physicians and dentists in the Bergen street precinct have been robbed in the last month by a young man using similar tactics.

West Side Free Bath Opened.—The new free public bath in West Forty-first street, near Ninth avenue, was formally opened last week. The building, which cost about $110,000, contains 101 shower baths, of which 29 are for women, and ten tubs devoted exclusively to the use of the aged and infirm of both sexes. There are eight male and eight female attendants. This institution is the second of its kind to be opened in this borough, the other free public bath being in Rivington street. Besides these there are others under construction in 109th street, near Second avenue; in Allen street, near Rivington; in West Sixtieth, in East Seventy-sixth, in East Eleventh, near Avenue B, and in East Twenty-third street at the East River. Appropriations for three more have been granted, but the sites have not yet been determined upon. In the baths in West Sixtieth and East Twenty-third streets there will be swimming pools for both men and women.

The Samuel D. Gross Prize of the value of twelve hundred dollars will be awarded on January 1, 1905, "to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations." The competitor who receives the prize shall publish his essay in book form, and shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery; on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery. The essay, written by a single author, an American citizen, in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 South Thirteenth street, Philadelphia," on or before January 1, 1905. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize. The trustees are Drs. John B. Roberts, William L. Rodman and William J. Taylor.

The Ninth District, Ohio, Medical Society held its annual meeting at Portsmouth on November 3, under the presidency of Dr. O. C. Andre, of Waverly. The society is composed of members of the societies of Lawrence, Jackson, Gallia, Pike, Meigs, Hocking, Vinton, and Scioto counties. The following officers were elected: *President,* Dr. Lester Geller, of Ironton; *Secretary and Treasurer,* Dr. J. S. Rardin, of Portsmouth; *Censors,* Drs. O. C. Andre, of Waverly; L. F. Roush, of Pomeroy, and W. R. Moore, of Orland. The next place of annual meeting will be Gallipolis.

Dr. B. Sachs has resigned his position as Professor of Neurology in the New York Polyclinic Medical School.

Dr. H. Newton Heineman will deliver a lecture at the New York Polyclinic Medical School and Hospital on Monday, December 5, at 2:30 P. M., on "The Nauheim Treatment of Heart Disease."

Dr. Wm. H. Welch, of Johns Hopkins University, who went to Cincinnati to attend the inauguration of President Dabney, of the University, addressed the students of all colleges at the Cincinnati Hospital on one of the days of his visit. On another afternoon he was given a reception by his host, Dr. Ransohoff.

Dr. Vietor C. Vaughan, of the University of Michigan, will address the Philadelphia Pathological Society on December 8, at the College of Physicians, on the Relation of Food Adulteration to the Public Health. A reception will be tendered to Dr. Vaughan immediately after the meeting.

The Eastern Medical Society.—At a meeting of the Genito-urinary Section of this Society, in Clinton Hall, on December 6, at 8:30 P. M., there will be a discussion on "Syphilis as Observed in General Practice." At the annual meeting of the Society, on December 9, an address will be delivered by Dr. A. Jacobi.

New York City Sanatorium Barred from Sullivan County.—The Sullivan County Board of Supervisors has denied New York City's application for permission to locate a sanatorium for consumptives in Mamakating. Several days ago the Assistant Corporation Counsel made the application and the Health Commissioner of New York City also appeared before the board and urged favorable action.

Chicago Orthopedic Society.—At the November meeting of this Society, the following officers were elected: *President,* Dr. John Ridlon; *Vice-President,* Dr. John Lincoln Porter; *Secretary and Treasurer,* Dr. Arthur B. Hosmer.

Gift of $100,000 to a New Hospital.—Mr. Otto Young has donated this amount toward the building fund of the McCormick Memorial Institute for Infectious Diseases in Chicago.

Milk Dealers Punished for Adulteration.—Thirty-two Brooklyn milk dealers were arraigned in the Court of Special Sessions in that borough one day last week, on a charge of selling impure and adulterated milk. One man was sent to jail for ten days—the milk he sold was found to be 66 per cent. water. Others were fined from $5 to $100.

Hospital for South Brooklyn.—Steps are being taken by the Brooklyn Samaritan Hospital Association to commence work on a new hospital building for South Brooklyn. It was found that the demands on the dispensary in the basement of the Fifteenth Street Baptist Church, which has been operated by the association for about four years, were so great that it has been decided to start a new hospital.

Appointment from a Rajah.—According to the newspapers a Pennsylvania physician is to remove to India in order to accept the post of private physician to the Rajah Tipe Sahib. Eleven years ago the doctor, while at the World's Fair in Chicago, was instrumental in saving the foot of a young Indian who had been trampled on by a camel, and the young man, who is the new Rajah, takes this means of honoring his benefactor.

Smallpox in Pennsylvania.—An outbreak of smallpox is reported from Morris Run, Penn., where there are said to be over 150 cases of the disease.

Yellow Fever Subsiding in Mexico.—Apparently the recent cold weather on the Gulf Coast has caused a falling off in the number of cases of yellow fever reported from Merida and other points. The Superior Board of Health of Mexico states that the situation is much improved and that there are no cases at Vera Cruz.

Scarlet Fever on Staten Island.—The Board of Health of Concord, S. I., has closed the public school at that place owing to a case of scarlet fever in one of the 650 pupils.

The Plague in Chile.—A despatch from Lima, Peru, states that, while the prevalence of bubonic plague has not been officially declared in Chile, it is asserted that there are cases that the Chilean Government daily conceals in order that steamers may not omit touching at ports at which there are no sanitary regulations. This alleged action is considered a great peril to the Peruvian coast, Panama, and the entire country bordering on the South Pacific Ocean.

Obituary Notes.—Dr. Nelson L. North, of Brooklyn, died suddenly, from pulmonary hemorrhage, on November 23. He was born at Elba, N. Y., 74 years ago, and was a graduate of the College of Physicians and Surgeons in this city, in the class of 1854. He was surgeon to the old metropolitan police from 1861 to 1869. He was a member of the American Medical Association, the New York State Medical Association, and the Kings County Medical Society. He was consulting surgeon to the Methodist Episcopal Hospital. He is survived by a son, Dr. Nelson L. North, Jr.

Dr. Henry M. Lyman, of Chicago, died on November 21 in an attack of angina pectoris. He was born at Hilo, Hawaiian Islands, November 26, 1835. He was a graduate in arts of Williams College in 1858, and in medicine of the College of Physicians and Surgeons in this city in 1861. He served on the Bellevue house staff until the spring of 1862, when he was appointed acting assistant surgeon in the Union Army. At the end of a year a severe attack of malarial fever compelled his resignation from the army, and he then went to Chicago and established himself in practice. He was connected during nearly his entire residence in Chicago with the Rush Medical College, holding successively the chairs of chemistry, physiology, nervous diseases, and theory and practice of medicine, and serving for a time as dean. He was also for several years professor of the theory and practice of medicine in the Woman's Medical College of Chicago. He was president of the Association of American Physicians in 1891-2, and of the American Neurological Association in 1892-3. He wrote a number of works, including "Artificial Anæsthesia and Anæsthetics," "Insomnia and The Disorders of Sleep," "Treatise on the Theory and Practice of Medicine," and was the author of the article on Gout in the Twentieth Century Practice of Medicine. He was for many years visiting physician to the Cook County Hospital and to the Presbyterian Hospital.

Dr. W. L. Newell died at Millville, N. J., on November 27. He was graduated from Jefferson Medical College in the class of 1859. He was a surgeon in the United States Army during the Civil War and for many years surgeon to the Pennsylvania Railroad Co.

Dr. W. L. Coleman died on November 28 in Houston, Tex., at the age of seventy-one years. He was well known for his active labors in several yellow fever epidemics, and received the Howard medal for services rendered during one of these epidemics.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SANITARIANS IN CONFERENCE—REBUILDING OF BART'S—FILARIÆ AND MALARIAL PARASITES TOGETHER—TO COMPARE TISSUES—LYMPHÆMIA—KING'S FUND COMMITTEE OF INQUIRY—BIRTHDAY HONORS—OBITUARY.

London, November 11, 1904.

Yesterday delegates from the public health authorities of England and Wales, to the number of 209, met in London to confer on measures for preventing the spread of infectious diseases by vagrants. There was a good deal of unanimity displayed as to the necessity of greater restriction on the movements of tramps, for the law as it stands is found to be utterly inadequate for the protection of the public. The conference agreed that further powers should be obtained, such as the right of compulsory vaccination on reasonable suspicion of exposure to infection, the right of detention and isolation, the establishment of bureaus for distributing information to authorities through whose areas suspected persons may be likely to pass. The medical officers of health have so often traced fatal outbreaks to tramps that the conference had no doubt that stringent measures were justified and called for. But the speakers recognized the distinction that ought to be drawn between habitual tramps, who never work if they can help it, and honest workmen who only become vagrants in order to procure work. The former are only pests, the latter should have every assistance, and the conference passed a resolution to the effect that the local government board should promote legislation for the establishment of labor intelligence bureaus similar to those at work in some countries. At present our tramp wards herd together honest workmen and lazy tramps, and it is time the distinction was duly enforced. A motion to make the cleansing of persons act compulsory, instead of permissive, was lost, after one delegate had expressed a fear about the Habeas Corpus Act, and that people would begin to think they were inspected too much. He would rely on the spread of education, which appears to me to be the panacea of every obstructive. I quite agree with another delegate, who held that every tramp should be inspected, have a warm bath, have his clothes disinfected, and then be put to work to make some return for the benefits he had received. Why should tramps live in idleness at the expense of honest citizens? Further, why should they train up children in the same evil ways? As to this last question, a resolution was agreed to that the State which takes over the parental rights of paupers should extend the same benefits to vagrants. To object that this is to infringe personal liberty is not worth serious discussion. The Home Office and the Local Government Board asked to have a copy of the proceedings supplied, so perhaps the government may wake up.

The controversy about the scheme for rebuilding St. Bartholomew's Hospital has been revived by the resignation of the treasurer and secretary. Those who so strongly opposed reconstruction on the present site, chiefly on account of its enormous value, though silenced for a time by the report of the Lord Mayor's committee, and the decision of the governors to adopt it and appeal to the public for funds, have again protested. Early in the year the governors sold securities for about a quarter of a million and asked the public to contribute a further half million. The appeal can scarcely be called a success. Only some £40,000 has been received at present, which, with £40,000 promised in advance, seems a very inadequate response to an appeal endorsed by the Lord Mayor and the committee. The authorities of the hospital, however, set about their reconstruction with a light heart, and the new out-patients' department is being erected at a cost of about £120,000. This is a sum which to many hospital reformers will appear an unjustifiable extravagance, but it is to be increased by another £100,000, for a new nurses' home. No wonder that many people are saying that hospital managers throw about their hundreds of thousands as carelessly as other public bodies pile up the debts of the rate-payers.

The governors have applied to the King's Hospital Fund for assistance, but any contribution from that source cannot amount to enough to extricate them from their difficulty. Then, it is remarked that the secretary of that fund all along opposed the present scheme and he exercises great —perhaps too great—influence in apportioning the distribution. Again, the resignation of the treasurer and secretary was thought to indicate dissatisfaction, or worse, and so much was made of this by the opponents to the scheme that Sir Trevor Lawrence (treasurer) has replied. He says the governors are not discouraged, that they are well satisfied with the response to the appeal, which

has reached £84,000, and that the first part of the new building will be finished by the summer of 1906. It is not probable that we have heard the last of the controversy.

The presence of filariæ in the blood, together with malarial parasites, must be a rare circumstance. At any rate, the coincidence was not reported until the last meetnig of the Pathological Society, on the 1st inst., when Dr. C. F. Selons exhibited a lantern slide establishing the occurrence. The patient from whom the film was taken had contracted malaria in India in 1899, and subsequently had many recurrences. He was admitted to St. Thomas's Hospital in an attack. The spleen was enlarged. He had never had any symptoms suggestive of filariæ. Blood films stained by Leishman's method showed numerous parasites of the benign tertian type; at one spot a filaria was also found. No eosinophilia. In filariasis pyrexial attacks ("Elephantoid fever") occur which simulate ague. The question whether the simultaneous presence of the two organisms may explain such attacks is, therefore, of interest. Dr. Graham Forbes asked whether the filaria found was *F. perstans* or *F. sanguinis hominis*. He said that in negroes filariæ were present in about twelve per cent. In three per cent. of these the variety was *F. sanguinis hominis;* in the other nine per cent. *F. perstans,* and the latter gave rise to no symptoms. Dr. Selons replied that the specimen was probably *F. perstans,* but his patient had only been in India where that variety had not been found.

Afterwards Dr. Selons and Mr. Shattuck showed sections illustrating two methods for comparing normal with abnormal tissues under the microscope. They are well adapted for class purposes and especially applicable for studying bone marrow, the central nervous system, and the blood. One plan is to mount a normal section directly under the diseased one without the intervention of a second cover glass, so that by merely altering the focus the two can be examined in rapid succession. There is a microscopic interval between the two, due to a thin layer of the medium. One section is fixed to the slide, the other to the cover glass. In the case of blood two cover glasses are mounted in opposition and then fixed to the slide.

The other plan is by what was called a composite block, *i.e.* a block composed of two, a broad face of tissue being first exposed in each of two blocks, which are then cemented togther in paraffin. Sections are then to be cut at right angles to the plane of opposition, so that by placing them with the line of junction across the field both are visible at the same time.

Mr. L. S. Dudgeon read a full account of a case of acute lymphæmia in a man of thirty-seven, admitted after a month's illness. He was intensely anæmic, with enlarged spleen and liver. Several speakers expressed different views of the case. One commented on the difficulty of determining the nature of the myelocytes by the staining of the granules, and thought perhaps the case was one of myelogenous leucocythæmia. Another referred to the presence of streptococci in the blood in a case which he attributed to terminal infection. Another observed that many such cases were septic. Another held that there was no difficulty in distinguishing between myelogenous and acute lymphatic leukæmia and denied that these cases were septic. Tow others maintained that it is by no means easy to differentiate the two conditions.

The anti-vivisectionists are a little jubilant. They have worried the King's Hospital Fund into appointing a committee to inquire into their allegations against the managers of those charities. The most pertinent of their accusations is that the hospitals divert money subscribed by the public for the support of the wards to the medical schools, and thereby encourage the "torture of animals." This is by no means the only accusation—others too shameful and too obviously false for most of the public, are continually insinuated by the less scrupulous of the antis. It would not matter so much if their statements did not inflame still further the hysterical sentimentalists of both sects.

Howbeit, the inquiry has been entrusted to a committee of three—a lord, a lawyer, and a bishop. All three have the confidence of the public and they will no doubt discharge their duty faithfully. That the opportunity will be seized to repeat all the old calumnies is to be expected. In this respect it would seem to most persons inadvisable for officials of the King's fund to concern themselves, and, so far the chairman's request to Mr. Stephen Coleridge to supply him with particulars might well have been omitted. The committee are to inquire how far the medical schools directly or indirectly benefit their hospitals, and in case they do, whether the return thus made by the schools equals any sum contributed by the hospitals directly or indirectly. Whatever conclusion may be reached you may be sure it will not satisfy the fanatics who see torpedoes in every hypodermic syringe.

Four doctors are included in the birthday honors, each getting a knighthood, viz., Shirley Murphy, M.O.H. for the County Council, Professor Wm. Sinclair, C. H. Marriott, surgeon to Leicester Infirmary, and Major A. Perry, R.A.M.C.

Herbert W. Allingham, F.R.C.S., died on the 4th inst., in his forty-third year. He was on his way to Egypt for the benefit of his health, but succumbed at Marseilles. He lost his wife in January last. He was surgeon to the household of the King, senior assistant surgeon to St. George's Hospital, and lecturer on operative surgery in the school. He had been formerly on the staff of St. Mark's and of the great Central Hospital. He was considered one of the most brilliant of our younger operating surgeons and was certainly one of the most successful. He edited and largely rewrote his father's work on rectal disease. His father, Wm. Allingham, survives him, but has been retired for some time.

The death is also announced of Dr. Vintras, senior physician to the French Hospital, aged seventy-five; also of Dr. B. C. Chandler, aged ninety-two.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

TRYPANOSOMIASIS—FISH POISONING IN SWITZERLAND—SUCCESS OF URETERAL CATHETERIZATION—THE READING HORSE—HARNACK AND HIS MAGNETIC POWER—DEATH OF ABRAHAM AND OF BARTELS.

Berlin, November 1, 1904.

The season opened well for the Medicinische Gesellschaft, for Robert Koch, who has hitherto held aloof, last Wednesday for the first time read a paper before this society. The whole medical world of Berlin listened with great attention for an hour and a half to his discussion of the trypanosome sickness. He said that the importance of infectious protozoa in etiology has but recently been recognized. They are transmitted from one patient to another by means of insects, as, for example, in malaria by anopheles, in Texas-fever by ticks, and in the tsetse fly disease by this insect. Koch described in detail the trypanosome with its flagellum anteriorly, and centrosome posteriorly. The trypanosome causes very different types of disease in different animals. The trypanosomiasis of rats can be communicated only to rats. The rat trypanosome is readily distinguished from the cow trypanosome by its sharp and tapering posterior extremity, that of the latter being more rounded and uneven. The cow trypanosome is also infectious to goats and sheep. In opposition to many other investigators, chiefly French, Koch believes that the tsetse disease of African cows, the surra disease in Asia, and the mal de cadeiras in South America are not in reality different diseases. The clinical picture in these three affections is the same. The animals begin to have fever, grow thin, show a decrease in the red blood cells, present glandular and splenic enlargement, and die. In men this protozoan was first found in the cerebrospinal fluid. Although in the beginning but little importance was attached to this discovery, later it was recognized that in it the cause of sleeping sickness had been found. When the trypanosome is present in the cerebrospinal fluid, the disease is fatal, for no such specific is known for trypanosomiasis of man as quinine for malaria. The German government, Koch maintained, should provide ample opportunity for studying this disease, because of the great losses through the tsetse disease among the cattle of the African colonies. Immunizing experiments have not yet been successful, so those affected must be killed or strictly isolated.

Professor Leyland opened the first meeting of the Verein für Innere Medicin with the announcement of many deaths, among them those of Wiegert and Finsen. He then told of a case of intoxication due to fish which he had observed at his summer home in Pontresina. This is a rare occurrence in Switzerland, because foreigners there avoid eating fish, which must necessarily suffer in its transportation from Ostend and Schweningen, and its inspection is as important as is that of meat.

Casper read a paper on the diagnosis and therapeutics of renal tuberculosis. After enumerating the symptoms, he spoke at length in regard to the diagnosis, referring to sixty cases of his own, and considering especially catheterization of the ureters. Three of the sixty cases required no operation, the disease having lasted four to eight years, and giving no symptoms, and but slight suppuration. But operation is the rule when pus has been found, and in fifteen cases the process proved to be advanced. Operation is contraindicated in general tuberculosis. Neither low vitality nor fever is a contraindication, when the kidney alone is affected. In the case of one young man, for instance, after extirpation of one epididymis and one kidney, the temperature became normal, and the weight increased, even though one lung was affected at the apex. Diabetes is, however, a contraindication, one patient of Casper's dying two months after operation. Weakness of the heart can be combated by saline injections. Tuberculosis of the bladder usually disappears after removal of

the affected kidney. The most important question is in regard to the condition of the second kidney. For this reason a comparison of cases before and after the introduction of catheterization of the ureters is very interesting. Without catheterization in one hundred and twenty-five cases of four operators, there were twenty-six deaths; with catheterization, in one hundred and forty-three cases of six operators, there were fifteen deaths. Before ureteral catheterization, the mortality was 21 per cent., and there were five cases of insufficiency of the second kidney; since its use, the mortality has been 10 per cent., with one case of insufficiency of the second kidney. This shows the effect of better diagnosis, and it is to be hoped that there will be even better results with more general application of ureteral catheterization.

A Berlin institution, which has recently celebrated its twenty-fifth anniversary, can boast of a remarkable development. In 1880 the newly founded Verein für haüsliche Gesundheitspflege sent one hundred and eight weak pupils to grow strong in the country, and by the sea. The Emperor and Empress Frederick were in favor of this organization, as was also the whole Berlin population, for it proved to be the most popular of all charitable institutions. This year a committee of two hundred and forty-six, with the help of two hundred and fifty-three physicians, chose nearly five thousand of the most suitable children, from the twelve to fourteen thousand who made application. Since the resources were not sufficient to provide a whole summer for all, arrangements were made by which children were taken for a day or an afternoon, and their food furnished them. In this way sixty thousand poor children have had a summer vacation in the last twenty-five years.

In the Psychological Society a member requested a paper on the reading horse, which has already been referred to in the Medical Record, and if possible to have it from the owner himself. The president, Dr. Moll, told of having seen this horse in 1903, and of having made some experiments with him, but these were successful only in the presence of the owner. Moll believes that the horse is governed by signals. Two letters which he had written to the owner asking for experiments under certain conditions had remained unanswered.

The time seems to be favorable for mysterious events, for the reports in the daily papers concerning Harnack and his magnetic power are endless. Harnack, professor of physiology at Halle, turns the magnetic needle by rubbing the glass cover of its box. With an empty stomach and after an exhausting speech, he can turn the needle but a little, while after dining and rest the effect is more marked. Harnack claims to have a magnetic power in his body, and thinks that a certain number of persons can in this way influence the needle by rubbing glass or caoutchouc.

Two of Berlin's oldest physicians died recently, both of whom were distinguished members of the Berlin Medical Society. The one, Adolph Abraham, was for many years vice-president of the Medicinische Gesellschaft, and the other, Max Bartels, was its treasurer. The latter is well known through his anthropological studies, and especially through his editing of "Die Medicin der Naturvölker," and "Das Weib in der Natur und Volkerkunde."

OUR VIENNA LETTER.

(From Our Special Correspondent.)

INFLUENCE OF COLOR ON SENSE PERCEPTION—CASE OF NEPHROLITHIASIS ON A GONORRHŒAL BASIS—SCHUH'S FIRST ASPIRATION OF THE PERICARDIUM—DEATH OF A WELL-KNOWN CHARACTER IN THE VIENNA CLINIC—RADIUM BROMIDE IN THE TREATMENT OF TELANGIECTASIS.

Vienna, October 25, 1904.

In the Gesellschaft der Aerzte, Professor Urbantschitsch gave an interesting address in regard to the "Influence of Color Perception on the Sense Function." On looking at a colored surface or through colored glass, changes frequently occur in the different sensations, and these are increased or diminished by the influence of colors singly or together. Many of the people examined, he said, experienced through certain colors an increase, and through others a decrease, of the sense function; while, again, many colors were without influence. When only one eye was exposed to a color, the changes in sensation usually occurred on the corresponding side of the body; but, in examinations otherwise similar, it frequently happened that the greater changes were on the opposite side of the body. The speaker examined the influence of different colors on the sense of hearing, equilibrium, taste, smell, touch, and temperature. By the influence of red, yellow, green, blue, and violet, the hearing was made more acute—the qualitative hearing, the localization of tone, and subjective hearing. What effect color perception has on the sense of equilibrium shows itself as a disturbance of equilibrium. The sense of taste influenced by color shows now an increase, now a decrease; the kinds of taste, sweet, salt, sour, and bitter, being for the most part affected equally. In many cases, certain colors cause a change of taste; for instance, sweet becomes salt or bitter. In addition to changes in taste itself, sensations as of tickling, scratching, or pricking may be felt on a tongue stimulated by colors. A similar examination of other senses shows a corresponding condition in regard to the influence of the single colors. None of the colors red, green, yellow, blue, and violet can be spoken of as always increasing or decreasing the sense function; so, for example, red often causes weakening and blue strengthening of the sense function. A number of persons examined he found indicated the colors which increased the sense function as their favorite colors, while those which decreased it were unpleasant. Subjective colors have an influence similar to those objectively perceived, as Urbantschitsch showed in other experiments. In the case of excitable persons, it is sometimes possible to influence sensation by rays of colored light thrown on a portion of the skin, as that of the hands, neck, or face. Urbantschitsch called attention to one person who had been examined who, under the influence of the color green, tasted sugar as bitter. Whenever green light fell upon the neck or the side of the head, the same phenomenon occurred, so that, with the eyes carefully closed and covered, the tongue having been sprinkled with sugar, this person could recognize the presence of the green light by the intensely bitter taste. Urbantschitsch finally made evident that a change in sense perception, especially an increase, can be brought about without the influence of color through alterations in body position, as lifting the arms or the feet, bending the trunk, or, again, through compression of the vessels of the neck, and therefore the experiment with colors should be carried on with the patient physically at rest.

Dr. Königstein, in the Gesellschaft der Aerzte, demonstrated a calculus of the pelvis of the kidney, which was of special interest, in that it was passed spontaneously, and that it occurred on a gonorrhœal basis. It was about the size of a hazel nut, dark reddish-brown, and had to a certain extent the form of the kidney pelvis. The chemical and microscopical examination showed a mixture of pus, mucus, and some phosphate and carbonate of lime. The patient was a 22-year-old woman, who had been married seven months, and was infected by her husband, who had had, at the time of the marriage, an acute ascending gonorrhœa. She also showed on examination the condition of an acute ascending gonorrhœa—urethritis, cystitis, endometritis, and left salpingo-oöphoritis. A fluctuating tumor, about the size of two fists, very tender to the touch, corresponding in position to the left kidney, led to the diagnosis of a pyelonephrosis on a gonorrhœal basis. Since the general condition of the patient was very bad, and the temperature high, an operation was considered, and Königstein had her admitted to a sanatorium. Under conservative treatment, her condition did not improve, an operation was determined upon, and the preliminary steps taken. During the manipulation incident to the preparation, accompanied by an attack of renal colic the stone passed spontaneously, and a large amount of pus followed through the bladder. Immediately the picture changed. The temperature fell to normal, the general condition was correspondingly bettered, and the kidney tumor disappeared. The opinion expressed that this was a case of two coexisting disease processes, on the one hand ascending gonorrhœa, on the other nephrolithiasis, was later disproved by the examination of the stone. For the rest, the patient is at present on the road to perfect recovery.

On October 17, the hundredth birthday of the founder of scientific surgery in Austria, Dr. Franz Schuh, was celebrated. This noted surgeon in 1840 was the first to aspirate the pericardium. In the department for lung and heart disease there was a woman, 24 years old, who was very ill, had a high-grade of dyspnœa, and could neither lie down nor sleep. Schuh's colleague, Professor Skoda, who was head of the department, was convinced that fluid had collected in the pericardium to such an extent that its pressure threatened to overwhelm the heart. Schuh immediately agreed to undertake a puncture in order to evacuate the fluid. The news that he was about to attempt so unusual an operation spread widely among physicians, and on the day set an unexpectedly large number assembled in the operating room. The patient was brought in, and, under the strained attention of the onlookers, Schuh passed a simple trocar into the third intercostal space directly to the left of the sternum. Immediately a quarter of a liter of reddish fluid flowed from the cannula. This case alone was sufficient to cause Schuh, then the first surgeon in the general hospital, to be known as a distinguished man in his profession.

There recently died in Vienna a laryngeal artist, an old woman who for twenty years supported herself by allowing students to practise and experiment on her throat.

There is hardly a physician of the present generation in Vienna who did not make his first laryngoscopical examination on this woman; in all courses and lectures she took her passive part. The efficiency which proved remunerative to her and valuable to the cause of instruction, she owed to her peculiar power of controlling her respiratory organs by will power. For instance, she could hold her vocal cords motionless, without cocainization, for a minute at a time, and that even if they were touched. The students could, therefore, learn to examine the larynx with unusual completeness. The woman had also the ability to cause such obstructions as frequently occur in the course of an examination, while, on the other hand, because of unusual sensitiveness of the mucous membrane, she could feel and specify each failure in the examination. She could always tell exactly in what part of her nose, her larynx, or her throat, the instrument was, so that the student was made aware of his blunders, and could improve. Finally, she would produce from a large, black bag, which she always had with her, different kinds of objects, which she placed as foreign bodies in different parts of her respiratory tract, for the student to find.

Dr. Gustav Ebstein of Prague tried the radium bromide treatment in a case of congenital telangiectasis in a five and a half months' old child. In three sittings, each separate place was exposed to the rays for eight minutes and the weighted, hard rubber case, which holds the radium, was pressed on the skin, so as by pressure on the tissue fluids and blood to bring the radium as near as possible to the vessels, in order to increase and hasten the effect. Previous to this the method consisted in fixing the hard rubber capsule to the affected spot by adhesive plaster. Reaction appeared after eight days, with the already described typical characteristics. In the places subjected to treatment, the blood vessels have entirely disappeared, and a white, shining, superficial cicatrix has replaced them. Three other cases with similar treatment give the same appearance.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE RÖNTGEN RAY IN LEPROSY—A CASE OF FILARIASIS—CONTAGIOUS DISEASES—BERIBERI.

MANILA, October 15, 1904.

A very interesting experiment is at present being conducted at the San Lazaro Hospital, in the treatment of a certain number of lepers with the *x*-ray. The work has not progressed sufficiently far to warrant any conclusions being drawn, and it is not the purpose of this item to embarrass the officials by reporting on their work before they can have had an opportunity to do it for themselves, but the improvement in a few of the cases has been so striking and successful that even if no further progress is made, the application of the *x*-rays in certain cases of this disease offers the best hope of accomplishing anything in the line of treatment. About six weeks ago a case of leprosy in a male adult was admitted to the hospital. Among other marked symptoms of the disease there was an enlargement of the left ear, so that its long axis measured more than four inches. The ear of the other side did not measure more than two in its longest direction. The rays were applied daily for about ten minutes, at a distance of twelve inches from the ear. After a few weeks' treatment there was a marked diminution in its size, and now it is almost as small as the one on the other side. About two weeks ago the ear commenced to break down and ulcerate. It is thought that this was due to the too constant application of the rays; accordingly it was stopped temporarily for a few weeks and at this writing the ulcers have almost healed. The improvement in this man's condition was, however, not confined only to the ear mentioned, but extended to the leprous nodules located about his head. The improvement was particularly noticeable in the nodules of the cheek on the opposite side, many of the smaller ones of which disappeared completely. The benefit thus derived from the indirect application of the rays is of the greatest significance. While the foregoing treatment was in progress a number of other lepers were exposed to the rays and required to revolve slowly in front of the tube. In every instance in which these applications were made the cases showed marked signs of improvement after a few weeks' treatment. These preliminary results open up a wide field for speculation on the future application of the rays.

At a recent meeting of the Manila Medical Society a paper was read by John R. McDill, M.D., and Wm. B. Wherry, M.D., entitled "Notes on a Case of Chyluria, Together with Some Observations on the Morphology of the Embryo Nematode Filaria Nocturna." The patient was a young woman who has been under treatment for this affliction at the Civil Hospital for the past three months. Practically all the drugs which have been recommended by standard writers on this disease have been administered, but without results. It is now proposed, after first experimenting on animals, to saturate the patient with quinine and then to expose her to the *x*-rays, with the hope that the adult worms may be killed. The prognosis at its best is not very encouraging. Dr. Wherry showed some excellent microphotographs of the organism found in the patient's blood. He also gave an excellent description of the filaria and called attention to the flagella, which he stated had been omitted in previous descriptions of other writers.

The health condition with regard to the more grave contagious diseases is probably more satisfactory at present than at any other period since 1900. The last case of plague was reported at Manila September 8, 1904. The ports of Hong Kong, Amoy, and other Oriental cities in which this disease has been present during the summer in epidemic form, are now almost entirely free from plague. A few cases of cholera still continue to be reported at Kobe, Japan, but the rigid inspection that is made of Japanese food stuffs before they are admitted to the islands, makes it extremely improbable that the Philippines are seriously menaced from that source. If the present satisfactory state of affairs continues the quarantine officials hope to be able to remove at an early date most of the restrictions that are placed upon vessels before they can clear for the United States.

Beriberi still continues one of the most serious diseases from which the Filipinos and Chinese suffer. It is very rare for Americans to be attacked by beriberi, and when they are, it can generally be shown that they were deprived of proper food. Such, for instance, are lighthouse keepers on remote islands, at which places it is sometimes not possible, owing to weather conditions, to deliver supplies for many months, and such individuals are compelled to live upon rice and fish. The prisoners at many of the provincial jails also suffer very frequently from this disease. Many of these prisoners are transferred to the main prison at Manila, and for this reason there is almost a death per week at the latter institution, and there are always a number of cases to be found in the wards of the prison hospital. There are many more cases among the local Chinese than the reports of the health authorities would seem to indicate, because as soon as a Chinaman becomes afflicted with a disease of a more or less chronic nature he immediately proceeds to China, and probably in most instances dies in his native land. According to the last report of the surgeon-general of the army, beriberi is also the most frequently fatal disease from which the Filipinos suffer who are enlisted in the U.S. Army as scouts. Since the principal part of their ration is rice it is quite possible that this may have something to do with the prevalence of the disease in the army.

THE OPTOMETRY BILL.

To the Editor of the Medical Record:

Sir: During the legislative session of 1904, a society of opticians known as The Optical Society of the State of New York petitioned the Legislature to enact a law creating a State board of examiners in optometry. Before this board would appear all persons who desired to practise optometry, which practice was defined in the act to be enacted as "the employment of any means other than the use of drugs for the measurement of the powers of vision and the adaptation of lenses for the aid thereof." The Medical Society of the State of New York opposed this bill, and with the aid of other organizations, especially the County Medical Societies and the Optical League (an organization of opticians doing a legitimate business), secured its defeat. Since the last election, this optical society has been forwarding to physicians in all parts of the State, as well as to the members-elect of the next Legislature, a document giving reasons why a law of this kind should be enacted, and asking their endorsement. At the time of the hearing on the Optometry Bill before the legislative committees of last year, the opticians presented a long list of names of physicians who had endorsed their efforts. The undersigned communicated with every name on the list, and learned that where reputable physicians had endorsed the measure, it was through a misapprehension of the real purpose of the bill, and when its true character was pointed out to them, they not only withdrew their endorsements, but in many cases wrote vigorous letters in opposition to it. Many of the names were fictitious, the communications addressed to the addresses given being returned as not found. A large number were the names of irregular practitioners, as osteopaths, spiritualists, and so on. There is no doubt that the object of the opticians in presenting the present arguments is to obtain the endorsement of physicians, so that at the next legislative session these signatures can be used to offset the opposition which will be presented by the

regularly organized medical bodies of the State. I therefore address the profession of the State, urging its members not only to refuse to endorse this and similar measures, but to make an effort to present to their representatives, both in the Assembly and the Senate, the true merits of the case, and urge their opposition to it. The arguments presented by the opticians are very misleading. Their claim, of course, is that they desire to protect the community from incompetent people, but the fact is (as every well-informed physician must know) that they are all incompetent. They seek to create a separate profession. This they deny, but in their remarks before the legislative committees they continually used the expression "our profession." They seek the legal right not only to apply lenses for the correction of defective vision, which may or may not be due to errors of refraction, but they also seek to treat headaches, dizziness, and the various reflex phenomena which may be due to affections of the eye itself, or to affections of organs remote from the eye. They pose as being competent to make a differential diagnosis. To prepare physicians to do this work, the law requires that a four years' course in a medical college shall be taken, after which a medical examination conducted by the State must be passed. Physicians themselves find that after this preparation, it is often difficult to be sure of one's ground; and, if this is so, there seems to be no good reason why opticians should be allowed to undertake the same work with any less preparation. It seems unnecessary at this time to go into an extended argument in opposition to this bill. The effort to secure its enactment is not an honest one. Opticians know that they are violating the law in following the occupation which they are now engaged in, and they say that if their bill is enacted, it will not give them any more powers than they now possess, while the fact is, that the enactment of the bill will give them the legal right to do what they are now doing in violation of the law. They really desire to use the Legislature as a tool to put them beyond the grasp of the law; and if this is once clearly brought to the attention of our senators and assemblymen, there is no doubt what the outcome will be. We have met this and similar efforts more than once in the past, and there is no doubt that we shall meet many more in years to come; but from our experience, we feel justified in making the assertion that if the medical profession will present a united opposition to measures of this kind, they will never be enacted into law in the State of New York.

Frank Van Fleet, M.D.,
Chairman of the Committee on Legislation of the Medical Society of the State of New York.

POST-PARTUM HEMORRHAGE.

To the Editor of the Medical Record:

Sir: I was much interested in your editorial on post-partum hemorrhage in your issue of November 19, 1904. Some time ago, in a conversation with Dr. N. F. Raines of Raines, Tenn., on this subject, he related the following case: A multipara had been delivered by him in an easy manner. The uterus seemed to contract nicely. After holding the fundus for some minutes, he let it go in order to get something out of his obstetric bag. In less time than it takes to tell it his attention was attracted to the bed by a peculiar sighing. He found the woman very pale and with imperceptible pulse. Throwing off the sheets he saw at once that a profuse hemorrhage had taken place. The uterus was in atony and not to be felt. Having no sterilized gauze or cotton with him, and realizing that something must be done quickly, he pulled a handful of cotton from an opening in the mattress and boldly plunged it into the uterine cavity. Immediate contractions were excited. The uterine cavity was then douched with hot water, and gauze having been procured in the meantime, the uterus was packed together with the vagina. Salt solution was administered and the patient made a good recovery. This case certainly goes to prove that tamponage is the treatment in these cases. It must also be admitted that a city practitioner would scarcely have thought of the cotton mattress in this emergency. Verily, it takes country practice to sharpen the bump of resourcefulness.

M. Goltman, M.D.
Randolph Building, Memphis, Tenn.

To the Editor of the Medical Record:

Sir: Referring to your article on post-partum hemorrhage in the Medical Record, November 19, 1904, permit me to suggest an addition to the excellent treatment outlined. I refer to the injection into the cavity of the uterus of brandy, as practised and taught by Prof. I. Algernon Temple, of Toronto University, for many years. The uterus is first emptied of clots or placenta, and the brandy is then injected. I have found this plan successful after bimanual pressure, hot water, etc., had failed. I am not aware of its advocacy by any other teacher.

John W. McCullough, M.D.
Alliston, Ont.

Progress of Medical Science.

The Boston Medical and Surgical Journal, November 24, 1904.

Metatarso-Tarsal Valgus or Humped Foot and Its Relation to Boots.—E. H. Bradford states that this deformity is characterized by a depression of the first metatarsal with an inward movement of the foot at the metatarso cuneiform articulation. Boots are cut so that there is not only no spread at the toes, but also none at the metatarsals, so the ligamentous strain in locomotion is not felt at the metatarso phalangeal articulation, nor can the whole foot swing to the inside at the midtarsal articulation, making a splay foot. The strain comes at the metatarso tarsal articulation. If a heel is worn, the boot gives a slope to the foot and causes a backward pressure on the sliding foot, causing a cavus, analogous to that in the foot of a Chinese woman. Irritation may result and exostoses follow. The writer discusses various other deformities of the foot with their causes. The most common deformities are caused by crowding the toes together, as the shoe is always made narrower than the natural spread of the foot. The great toe is pushed toward the middle of the foot and often partly dislocated. But slight deformity can take place with slight discomfort, provided individuals do not lead active lives. It is not always the short or tight boot that does the injury. A loose boot which is narrower than the width of the toes will cause deformity. A stiffened toe cap acts as a clamp, holding the toes together when they would naturally spread in walking. Deformities due to badly shaped shoes will vary according to the fashion of the shoes. The writer believes that when working people realize the extent to which their feet are injured by shoes, there will be an increased demand for less harmful footwear. People should have both working and dress boots, relieving the foot from all pressure when at leisure by wearing moccasins or Turkish slippers. The working shoes of women should be like those of men, giving freer play to the foot. Children should wear moccasins, sandals, and loose, light boots and shoes.

New York Medical Journal, November 26, 1904.

Methyl Alcohol; Its Properties, Uses, and Abuses.—H. W. Wiley describes the methods of producing methyl alcohol, and enumerates the various tests for its detection, especially for its presence in ethyl alcohol. Its general effects when taken internally are such that it should be classified among the poisons. Its introduction into any substance, to be used internally as a medicine or beverage, should be absolutely prohibited, and stringent precautions should be observed in the marking of all vessels containing it. It may be safely used in the arts as a solvent and in spirit lamps. It is most easily obtained from mixed hard woods and southern pine. It occurs in traces in the juices of certain plants, and is well known in a compound form as methyl salicylate in the oil of wintergreen.

The Surgical Cure of Certain Cases of So-called Chronic Dyspepsia.—C. A. L. Reed presents the following propositions as summarizing the ideas offered in his paper: (1) The majority of cases of so-called "chronic dyspepsia," "gastralgia," "nervous gastralgia," "neuralgia of the stomach," "cardialgia," and "hyperchlorhydria," are, in fact, cases of ulcer, or the organic consequences of ulcer, of the stomach or duodenum or both. (2) Cases amenable to medical treatment should be cured in from five to six weeks, after which time they should be placed in the surgical category, while hemorrhagic cases should be operated upon without the delay prescribed by medical writers. (3) Surgical ulcer of the stomach, if neglected, may develop adhesions, perforations, hemorrhages, or cancer, or, in the absence of these, may provoke sepsis and anæmia, which, if the underlying conditions are not corrected by operation, may and frequently do prove fatal. (4) It is important, therefore, that the cases should be promptly brought to operation which, without reference to details, should establish rest and maintain drainage for the diseased organ. (5) The comfortable after course of these cases, the low primary mortality, and the permanent curative results following the operation comprise its complete justification.

Medical News, November 26, 1904.

Operative Treatment of Retroversion and Retroflexion of the Uterus.—Walter A. Jayne, after considering the advantages and disadvantages of the Alexander operation,

and of ventral fixation, declares that whatever opinion may ultimately be held regarding the relative value of shortening the round ligaments in the groins and suspension of the uterus for cases of uncomplicated retrodisplacements, the value and efficiency of the fleshy inner part of the ligament, as utilized in the Alexander operation, appears to be generally recognized, and attempts are being made to extend its use. Recently, methods have been proposed of attaching a loop of the intraabdominal part of these ligaments to the anterior abdominal wall more firmly than by the peritoneal adhesions formerly depended upon, by threading a loop through a small wound in the peritoneum, muscle and fascia on either side of the abdominal incision, and fixing it by suture, thus suspending the uterus by the strongest part of the ligaments and imitating as nearly as possible in intraabdominal work the result following the Alexander. If after trial sufficiently long this operation proves to be free from postoperative objections, and quickly performed, it may offer a ready means of correcting these displacements in cases in which abdominal section is required in a safer, more physiological and efficient manner than heretofore performed, and go far toward giving a satisfactory substitute for attachment of the fundus to the anterior abdominal wall, especially for women in the childbearing period of life.

Diagnosis and Operative Treatment of Stone in the Kidney.—Joseph Ransohoff divides the symptoms of stone in the kidney into two great groups: (1) those due to the supposed passage of the stone through the ureter,—the renal colic proper; (2) those due to processes constantly at work in the kidney because of its containing a stone, a condition of chronic neprolithiasis. He believes that as an element of diagnosis, the kidney colic *per se* is largely overrated. For in many cases of kidney stone there is no renal colic at all; and various other conditions, such as a twist of the ureter, may produce symptoms which cannot be distinguished from those usually ascribed to the passing of a stone. More important than colic, is the symptom group of chronic neprolithiasis. The writer describes his method of eliciting pressure tenderness in these cases as follows: The patient is made to stoop over, resting his hands on a chair. With extended fingers placed over the lateral costo-iliac interval, the writer makes simultaneous and equal pressure with his thumbs along the lower borders of the last ribs from end to end. This method is an excellent one for eliciting tenderness due to stone. The urine in chronic nephrolithiasis presents abnormal elements which afford a most valuable guide to diagnosis. Almost every specimen examined during a period of months will contain from one to twenty red cells in the field. To the naked eye, the urine appears to be normal until pyelitis has developed, the preponderance of the red cells over the leucocytes, as found in the urine, is like that of normal blood. Crystals are of little diagnostic value. Albumin and casts should be looked for. The temperature chart is of secondary importance. However, in the chronic state of nephrolithiasis, slight elevations of temperature continued through a long period and with a distinct tendency to recur irrespective of any renal colic, are a most important element in the diagnosis. The newer methods of cystoscopic, ureteral examination and separation of the urines, are of less significance in the therapy of kidney stone than in other surgical affections of the kidney requiring operation, since nephrectomy practically is never justified as a first operation for kidney stone. The writer declares that although subject to occasional errors, a radiographic presentment is with our nearly completed technique a *sine qua non* for a positive diagnosis. As to operation, it is becoming among surgeons an axiom that the presence of a renal calculus is an indication for operation. Calculous anuria is an absolute indication for operation. No other major operation presents so low a mortality as nephrolithotomy. The choice between incision of the kidney and incision of the pelvis, has been definitely settled in favor of the former. Retrograde catheterization of the ureter is essential to every operation for stone in the kidney. Primary nephrectomy should never be performed for stone except when the hemorrhage is uncontrollable. There are other pathological conditions of the kidney, the symptom complex of which cover that of stone. And the writer advises that in every case operated upon with a result negative as to the finding of a stone, a small section of kidney be removed for microscopical examination. In this way only, can the changes be detected, which although seemingly slight, are often capable of producing symptoms of great severity.

American Medicine, November 26, 1904.

Laboratory Aids in the Rapid Diagnosis of Rabies.—Walter H. Buhlig first mentions Babes' tubercle. It consists of leucocytal thrombi of capillaries and of accumulations of embryonal cells around the vessels and around the nerve cells of the medulla of a rabid animal. These microscopic changes are found by him with certainty in dogs that have died of rabies, but less constantly in animals that have been killed in the course of the disease. In 1900, Van Gehuchten and Nélis reported a pathological change found in the spinal, gasserian, and pneumogastric ganglions, which consists of a proliferation of cells, probably from the capsule of the ganglion cells. As a result, the space between the capsule and the nerve cell is more or less completely filled up, and the number of cells outside of this ganglion cell envelope is increased. Although this picture is very striking in animals that have died of rabies, it is not so clear in those which have been killed before the disease has run its full course. Somewhat similar lesions have been found in other conditions, such as diphtheria, so the clinical history of the animal must be carefully looked into. Its presence, however, is considered almost pathognomonic by those who have worked on the subject. This reaction stands to-day as the most trustworthy aid in the rapid diagnosis of rabies. Recently, Negri has found a structure in the central nervous system of different mammals afflicted with rabies, which he suggests may be a parasite and perhaps the causative agent of the disease. The ordinary fixing agents are adequate to discover it. Mann's method of methylene-blue and eosin is considered the most perfect. The so-called parasites are found in the nerve cells of the horn of ammon, in Purkinje's cells of the cerebellum, in the cortex, principally in the pyramidal cells, and sparingly in the pons, the medulla, the spinal cord, and in the various ganglions. These bodies are spherical, elliptical, or pyriform in shape. Their size varies from 1 or 1.5 microns to 10, 12, or 15 microns in diameter. Those which are not round are at times 22 to 23 microns long and 6.5 microns wide. They are found within the protoplasm of the nerve cell and often within the processes, and often several may be present in one neuron. Two distinct characters are distinguished within the organism: small, round, glistening forms, and large, oval, less glistening central bodies. Negri states that when dogs are inoculated by the sciatic route, the parasites are found practically only in the spinal cord region; when the subdural, intraocular, conjunctival, or mucous membrane path is selected, the organisms are found most abundantly in the brain in the usual locations. Negri's general conclusions have been verified by others. Another aid in the diagnosis of rabies is the presence of foreign bodies in the stomach. Like the ganglion cell lesion, it speaks for the disease when it is a positive one, and is noncommittal when there are no such extraneous matters. Leucocytosis is constant in rabies. A doubtful aid is the alteration in the voluntary muscles of rabid animals, as found in rabbits. It is reported that the muscle fibers show a longitudinal division into fibrillas, and many are entirely transformed into such threads. The nuclei are increased in number, and amyloid degeneration is sometimes seen.

Inversion of the Uterus: The Treatment in Cases Complicated by Necrosis of the Inverted Part.—Brooke M. Anspach reports the case. The patient had had two labors, both of which were marked by difficulty in delivering the placenta. The last labor was in September, 1903. In the following December, the patient noticed a slight irregular hemorrhage from the vagina, which continued till June, 1904, when every ten days there was a free loss of blood. In July there was a hemorrhage greater than any preceding one. There was backache and bearing-down pain. The discharge became greenish and very offensive. Under ether, the diagnosis was easily made. The uterus was completely inverted, and the inverted part was gangrenous. Section was made in the middle line and the necrotic mass was cut away beneath the forceps, which were left in place, their points being pushed back into the uterus and packed with gauze. The ovaries and the lower third of the endometrial cavity were left. Future childbearing was out of the question, but the other functions were left intact. The forceps sloughed off on the fifth day and convalescence was uninterrupted. This inversion must be ascribed to the puerperium. Apparently from the very beginning of the inversion there was serious disturbance in the blood supply of the inverted part. In amputation of the inverted part, there is no danger of infection. A suture might carry infection to the peritoneum, so it is better to clamp the pedicle. The danger of injuring a knuckle of intestine in the funnel of the inversion may be avoided by incising longitudinally the inverted part before cutting it away below the forceps.

Variations of Radiotherapeutic Technique.—Russell H. Boggs believes that technique is the key to success in Röntgen ray work. The application of this treatment either in diagnosis or treatment, should be done by mathematical calculations to do the most successful work. Usually the combination of surgery and the Röntgen ray will produce the best results. Tube distance is very important in treating deep-seated glands. The Röntgen ray should be of large volume when deep lesions are to be

treated. The Röntgen ray, like the intensity of light, varies inversely as the square of the distance. In treating deeper lesions, the best results will be produced by using a light which affects the different layers of tissue the most uniformly. The intensity of the rays, for example, is more uniform in the different layers of tissue with the tube placed at 16 inches than at 8 inches. In the treatment of superficial lesions a low tube placed near to the surface of the skin eliminates the danger of injuring the deeper tissues. Periostitis has been caused by a high tube placed at a distance. Each case is an individual one and should be treated as such. Adjunct treatment in these cases should not be overlooked. Every help possible should be taken advantage of to keep the system in perfect condition. In cases of carcinoma, when toxæmia is present, electric light baths are very valuable. Diet is important. Much liquid should be taken. Alcoholis, syphilitic, or very anæmic patients as a rule do not improve rapidly, and such patients often burn easily.

Journal of the American Medical Association, Nov. 26, 1904.

Injuries to the Rectum Caused by Gynecological Examinations.—H. A. Kelly makes a plea for more gentleness in making gynecological examinations. Of all organs liable to injury, the rectum is the most delicate, and the author reports four cases in which the coats of the bowel were actually perforated by the examining finger, which was thrust through into the rectum and into the peritoneal cavity. One case was his own, and the other three occurred in the practice of competent assistants. All four recovered. Predisposing causes are the age of the patient (average 57 in three of the four cases), and the weakened muscular tone of the bowel. Kelly believes that in the presence of such an accident, the proper procedure is to open the abdomen and suture the tear from the peritoneal side. An important prophylactic point is that the examiner should avoid the natural impulse to invaginate the wall of the rectal ampulla on the end of the finger, pushing it to a point higher up in the pelvis. This error will not occur if, after introducing the finger into the ampulla, the next step made is that of seeking out the so-called "third sphincter"—that is to say, the rectal valves behind the cervix. The finger ought to be introduced between these distinct anatomical structures and then up into the pelvis, where the bowel lies in its natural relation in contact with the posterior surface of the uterus and the left broad ligament.

Constipation in Infants.—According to J. R. Snyder, errors in diet are the great cause of infantile constipation. Consequently the treatment is something more than the removal of the immediate condition. If the disorder results from bad hygiene, it is useless to merely give castor oil and nux vomica. If the diet is too high in proteids, salts, suppositories, and enemata will not lessen the proteid percentage, and will consequently fail to be curative. If the condition is neglected while the child is still a young infant, the problem becomes more complex. Whereas formerly the bowel contents were at fault, we now have to deal in addition with changes in the bowel structure itself. This matter cannot be corrected by diet alone, and it is here that the judicious administration of drugs becomes permissible. If the constipation is not of very long standing, atony of the bowel may be overcome, after correcting the diet, by an endeavor to establish habit. The simplest way of accomplishing this is by holding the child at regular hours, preferably after the morning and evening bottles, on a chamber in such a posture as to favor an evacuation. For the success of this method, regularity in feeding, because it favors rhythm in the stages of digestion, is necessary. If the bowel still remains obstinate a stimulus should be given. At the same time it should be recognized that this is unnatural and foreign, and that not only must it be as slight as possible, but it must be withheld at the earliest possible moment.

Perinephritis in Children.—W. R. Townsend reports six cases, and gives a general description of the disease. In no instance of the six reported was a correct diagnosis made by the physician who sent the case to the hospital, where it came under the author's observation, but all were sent in under the impression that they required either spinal or hip braces. The most common errors are to mistake the condition for beginning spinal ostitis, Potts' disease, ostitis of the hip, or hip-joint disease, as acute osteomyelitis of the vertebræ. Treatment must be based on the conditions present. If the patients are seen early, rest in bed, tonics, laxatives, and mild stimulation are indicated. If an abscess is present, immediate evacuation is necessary to prevent death from sepsis, burrowing of pus, and sinus formation.

The Lancet, November 19, 1904.

Infantile Syphilis.—In discussing this disease, G. F. Still expresses, concerning, treatment, his preference for gray powder, which he uses in combination with aromatic chalk and occasionally with Dover's powder, if there is any tendency to loose bowels. Combined with the internal remedy, inunction may be employed. The author is not in favor of intramuscular or intravenous injections of iodine or mercury. Such methods he regards unsuitable for infants. They cause unnecessary infliction of pain and risk of inflammation. Iodides may be advantageously given along with the mercurials, and in any event treatment should be continued for at least six months after the disappearance of active symptoms. When the latter tend to recur on the omission of treatment it is necessary to continue it for a year or more.

Non-Fatal Rupture of Aortic Aneurysm.—After alluding to the few other cases reported in literature, C. H. Melland gives notes of the case of a laborer of 58 years who was admitted to hospital with the history of having raised a large amount of blood. He was in a state of collapse, but rallied after a saline infusion. On recovering he stated that he had been coughing for eight months and that for a few years he had had a stabbing pain in the chest from the right shoulder to the ensiform cartilage. He continued at work, and his bleeding before coming to hospital resulted on his making an unusual physical exertion. He did well for three weeks after admission, but then succumbed to recurring hemorrhages. Autopsy showed an atheromatous aorta, with a sacculated aneurysm from its convex arch, immediately beyond the left carotid and about the size of a hen's egg. The subclavian artery came off from the upper and outer part of the sac, which was nearly full of firm, laminated clots. Tracheal pressure had resulted, leading to a softening of the mucosa, and in this softened area was a vertical slit, about three-eighths of an inch long. The author assumes that a portion of the laminated clot had been carried across the rent so as to plug it effectively and so temporarily stop the bleeding.

The Action of Perchloride of Iron in Blood Poisoning and Other Disorders.—According to P. W. Latham, the beneficial effects of this preparation of iron are largely due to its free chlorine. Heroic doses are not necessary. Moderate dosage, say, every six hours, will meet most clinical requirements; if further antiseptic action is desired we may bring this about by the internal administration of chlorine water, alternating with the iron. The author discusses the uses of the remedies in scarlet fever, diphtheria, and other conditions of blood toxæmia. The question remains whether these remedies should be used independently of the antitoxin serum or in conjunction with it, and, if so, at what stages should one or both be administered. These questions must be settled by further observations.

A Case of Encephalitis Cerebelli.—F. Taylor refers to the case of a boy of four years, seen nearly thirty years ago. At the time the diagnosis was supposed to lie between disseminated infantile sclerosis and a cerebellar tumor, but the more recent development of the entity we call encephalitis cerebelli has convinced him that his earlier case belonged in this category. The patient had tremors and ataxia of the cerebellar type, nystagmus, absence of optic neuritis, a possible origin of symptoms in pertussis and recovery after a duration of three and a half years of symptoms. At the present time he is alive and well at the age of 33 years, without any trace of his early trouble. His muscular power, patella reflexes, and optic disks are all normal, and he is able to indulge in athletic exercises.

British Medical Journal, November 19, 1904.

A New Method of Dealing with the Stump of the Appendix.—J. M. Y. Stewart describes the method recently adopted by him as follows: The mesentery of the appendix is first tied off and then divided with scissors, leaving the appendix free up to its junction with the cæcum; a purse-string suture of catgut is then inserted near its base through the peritoneal and part of the muscular wall of the cæcum; a ligature is next tied round the appendix close to its base. While an assistant holds the cæcum just beyond the purse-string suture the base of the appendix is cut through with a single cut of the scissors, leaving a stump resembling a nipple; there is no pouting of the mucous membrane in the stump, but rather an invagination at its very apex; the stump is gently invaginated into the cavity of the cæcum as the assistant tightens the catgut suture; the peritoneal surfaces come well together, and the operation is finished as far as the removal of the appendix is concerned. In the writer's six cases, at the end of the first week, when the skin stitches are removed, there is an entire absence of pain on deep pressure over the seat of the operation, and no feeling of soreness is complained of when first the patient walks about. The muscular fibers in the appendix near its base are chiefly circular, and when the appendix is divided those in the stump at once contract and shut off the mucous surface and practically close the lumen. So there is no risk at all, and the advantage is two-fold—no pocket, with possibly an infectious stump in it, and no raw surface in the abdominal cavity.

The Treatment of Sea-Sickness.—Charles W. T. Woods has had much success in relieving this complaint. At the first onset of uncomfortable sensations, a broad, tight, flannel belt should be worn, and the patient should stay on deck if possible. Usually, lying on the back is preferable to the side. As low a pillow as possible should be used. The food most readily retained is devilled biscuit—dry biscuit, buttered, and lightly sprinkled with cayenne pepper, and then roasted—or egg flip. The latter must be given to the patient with his eyes closed, for the color is repulsive. Except in very severe cases, the less fluid taken the better. Alcohol is inadvisable until the worst is over, then champagne is often of great service. The writer has found the following prescription of great value: Two drachms of syrup of chloral and one-half drachm of ammonium bromide, made up to one and one-half ounces with water. This should be taken at the rate of a teaspoonful every five minutes until either relief or sleep results. Four or five doses are usually sufficient. When this prescription fails, one-minim doses of tincture of iodine in water every half hour is often successful. When the patient is not seen till he has been ill for a day or two, it is well to begin the treatment with two grains of calomel.

Hyperpyrexia Following Parturition.—Mark Farrant reports this case. The patient, a woman aged 42, had had five children. Delivery of the sixth was natural, but the child was a very large one and was stillborn. The patient was exhausted after delivery, the pains having been very severe. The placenta did not separate and there was too much tenderness to admit of its expression. About three-quarters of an hour after delivery, the patient became restless and threw herself about on the bed, not seeming to understand when spoken to. She soon became unconscious, with noisy breathing. There was no convulsion. The temperature was 107° per axillam; in the rectum a few minutes later it was 109.2°. She was cold-packed and the temperature fell to 101.4°, but the heart failed and she died without regaining consciousness. As soon as the patient had become unconscious, the placenta was expressed and a hypodermic of morphine was given, and afterwards injections of strichnine and quinine per rectum.

Acute Lobar Pneumonia Following Septic Tonsillitis.—Edward Carnall observed this case. The patient, a woman of 34, had a sharp attack of tonsillitis. The temperature was 105°. Salicylate of sodium was given and a throat-wash of boric acid and glycerin. The next day the temperature remained the same, and antipyrin was given, but with no reduction in temperature. The throat looked better, however. Five days after the onset, distinct dullness and harsh breathing sounds were noted over the lungs. She was placed on quinine and aconite mixture, but died during the night. The writer believes that this was a case of acute specific infectious fever. Doubtless the general state of health had been lowered previous to the throat attack. The winds at the time were carriers of dust as well as abstractors of heat. Probably if the patient had been removed to another house the chances of recovery would have been greatly enhanced. No bacteriological examination of the throat was made.

Berliner klinische Wochenschrift, November 7, 1904.

The Effect of Cold on the Arteries.—Herz experimented on the blood pressure in the forearm after the application of cold by adjusting a Gärtner's sphygmograph proximal or distal to the region to which the stimulus was being applied. According to his observations, the large arteries are not affected in size by cold stimuli, while in the smaller arteries, situated distal to the stimulus, the pressure is raised, owing to contraction of the arterioles, and in the centrally placed vessels the pressure falls in consequence of dilatation of the arterioles.

Intestinal Tuberculosis in Children.—Richter, who is attending physician to 1,200 coal miners' families, describes a somewhat unusual type of tuberculosis very common among the children of this class. It affects the intestinal and mesenteric glands, and though rarely fatal, forms an illness of much gravity. The patients emaciate rapidly, lose appetite, are extremely pale, suffer from abdominal pain and tenderness about the umbilicus, headache, insomnia, and slight evening temperature. The cervical and submaxillary glands are frequently swollen. The disease often progresses very rapidly for a time, and then takes on a chronic type, which is apt to be more prolonged the older the child. After the subjective symptoms finally disappear, anemia, emaciation and general weakness persist for a long time. Most of the children affected are from 1 to 4 years old. The author ascribes the prevalence of the disorder to the fact that the milk supply of the region is of extremely poor quality, and that the hygienic conditions are also very deficient. In view of v. Behring's statement that tubercular infection in childhood protects against reinfection later in life, it is interesting to note that tuberculosis is very rare among the adult inhabitants of this district.

Münchener medizinische Wochenschrift, November 8, 1904.

Intravenous Injections of Salicylates for Rheumatic Affections.—Behr lauds the method advocated by Mendel for the treatment of rheumatic conditions by means of the injection of a salicylate solution consisting of sodium salicylate 8.0, caffeine sodio-salicylate 2.0, distilled water ad 50.0. The therapeutic results of this method are excellent, and prompt relief is afforded in nearly all forms of rheumatic affections. A careful diagnosis is necessary, however, for non-rheumatic disorders are not amenable to this plan of treatment, and the effect in rheumatic cases is less pronounced the longer the duration of the trouble has been. The injection should be made with all due aseptic precautions, and care should be taken to see that the presence of the point of the needle within the lumen of the vein is demonstrated by the appearance of a column of blood within the syringe before the fluid is expelled, as the solution gives rise to severe pain if thrown into the tissues instead of directly into the vein. The author has seen no disagreeable complications attend the method when carefully employed, and recommends it especially for cases where it is of great importance not to upset the stomach, as in treating tubercular patients, for example.

Acute Dilatation of the Stomach.—Hoffman says that this condition may be of central origin, as when there is paralysis of the motor nerves of the stomach after cerebral injuries, or may be due to errors in diet. That the condition may appear in those who have never suffered from digestive disturbances is shown by a case of the author's which terminated fatally. The patient was a youth of eighteen, who had always been a gluttonous eater, but in spite of the quantities of food he consumed, did not gain weight. His illness began suddenly, with vomiting and pain in the pit of the stomach. There was intense thirst, and the symptoms of intestinal obstruction appeared and resisted treatment, so that on the sixth day the abdomen was opened. The stomach was found enormously dilated, and on opening it six liters of brownish fluid were evacuated, together with large pieces of cucumber. The pylorus was unobstructed. A drainage tube was left in the stomach, but the patient died the next day of collapse following a return of the vomiting. The author believes that the gastric atony already existing as a result of habitual overeating was rendered complete as a consequence of some error in diet, possibly the overindulgence in cucumbers, and that dilatation began. The thirst caused the patient to drink large quantities of water, which increased the dilatation, while at the same time the stomach ceased to absorb, and consequently the tissues did not receive the necessary amount of fluid, and the sense of thirst was increased, thus completing the vicious circle. The pancreas was found enlarged at the autopsy and was studded with areas of necrosis.

Pericystitis Following Latent Perityphlitis.—Walko says that idiopathic pericystitis is a very rare condition, and describes two cases in which only prolonged observation revealed the fact that the pericystitis was secondary to a pericoccal inflammation. The symptoms of pericystitis comprise vesical irritability and painful micturition, due to the mass of unyielding exudate about the bladder, and reflex pain in the rectum. Complete urinary retention may be caused by the pressure of the exudate, as well as albuminuria secondary to occlusion of the ureters. A rounded mass of more or less doughy consistence is to be felt above the symphysis, usually to one side of the middle line. Emptying the bladder, even by catheter, does not change the size of the tumor. The urine commonly shows the changes of cystitis to a greater or less degree. It is essential to treat the process actively, as the exudate is otherwise not often absorbed, but rather goes on to suppuration and rupture into the bladder, rectum, peritoneum, vagina, or through the skin. The author considers ice, combined with 50 per cent. alcohol, comprises the most suitable treatment for the earlier stages, to be later followed by the application of moist heat.

Deutsche medizinische Wochenschrift, November 3, 1904.

The Faradic Treatment of Uterine Myomata.—E. Witte says that in spite of Apostoli's failures in this direction, he has persevered in the faradic treatment of uterine myomata, and has perfected a method which gives satisfactory results. His plan is to produce firm uterine contractions by strong faradization, with the idea of causing the blood-vessels to contract, and so check hemorrhage, while at the same time the nutrition of the tumor is interfered with, and it is caused to diminish in size through absorption. The method is as follows: one electrode is carried through the cervix and well into the uterus, while the other is applied to the abdomen. If possible, the treatment is continued daily for from twenty to thirty minutes, and the current is used as strong as the patient can stand it without

discomfort. Both the strength of current and the frequency of application must be carefully regulated in beginning the treatment, in order not to overtax the patient. The author has never noticed any untoward effects due to the treatment, and has found that the metorrhagia is entirely controlled and the tumors are greatly reduced in size, so that operation is rendered unnecessary.

The Use of Rubber Gloves in Manual Removal of the Placenta.—Wormser gives the comparative results obtained in a series of cases of retention of the placenta treated in the Woman's Hospital of Basle, with and without rubber gloves. This series of statistics is of especial interest, since on the service of one chief of clinic the gloves were used, and on the service of another the bare hand was employed, so that in all respects save this one the conditions of delivery were practically the same for all the patients. While no deaths occurred in either series of cases (forty cases without, thirty cases with gloves), the patients treated with gloves showed less febrile reaction during the puerperium than the others, and the author is outspoken in his preference for the use of gloves. This is still more advisable in private practice, where the exigencies of the work frequently allow but little time for sterilization of the hand if the life of the bleeding patient is to be saved, and where the practitioner must constantly contaminate his hands with infectious material. It is a simple matter to keep a pair of sterile gloves ready for use, and thus safety is secured and no loss of time incurred in dealing with emergencies.

The Etiological Basis of Smallpox Diagnosis.—Jürgens believes that the difficulties in the way of making a positive diagnosis one way or the other in conditions simulating smallpox may be greatly simplified by resorting to a search for the cell inclusions which Guarnieri and later Wasielewski consider the cause of the disease, and to which Guarnieri has given the name of *Cytorrhyetes vaccinæ*. According to the author these protozoan-like structures may readily be identified in innoculations in the cornea of rabbits, and by this means a positive diagnosis be made. A pustule considered as suspicious is punctured with a sterile lancet needle, and the cornea of a rabbit then scarified in a slanting direction with the same instrument so as to bring some of the adhering pus into pockets in the cornea. This structure becomes cloudy as early as the second day, and in one or two days more microscopical sections in positive cases reveal the parasites in abundance. While the method is not infallible, in that apparently negative results may sometimes be due to lack of virulence in the particular pustule from which the material is obtained, the author considers the plan as of great value in identifying doubtful cases, and describes six instances examined in this way, in which the clinical evidence was insufficient, and the subsequent course of the disease corroborated the innoculation experiment. Two of the cases were positive and two negative.

Deutsche medizinische Wochenschrift, November 10, 1904.

The Relation of Avian Tuberculosis to That of Mammals.—Rabinowitsch describes observations made on the material of the Berlin Zoölogical Garden to determine the relationship existing between the bacilli of fowl tuberculosis and those causing the disease in mammals. In two hundred autopsies on birds of many species it was found that over 25 per cent. showed more or less well marked tubercular lesions, mostly of the abdominal organs, but to a greater extent than usually supposed of the lungs also. Infection usually takes place through the food or feces, and direct infection from one bird to another is rare, as well as congenital infection. It is possible, experimentally, to infect many mammals with avian tubercle bacilli, and spontaneous infections also occur. The converse is less easy to demonstrate, though the author observed two cases in which eagles had become infected with mammalian bacilli. By inoculating hens' eggs with avian bacilli, human bacilli, and the bacilli of perlsucht, the author determined that the susceptibility of the embryos for these different organisms was in the order named, the bovine bacilli being the least virulent. As the result of this and other work, the author believes that the mammalian and avian types of tubercle bacilli are but varieties of a single species adapted to different races of animals.

The Immunization of Cattle Against Tuberculosis.—Friedmann has found that the tubercle bacilli of the turtle are harmless to warm blooded animals, and reports on a series of experiments undertaken to investigate the possibility to using them as a means of immunizing cattle against the bacilli of perlsucht. It was found that a single injection of the turtle baccilli produced a degree of immunity sufficient to protect an ox against a dose of perlsucht bacilli fatal to an untreated animal, and that cattle suffering from perlsucht are apparently cured by injections of turtle bacilli. The author claims that this method of immunization possesses advantages over others now in use, in that the bacilli employed are perfectly harmless, and that a single injection produces a well-marked degree of immunity. The serum of animals, such as guinea-pigs and cattle, immunized in this way, is strongly protective, and when injected into other animals guards them against otherwise fatal doses of virulent bacilli.

Nervous Throat Pain.—Boenninghaus says that a not unusual class of patients comprises otherwise healthy and not neurotic individuals who complain of more or less constant pain in the throat, which is increased on swallowing. Examination of the throat reveals no satisfactory explanation, for the slight chronic catarrhal condition usually present is not sufficient to account for the symptoms. By palpating the neck, however, two localized painful spots will commonly be found, one over the point of emergence of the superior laryngeal nerve through the thyroid membrane, and the other above the clavicle over the recurrent laryngeal nerve. Pressure on these spots causes the throat pain to be felt, and the author considers that the condition is due to neuritis of one or both of these nerves. Treatment consists in massage of the painful regions in the neck, and is usually effectual. In the few cases in which it fails, other plans of treatment usually are also without result. The catarrhal condition which probably forms the starting point of the neuritis should of course receive the usual treatment.

French and Italian Journals.

Definite Results of Excision of the Stomach.—Kocher states that the number of definite cures in the cases of cancer is continually increasing. Certain surgeons already have a record of 40 per cent. of cures in the case of cancer of the breast. These results are due to early diagnosis and to perfection of operative technique. The results for cancers in other locations will probably become as good as those just quoted, with the constant progress of surgery. Kocher has performed 99 cases of partial resection of the stomach, 23 of which have been done in recent years. Of the forty-five cases which have been operated on in the last six years, the operative mortality is only 5 per cent. Of these fatal cases, one died from perforation; one from gangrene of the colon; while the other patients died from pulmonary complications which existed before the operation. Of the cases operated on, twenty patients are living and enjoying very good health. Their digestion is good, in spite of the absence of free hydrochloric acid, and the functioning of the stomach is perfect. These cases have remained well for varied periods: Two for several months; two for two years; three for five and one-half years; one for six years; one for seven years, and one for sixteen years. Kocher urges surgeons to operate in these cases as soon as possible, as this is a sure way of obtaining excellent results.—*Le Bulletin Médical*, October 19, 1904.

Hysterectomy in Puerperal Infection with Phlebitis.—Doléris calls attention to the fact that in cases of puerperal infection, even after the uterus and appendages, with the neighboring venous trunks, have been removed—that is, after the total suppression of the pelvic-abdominal foci of infection—the patient may die later, and after a period of apparent recovery from the effects of distant septic foci. He cites two cases in point. In the case of the first patient, operation was performed on the twentieth day after the beginning of the infection. In spite of multiple complications, the patient was apparently cured. The temperature had been normal for some time, when there developed an empyema. The patient died just as chloroform was being administered preparatory to the evacuation of the pus. This was two and one-half months after the hysterectomy. A very virulent streptococcus was found in the pleura. In the second case, infection developed before labor and premature labor was induced. Within the next few days various examinations showed that the blood was invaded by the streptococcus. Intervention was decided upon, and total abdominal hysterectomy was performed. Death supervened within two days. This was a characteristic case of phlebitic infection. There was no trace of peritonitis nor of lymphangitis nor any serious lesions—nothing but blood infection due to suppuration of the utero-ovarian vein. There were myriads of tiny abscesses in the liver, the spleen, and the kidneys, and there were infarcts in the lungs. Bacteriological examination of the lochia, blood, and uterine wall revealed the streptococcus.—*Annales de Gynécologie et d'Obstétrique*, October, 1904.

The Role of Intestinal Worms in Various Affections.—Blanchard presents a report on the work of Guiart in relation to the influence of intestinal worms, especially the trichocephalus, in different infections. These worms are capable of being the agents of intestinal infection, especially in typhoid fever. In a recent epidemic of typhoid fever, Guiart found the presence of the eggs of the trichocephalus in appreciable quantity in the stools of ten of the twelve patients which he examined. In one case there were 28

eggs in three preparations. In the case of one patient who died, six living worms were found in the cæcum at autopsy. No eggs were found in the stools of the other patients in the hospital excepting one, and in this instance they were very few. These patients were not suffering from any intestinal trouble. As early as 1762, Roederer and Wagler found the trichocephalus in the stools of patients suffering with *morbus mucosus*. There seems to be a relation between the presence of these worms and typhoid fever. According to Guiart, an individual without worms could with impunity drink infected water, and this theory would explain the paradoxical immunity of certain quarters in which infected water is taken. It must be remembered, however, that this worm is found in the cæcum, while the typhoid foci are in the small intestine. But the egg develops first in the stomach and then descends the length of the digestive tube. The practical conclusion drawn by Guiart is that, in the presence of an enteritis whose diagnosis is not determined, even before the serum-reaction or other methods have clinched the diagnosis, treatment should be instituted to clear the intestines of worms and of microorganisms.—*La Tribune Médicale*, October 22, 1904.

The Curative Action of the Serum of Roux in the Paralyses of Diphtheria.—The opinions of clinicians remain contradictory in regard to the action of serum in the paralyses of diphtheria. Some not only deny that serum has any beneficial action on these paralyses, but they even attribute to it a harmful effect. Others, however, have published favorable instances, and the number of these is constantly increasing. Comby reports the case of a child of four years who was cured in three days of a severe paralysis, after injections of serum. In another case of late paralysis, which had resisted all ordinary means, injections of serum were tried, and after a short time a complete cure was effected. Comby believes that all children afflicted with paralysis following diphtheria, whether they have had the serum treatment or not, should receive injections of serum. There is never sufficient certainty that diphtheria has exhausted all its virulence, even after some weeks, to refuse to children the chances of the antitoxic action of the serum of Roux.—*Revue Française de Médecine et de Chirurgie*, October 24, 1904.

Intestinal Obstruction from Biliary Calculus.—Annibale Passaggi records a somewhat rare case of intestinal obstruction from a large biliary calculus, which had ulcerated its way out of the gall-bladder into the intestine, and passing down into the lower small intestine, had entirely obstructed its lumen. The patient had for a year previously complained of uneasiness and weight in the right hypochondrium, with digestive disturbances and diarrhœa. The acute condition was ushered in by meteorism, violent intestinal spasms, and fecal vomiting. An abdominal section revealed a calculus obstructing a portion of the middle segment of the small intestine. When removed, it proved to be of an irregular ovoid, 35 by 48 mm. in dimensions. Perforation of the gall-bladder by a calculus is always preceded by a long period of discomfort over the liver. The stone finally pushes its way through into some hollow viscus, such as the intestines, and follows its way downward until the lumen becomes too small to allow it to pass further. The author recommends operation as soon as the diagnosis of obstruction can be made.—*Il Policlinico*, October, 1904.

Tuberculosis of the Cæcum and Vermiform Appendix.—Natale Palermo asserts that the literature of tuberculosis of the appendix is small, while the disease is comparatively frequent. Only a microscopic examination of the tissues removed, according to Billroth, can make the diagnosis certain. Many cases supposed to be carcinoma turn out to be tuberculous. Failure in diagnosis accounts for the comparative rarity of this disease, for in reality it is more frequent than tuberculosis of any other part of the intestine. The bacilli taken into the mouth are not all destroyed by the gastric and intestinal juices, but are swept on into the cæcum, whose lymphoid structure furnishes a favorable soil for their growth, while the angle in the intestine causes the current to be slow, and the fæces are retained longer here than at any other point. The appendix is a veritable Peyer's patch, and from its lymphoid structure, peculiarly liable to tuberculous infection. Infiltration occurs, followed by the formation of nodules, ulceration, and caseous degeneration. The lumen of the intestine is contracted and obstruction results. Tuberculosis of the ileocecal tract is rarely primary, but usually secondary to an appendicular infection. The author cites seven cases, in which he made a careful pathological examination, as confirmatory of his statements. He concludes that in all chronic cases, operative interference is indicated, as they may be tuberculous in nature.—*La Riforma Medica*, October 12 and 19, 1904.

Sterilized Milk or Plain Milk?—Spolverini has carefully considered whether the use of sterilized milk has more to recommend it than the use of uncooked milk, and has concluded that plain milk, when produced under the best hygienic conditions, is superior in point of nourishment to sterilized milk, and that the advantages of the removal of bacteria do not counterbalance the disadvantages of sterilization, especially when we consider that the infant takes in the dead bacteria and all the poisonous products of their life, and that the milk is never entirely aseptic when it reaches the stomach. In sterilizing milk, the following changes take place in the composition of the milk: 1. Expulsion of the carbonic-acid gas of milk, which stimulates the secretion of gastric juice. 2. Diminution of the amount of lime and free phosphoric acid, increase of insoluble calcium phosphate, which is not absorbed, and precipitation of the antiscorbutic citric acid. 3. A large part of the lecithin and nucleon is destroyed and precipitated as unabsorbable inorganic compounds. 4. The casein is changed and rendered unabsorbable, and the soluble albumin is coagulated. 5. The fat globules unite into larger masses, that are less easily absorbable. 6. The ferments are destroyed, and thus are lost antitoxic and immunizing substances, and microbicidal compounds of great value to the child. These disadvantages result in the child being pale, with soft flesh, having a predisposition to intercurrent diseases and a lack of resistance to ailments, with slight rickets, showing disturbances of nutrition.—*Rivista di Clinica Pediatrica*, October, 1904.

Pseudo-Fluctuating Sarcoma of the Parotid.—M. A. Cantonnet reports a tumor of this kind. The growth was the size of a fist, without ulceration of the skin, and presenting at the time of the patient's entrance to the hospital a rather large central zone with very distinct fluctuation. The tumor adhered rather loosely to the ascending branch of the internal maxillary. The patient had fever. An incision was made at the fluctuating point, but only blood came out. Extreme dyspnœa, cyanosis and high fever developed. Death soon intervened. At autopsy the tumor was found to be a large-celled sarcoma. The nuclei of the cells were fusiform. Some interstitial hemorrhages were noted, very little connective tissue, and vessels without normal walls. The growth was clearly a fuso-cellular sarcoma. There was too little connective tissue for a febrile sarcoma. Distinct caseous bronchopneumonia was found. The pleura showed some granulations. The peritoneum and meninges were not involved.—*Bulletin et Mémoires de la Société Anatomique de Paris*, June, 1904.

Very Marked Mitral Stenosis Unrecognized on Account of Insufficiency of Physical Signs.—De Massary and Tessier have studied a heart whose mitral orifice was so retracted that a pencil could not be passed through it. The right ventricle was very much dilated, giving rise to marked tricuspid insufficiency. The patient died from pulmonary embolism. This fact is of interest only because the very marked mitral stenosis was not revealed by any physical sign. There was perceived only a very strong systolic murmur, which was interpreted sometimes as a murmur of mitral insufficiency, sometimes as a murmur of aortic stenosis, and finally as a murmur of tricuspid insufficiency (confirmed by autopsy); but never, during the several months in which the patient was under observation, was mitral stenosis suspected. Thus again, the opinion of Rendu has been confirmed—that very marked mitral stenosis is not manifested by any stethoscopic sign.—*La Tribune Médicale*, October 15, 1904.

Hysterical Hemianopsia.—J. Valobra considers the study of the eye symptoms of hysterical cases to be of great importance and interest. Hemicrania may be perfectly simulated by hysteria, and there may be present a homonymous hemianopsia that seems to be of organic origin. In hysterical cases the symptoms are only transitory, and follow the attacks of hemicrania for a short time only. These symptoms are somewhat rare; hence the author publishes a case in point, in a young girl of twenty-one years, who had all her life suffered from hysterical hemicrania, anæsthesias and other hysterical manifestations. Following a severe attack of headache she had homonymous hemianopsia of the left eye, persisting for ten days, and then cured very quickly by electrical suggestion. She had also abundant lachrymation of the left eye, and mydriasis. Hysterical mydriasis usually accompanies amourosis. It is probably due to a spasm of the radiating muscle of the iris, innervated by the sympathetic. The pupil reacts to light and accommodation. The excitation of the cervical sympathetic also resulted in an excitosecretory action on the lachrymal gland. The psychological theory regards such phenomena as due to fixed ideas, spontaneous or suggested. The physiological theory regards them as due to an alteration in the function of the cerebral centers, independent of any ideas. Organic hemianopsia remains permanent, while hysterical hemianopsia is cured by means of suggestion.—*Rivista Critica di Clinica Medica*, September 17 and 24, 1904.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 17, 1904.

Dr. Andrew H. Smith in the Chair.

Demonstration of the Hoy Opaque Projector.—Dr. H. Holbrook Curtis made this demonstration and said that for a number of years an attempt had been made to throw upon the screen sketches without the intermitting stereopticon slide. Most endeavors to do this had been unsuccessful because of the immense amount of heat developed. In his demonstration two arc lights were used having 2,600 candle-power. Several anatomical pictures, photographic views, photographs of individuals, etc., were thrown upon the paraffin screen with wonderful success, especially as to the reproduction of colors.

Dr. Henry G. Piffard said the projector was by no means new, for Arnold had, about thirty years ago, in his university lectures, used one which, at that time, was looked upon rather as a "stunt." The heat might be overcome by passing the rays through solution of alum.

The Influence of Preservatives and Adulterants in Foods upon the Public Health.—H. W. Wiley, Chief of the Bureau of Chemistry, United States Department of Agriculture, Washington, D. C., delivered this address. The question he was to discuss was interesting to every citizen of the United States. The fact that preservatives were used in foods was well known, and he thought that perhaps the chemist was as much responsible for this as anyone else. The preservation of food was known as long as the history of man. The preservation of food was considered a necessity not only to human life, but to commerce and trade. Certain foods, as cereals, had the property of preserving themselves for a long time, and they have been found in the catacombs of Egypt in good condition. Some foods were improved by being kept for long periods of time, and some, like milk, fish, and oysters, were not good after being kept. With the progress of civilization and science, and the intercommunication of nations, men have changed, and they were not content to-day with foods of one season, but they wanted on their tables foods of all seasons. Of course, this would be impossible without the use of preservatives. The preservation of foods was a legitimate practice, necessary to the welfare and prosperity of mankind. He asked what kind of preservatives should be employed, and were there other forms more desirable than those now used. More especially, what effect had preservatives used in keeping foods, upon the health of the consumer? It was well known that when the moisture in food was below a certain percentage, germs would not act. Sodium chloride, sugar, vinegar, and smoke were antiseptic in their nature, but their use could be revealed by taste as well as by odor. Certain substances used as preservatives were themselves foods, as sugar. Others were absolutely necessary to the metabolic processes going on in the human body, as sodium chloride. So there were legitimate reasons for the use of certain substances. When Pasteur demonstrated that decay was due to ferments, the chemist immediately got busy devising means by which this could be prevented. There were certain substances that had neither odor nor taste that could be added to foods and prevent any further decay; they were capable of killing or paralyzing the ferments that caused decay. There were a large number of chemical substances, antiseptic in nature and used in large quantities, which did not give taste or odor to foods, and it was to bodies of this class that he wished to call attention. Mention was made of salicylic acid, borax, boracic acid, benzoates and benzoic acid, sulphates, formaldehyde, etc., these being the principal ones used to-day quite indiscriminately. The question of their effect upon the public health was a grave one. The manufacturer had a right to be heard on this question, because of its effect upon his business; with the use of preservatives, he could get a wider market for his foods. The consumer had a right to be heard, because he was the one who partook of these foods. The physician had a right to be heard. The scientific man had a right to be heard, and so had very many others, for obvious reasons. This was a many-sided problem and could not be considered in any dogmatic manner. An antiseptic, to be effective, must be capable of killing or paralyzing ferments; the whole process of digestion was one of fermentation. It was not the living cell which caused fermentation, but enzymes which they secreted. Experiments on digestion could be carried on in laboratories. Certain animals might be used, but every scientist knew that all these had peculiarities regarding food digestion, some being vegetarians, some carnivorous, and some omnivorous. Therefore any experiment upon lower animals gave results that were valuable only for that animal, and which could not be applied to any other genus. Experimentation upon the human animal had limitations, of course, but in his experiments he was aided by the inexhaustible resources of Uncle Sam. The experiments carried on with twelve young men were now of three years duration, *i.e.* this was the third year of this work, and what he had to say was about the first year's work only, and had to do only with the effect of boracic acid and borax. The whole year was used with experiments of this kind. The time was divided into five periods, four short ones of ten days each, followed by a period of observation of from twenty to twenty-five days, giving increasing doses of boracic acid and borax; this was followed by a period of ten days for the purpose of restoring the individual's equilibrium. He began with small quantities; after five days the amount given was increased; after another five days the amount was doubled, and so on until the limit of toleration was reached. The quantity given was what might be expected to be contained in food as a preservative, *i.e.* 7.5 grains per day. As a result it was shown that there followed some disturbance in the metabolic processes, that is, there was a disturbance in the relation between the excreted elements and the ingested elements. Phosphoric acid, sulphur, and nitrogen excreted should be in equilibrium with that ingested and, in every instance, this changed equilibrium showed some disturbed metabolic process. There was in every instance inhibition of digestion, absorption, and assimilation whenever borax or boracic acid was given in the short periods in increasing doses, and, at last, there appeared a feeling of fullness in the stomach and in the head, and in the majority of instances bleary eyes and a marked continuous dull headache. There was also inability to perform mental operations. The nausea and diarrhœa described by the Germans in their reports could not be gotten in a single instance, despite many attempts. Even four grams taken in a day was not productive of this result. In such doses the men were made really sick, and the appellation "poison-squad" was, therefore, not wholly unjustifiable. Seven and a half grains per day, given for thirty-five or forty days, was followed by the usual symptoms, but these symptoms would not be observed before this time had elapsed. In answer to the question, "What was the fate of these substances in the body?" he said that 80 per cent. of the substance was excreted by the kidneys, and 20 per cent. by way of the skin, and that there was but very little change in either borax or boracic acid in its passage through the body. The report of his experiments will embody 500 or 600 pages, and no conclusions would be drawn until all the data were collected, and then only general averages would be given. He said that the German chemists found that boracic acid was almost a poison to the human system; he found no such thing. He said the chemists in Germany were called upon to justify the action of the Government in keeping borax from foods; they were called upon officially to justify its action. Under certain conditions, just the opposite conditions might prevail. The views of the German chemists, he said, were widely parted, but his own views were between the two, and he wished to be understood that, in making these statements, he did not intend to throw any imputations upon the work of others. What should be the attitude of physicians? If

questioned in this matter, the only safe way was to advise that the suspicious material be left alone. Boracic acid or borax was not necessary for the preservation of food, especially in a country like ours; therefore, why use it, when it was open to suspicion? In England the use of boracic acid was justified in the preservation of butter and meats. Such agents could be used without danger, possibly, but that fact did not justify their use. If introduced into foods, a label should be pasted on, advertising the kind and quantity of preservative used.

Dr. George L. Peabody said that at the International Medical Congress, held in Paris in August, 1900, this subject had been discussed. The courts usually asked the expert this question: "Is this substance under discussion added to food in that way consumed in the dose admitted capable of damaging the health of the consumer?" When put in this way the reply must usually be a negative one, for the substance was guardedly used in such small doses as not to be productive of immediate bad results. The use of an antiseptic in preserving foods could only render them less easy of attack by the organisms of decomposition and putrefaction. Now the utility of foods depended upon their instability, upon their openness to attack by the digestive ferments. The addition of antifermentative agents to foods was therefore irrational from the point of view of nutrition, and distinctly diminished their nutritive value, even if it did nothing more. Army surgeons had attested the truth of this statement. Apart from the army and navy, these foods reached largely the less well-to-do classes, those especially in need of highly nutritious and easily digestible foods. We could not tell how many cases of digestive disturbance in hospital wards, how many anæmias, how many chronic diseases of obscure origin had been caused by the prolonged ingestion of foreign materials. Lancereaux said that the so-called plastered wine of France was a common cause of cirrhosis. Of 210 cases, excessive use of wine seemed to be the sole cause in 68. He thought it was the sulphate of potassium, used to give the wine a dry flavor, which damaged the liver. The question of importance was not the danger of the ingestion of a certain small amount of an antiseptic in food, but whether the daily use of such an agent could do damage. As an illustration, it had been believed that pneumonia could be aborted by giving large doses of calomel soon after the initial chill and before the development of consolidation. He said that he had frequently given twenty-grain doses, repeated once or oftener in twenty-four hours. The only effect had been that of a very active purgative, with its evident depletion. Had forty grains of calomel been divided into tenth or twentieth grain doses, and had they been taken an hour apart until the entire amount had been consumed, the effect would probably have been a very destructive and perhaps a fatal salivation. Again, water highly impregnated with lead might be taken occasionally with impunity, but if taken in small amounts indefinitely it would cause serious damage to nutrition. It was well known that boiled milk was so altered in composition as to be unfit for infant food and responsible in certain instances for serious attacks of scurvy. Might not the same history some day be written of some of the substances now tolerated as harmless preservatives. He thought that the burden of proof should be shifted to the shoulders of those who desired adulterated foods, and that the benefit of any doubt should be given the public rather than the manufacturers. Brouardel told us that an antiseptic which was harmless to a person whose powers of elimination were active might become toxic if taken by one whose eliminative powers were sluggish. His study of the elimination of salicylic acid showed that this power was dependent upon the patient's age. In the case of a person aged 25, the acid appeared in the urine in three-quarters of an hour and was wholly eliminated in twenty-four hours. In one aged 44 years elimination commenced after a lapse of from seven to eight hours and was not completed until after forty-eight hours. In a person aged 66 years elimination commenced in two days and continued for eight days. It was fair to conclude that this last subject was particularly susceptible to the danger of the accumulation of small doses of salicylic acid. In this instance the kidneys were normal; had it been otherwise his danger would have been increased. In 1881 the French Government interdicted the use of salicylic acid as a preservative of beer, wine, and food. In 1885 a commission appointed by the Academy of Medicine of Paris reported that it had proved that the prolonged use of small amounts of salicylic acid was dangerous, and that in susceptible individuals it was apt to cause disorder of digestion and renal disease. The common assumption that boric acid, because of its feebleness as an antiseptic, was harmless was a dangerous conclusion. Cases of non-fatal poisoning had occurred where patients took from ten to twenty grains a day. Kittens had been killed in the fourth week by feeding on milk which contained eighty grains to the gallon. Parenchymatous nephritis had been caused by it. Boric acid had been used some years since in the treatment of epilepsy, and experience obtained in this way proved that it could cause albuminuria, uræmia, and death. While it could not as yet be proved that in very small amounts it had caused damage to man, it seemed that, in view of what we already knew, it was wholly irrational to permit its use in this way. The diagnosis of conditions brought about by the daily absorption of small amounts of moist antiseptics, of their effects on metabolism and nutrition, was surrounded by many difficulties, and even if there seemed to be no immediate bad effects, it was not fair to assume that future serious results might not follow their prolonged ingestion. The Paris Medical Congress of 1900 adopted the following vote: "In view of the damage recorded by various writers which results from the habitual use of foods and drinks whose preservation is assured by chemical agents, the use of these agents (borax, salicylic acid, formol, saccharin) should be forbidden in alimentary substances." The International Congress of Hygiene and Demography, held in Brussels in 1903, adopted the following proposition: "There is no ground for the toleration of antiseptics in preserved foods." Dr. Peabody said that we should first convince ourselves of the harm of these and similar adulterations, and then do what we could to convince the public, and to promote restrictive or prohibitive legislation.

Dr. Thomas Darlington, Commissioner of Health, said that the Health Board only examined such foods as were supposed to be adulterated, or those foods which contained some preservative which was detrimental to health when ingested. The work in this department lately had increased, and the Health Board had added two chemists to the present staff to assist in the analysis of foods. The foods sent for analysis were those suspected of containing some poison. Dr. Darlington referred to the cases of wood alcohol poisoning that had occurred in the Striker's farm district recently; a large percentage of wood alcohol had been found in the whiskey sold, and also in the stomachs of some of those who were poisoned. He believed that every particle of food containing preservatives should have that fact placed upon the labels, particularly in certain types of food, as milk. Preservatives should not be allowed to take the place of cleanliness. In Chicago milk was brought about 40 miles, while in New York city milk was supplied from a distance of over 400 miles in many instances. The milk brought to New York could be preserved by cold, and no chemical preservative should be allowed. Such use was a fraud upon the public and should be interdicted. Every one had the right to know just what his food contained. Whenever preservatives were used, that fact should be advertised upon the label.

Dr. Roland G. Freeman was interested in the preservation of milk, and this was first brought to his attention by a manufacturer of formalin, who wished to have it used

as a preservative of milk. Milk properly handled did not require any preservative, and it was possible to bring milk to this city from long distances if it was handled right and kept cold. Dr. Freeman referred to an article published by Dr. Harrington in the *American Journal of the Medical Sciences,* in which it was shown that kidney disease was caused by the intaking of 45 grains of boracic acid in three successive doses.

Dr. Andrew H. Smith said that interest in this subject of preservatives was upon the morbid process which they engendered in the body, and during twenty or twenty-five years their use did not seem to have increased to any degree gastric disorders. The fact that borax and boracic acid were capable of giving rise to subjective feelings referable to certain organs was to him interesting, and he hoped that Dr. Wiley would make further experiments to determine how gastric disorders were produced by these agents.

Dr. Henry G. Piffard referred to an Albany trip of his, four or five years ago, at a time when a bill was introduced forbidding the use of borax in dairy products. The borax people had their experts, and among them was Prof. Chittenden, of Yale University, who testified that borax so used was entirely harmless. Dr. Chittenden was supported by the testimony of several other experts. The bill was reported and passed. Soon a chance occurred to test the bill in the courts, and the judge threw the case out and refused to allow it to go to the jury because there was no evidence that borax was harmful. Dr. Piffard spoke of the use of wood alcohol; methyl alcohol, he said, was used to adulterate some Scotch whiskeys. The use of acetanilid as a preservative, he believed, should receive the attention of the Health Board.

Dr. A. Jacobi referred to the development of tuberculosis from the ingestion of tainted cow's milk, and said that the best way to kill off tuberculosis in mankind was to kill the tubercle bacilli, and this could be done by the use of formalin in milk. Other agents than formalin were used in milk, such as bicarbonate of sodium, and milk containing this was far from being innocuous. Regarding the reports of the German chemists, he said that they probably were right; a great deal of boracic acid was found in the food stuffs on the other side. He thought Dr. Wiley was in error regarding what he said of the report of the German chemists.

The Fourth Pan-American Medical Congress.—Dr. Joseph D. Bryant and Dr. Ramon Guiteras were appointed Delegates to this Congress, which meets in Panama in January, 1905.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held November 21, 1904.

Dr. Francis J. Quinlan in the Chair.

The Dangers of the X-Ray.—Dr. Milton Franklin read this paper, confining his remarks to a consideration of the factors of obscure and perplexing nature which rendered one liable to accident, causing damage to patients as well as operators. In 1896 the first case of alopecia due to the *x*-ray was reported, and in 1896 cases of injury to the skin and falling of the hair became alarmingly common. In 1897 many more cases were reported, and among these were instances of exostosis. To-day the situation he believed to be truly alarming. If one understood to-day just what caused these *x*-ray burns or injuries, one might then be in a position to avoid them. The number of deleterious effects produced now was legion. It was strange that the very agent used to cure carcinoma was itself capable of causing the disease. Dr. Franklin reviewed a good part of the literature on *x*-ray injuries. The pathological changes occurring in *x*-ray burns could not be said to be characterized by anything. Sometimes five or six months intervened between the application of the rays to a surface and the appearance of the first evil effect. An important point in this connection was the unanimity of opinion regarding the effects upon the blood-vessels and skin appendages. It was stated that the effects of the *x*-ray were due to the ionization of the tissues at the point of impact of the rays. According to Lodge's theory, oxygen was wanted in available form, and blood was that substance containing it, and this, Dr. Franklin believed, might account for the invariable action of the *x*-ray upon blood-vessels and skin appendages. This was the most logical theory yet propounded. The dangers now of the *x*-ray were well recognized, but when used by experienced operators accidents rarely occurred. Too much stress could not be laid upon individual idiosyncrasies. A recent canvass among skiagraphers failed to reveal a single serious result during recent times from the use of the *x*-ray. Dr. Franklin thought that one of the great factors of danger was the inability to measure the energy of the emanations from the tube. Whatever theory was accepted, it was unanimously admitted that the reaction was in direct proportion to the quantity of rays emitted. The electroscope was placed at that distance from the tube that it was desired to place the patient or plate. The rays were then permitted to fall on the air between the terminals of the electroscope, and the passage of a filament between the two marks in the field of the instrument was timed with a half-second simple pendulum attached to the instrument. The number of half-seconds required in the transit would give the exact numerical value of the radiation compared with any desired standard. The fact that many injuries had occurred when the *x*-ray was used by the tyro ought not to condemn the method. The application of the *x*-ray when not indicated was most reprehensible and unwarrantable. From a long experience the speaker advocated the following: Every patient should be placed in the recumbent position and protected with sheets of lead foil. Only the part to be treated should be left unprotected; *i.e.* if the female breast was to be treated, both extremities and the neck and head should be properly protected. The exposure should be made with a definite potency, small at first and gradually increased to the point desired. The hands of the operator should be protected by rubber gloves, especially when using the developing solutions. He believed that with the general adoption of the radiometric technique all dangers would be eliminated.

Dr. William B. Coley took up the consideration of the treatment of malignant growths with the *x*-ray. Burns were not now so frequent when the *x*-ray was used by an expert, although the danger of them still remained. He had seen many cases in which there were small recurrent malignant nodules of the breast which did not give the patients a great deal of pain or discomfort; but after two to four exposures to the *x*-ray, burns resulted which required months to heal and gave the patients much pain and discomfort, even more than did the tumors. Another great danger was from a necrobiosis of the tumor and its transferrence into other parts of the body. He knew of several instances in which this had occurred. He referred to a case of carcinoma of the breast which was gradually decreasing in size; following the application of the *x*-ray, glandular involvement occurred and an extension took place in the spinal cord, pleura, and sternum. The dangers to the operator should not be overlooked. Extensive lesions had occurred, as shown by ulcerations; malignant disease had developed upon the ulcerated areas. Investigators who were looking for the cause of cancer should consider the *x*-ray, which seemed to be able to produce this malignant disease. Four cases had already been reported which developed epithelioma six months after the application of the *x*-ray. A very peculiar feature of *x*-ray injuries was the multiplicity of the lesions. Dr. Coley referred to the danger to the public involved in the flattering reports of successful treatment of malignant disease. The *x*-ray treatment had its limitations, and should be applied only to inoperable tumors or after primary operations.

Dr. Carl Beck said that the dangers of the *x*-ray had been underrated at first, but now he thought they were exaggerated. It was quite interesting to note that the same means which was expected to cure carcinoma had

been the cause of epitheliomas in many instances, and he believed this to be an argument in favor of the non-parasitic origin of cancer. There were two points of view to be taken in *x*-ray treatment; the conditions were entirely different in cases in which one used irradiation for cosmetic purposes from those in which it was applied in the treatment of malignant neoplasms. In the latter case it was far better to give less heed to the amount of tissues covered by the *x*-ray than in the former. Idiosyncrasies had been shown in many patients, and if one treated a patient for cosmetic purposes one should give tentative exposures. In the treatment of malignant disease, these tentative exposures were not required. It was not necessary to so protect the patients, and the vicinity of the tumor need not be covered. In cancer of the breast, carcinomatous cells had been found far away from the site of the lesion, and, therefore, this protection was not required. If protection was given, one protected the carcinomatous cells. He endorsed all that Dr. Coley had said, and believed the *x*-ray was for the treatment of inoperable cases in particular.

Dr. Charles W. Allen presented a patient who came to him two years ago with the diagnosis of carcinoma of the liver. He accepted this diagnosis and gave her *x*-ray treatments. On one occasion the tube was placed either too near the surface, or else the ray was too energetic, or else the time of exposure was too long, and at her next visit there were evidences of a severe dermatitis. The rays were then stopped, but the condition went on to a deep and extensive ulceration of the abdomen. She then disappeared from view, after he had advised her to go to some surgeon and have it all excised. Upon his return from Europe he was surprised to find that she had had nothing further done and had not consulted a surgeon, but had continued to improve. The burn was not well yet, but the patient presented a greatly improved appearance. Dr. Allen believed that the experience gained by practice with the *x*-ray was better than could be had with the use of the radiometer presented by Dr. Franklin.

Dr. William J. Morton emphasized the fact that the *x*-ray must be applied in an expert manner. In the light of modern research he thought that the dangers of *x*-ray injuries could be overcome by simple management. The results were pathological ones, and gave certain symptoms. The effect of the *x*-ray was to produce an atrophy, or degeneration, or death of the parenchymatous cells. He emphasized what Dr. Beck had stated regarding shields; he believed they should be avoided, and he disapproved of what the reader of the paper had said regarding them. The Röntgen rays should be used after operation for malignant neoplasms; if it was conceded that these rays were of value after operation, why not of value before operation, in order to curtail the spread of the initial disease?

Dr. Milton Franklin said that idiosyncrasies were of no more importance in *x*-ray work than in other measures of modern therapeutics. Such cases did exist, but they were not more common in this than in other treatments. Regarding the use of shields, he probably was misunderstood; he did not intend to convey the impression that he covered all but the area he desired to treat. The description of his instrument would soon be published in detail, and he wished it understood that it was a practical one, could be used by a child, and was "fool-proof."

The Medical and Surgical Features of the Russo-Japanese War.—Dr. L. L. Seaman read this paper. His remarks were practically the same as those made before the International Congress of Military Surgeons, held in St. Louis in October. His experience during the late Spanish war had taught him that the principal enemies of our army were ferment and microbes, and that the main fighting was done by the Medical Department. Led by the desire to see a conflict where powder and shell played at least an incidental part, he had visited the Japanese frontier. He had found the Military, Red Cross, and University Hospitals at Tokio conducted on broad, up-to-date principles. Up to July 1, only about 1,100 wounded had reached Tokio, and no medical cases. They were mainly from the Yalu, Nanshua, and Telissu fights, and included many severely wounded by shell fragments, bullets, shrapnel, and explosives. The physical condition of these patients was remarkable, considering the campaign through which they had passed and the severity of their wounds, for their faces showed little evidence of illness or suffering. Up to July 1 not one of these cases had ended fatally, and those remaining in the wards showed favorable prognoses. Little or no operating was done at the front, except in cases of extreme emergency, or when hemorrhage threatened death. All patients were treated by first-aid applications and were then sent to the rear as quickly as possible, and thence to the base hospitals in Japan. The Tokio surgeons complained that they had little to do, for by the time the soldiers arrived the vast majority of wounds had healed by first intention. At the base reserve hospitals at Hiroshima hundreds of wounded arrived every few days from the field around Port Arthur. The high velocity bullets, at such short range, produced almost every conceivable type of wound. The speaker had seen instances of bullets passing directly through the great cavities—seven through the cranial, nine through the thoracic, eight through the abdominal, and so many through the extremities that the number was quite lost, cauterizing their course and healing both entrance and exit wounds by first intention after first-aid dressings. Suppuration, even in cases in which the balls ricocheted, was comparatively rare. Operations for appendicitis, hernia, floating kidneys, gall-stones, etc., were conspicuous by their absence. The Japanese soldier had been taught how to treat his intestines. His diet was plain and rational, consisting of an easily prepared and easily digested ration, which could be thoroughly metabolized and converted into the health and energy that makes the Japanese soldier the ideal fighting machine of the world today. At Shimonoseki, the chief naval base, the character of cases in the hospital was of a type distinctly more severe. Prior to July 16 the total casualties in the navy amounted to 1,429, of which 1,209 were fatalities. Over 500 of these occurred on the occasion of the torpedoing of the *Hatsuse*, and a large proportion of the remainder were on the ships that were exploded or sunk. Less than 200 wounded were rescued, and of these only five had died, and the remainder were rapidly convalescing. The wounds in these cases were usually not from bullets, but from fragments of shell, causing fearful lacerations, contusions, comminuted fractures, etc. The medical wards of the hospitals were complete in every detail, but the beds were conspicuously empty, voicing more eloquently than words the most important lesson of the war. There were only a few cases of diseases of the respiratory tract, caused by unusual exposure, and scarcely a dozen under the head of diseases of the digestive system. Internal diseases were practically an insignificant factor in the naval hospitals, and up to July 20 not a single case of beriberi had developed. Dr. Takaki had demonstrated after an epidemic in 1882 that beriberi was a neurotic disorder, resulting from a lack of nitrogenous matter in the food. The ration was remedied and the disease practically eliminated from the hospitals of the Admiralty. The ration table contained a daily allowance of three ounces of liquor—saki—which was considered beneficial. A well-regulated army canteen existed, where beer was dispensed under official supervision, this beverage being recognized as bread in solution, that had undergone fermentation, thereby saving the stomach labor. He mentioned a number of medical officers in the Japanese army who had the rank and emoluments of major-generals, a rank at least two grades higher than the highest rank obtainable in the army of the United States by a surgeon. Dr. Seaman outlined the medical organization, showing how perfect the system was, how high the men ranked, and the duties that they performed. The Japanese were the first to recognize the true value of an army medical corps. Care of the sick and wounded consumed but a small part of their time. The solution of the greater problem, pre-

serving the health and fighting value of the army in the field, by preventing disease, by careful supervision of the smallest details of subsisting, clothing, and sheltering the units, was their first and most important duty. The medical man was as much in the front as in the rear. He was with the first screen of scouts with his microscope and chemicals, testing water and foods, and investigating sanitary conditions. Notices were posted so that the approaching column was warned of danger where it existed. Bacteriological experts formed part of the staff of every divisional headquarters. A medical officer also accompanied foraging parties. In the camp he lectured the men on sanitation and personal hygiene. He had recognized that disease had brought more campaigns to disastrous terminations than the strategies of opposing generals or the bullets of their followers. Up to August 1, 9,862 patients, of whom 6,636 were wounded, were received at the Reserve Hospital at Hiroshima. Of these, up to that time, only 34 had died. This happy result was due to non-interference on the field and thorough antiseptic methods in after-treatment. In war four men died of disease for every one who fell from bullets. In this way the Japanese neutralized the superiority of Russian numbers. Japan was the first country in the world to recognize that the greatest enemy in war was not the army of the invader, but preventable disease. It was against this enemy that she had made her hardest fight and won her most signal victory. She had kept her men in superb condition. Major Seaman spoke of the contrast he had noted on visiting the Russian lines, where brutality, debauchery, and criminal carelessness existed. The three great lessons to be learned from the Japanese war were from the medical, the commissariat, and the transport department. The Japanese Government permitted our Government to send five military attachés to accompany their army in the field, but no surgeon or quartermaster had been detailed. The life-saving and life-preserving departments were omitted; the killing departments got the appointments, and the Japanese officers were laughing at our folly. But what could be expected of a Government that, as in 1898-9, gave its men a ration that prostrated 50 per cent. of its 250,000 units with intestinal disease within six weeks and sent 3,000 to their last home? What could be said of the business principles of a Congress that preferred pensions to prevention; that permitted misguided women to deprive its army of one of its most beneficial features, a well-regulated canteen; that provided no instruction in physiology and hygiene in its great preparatory schools—Annapolis and West Point? Major Seaman said that it was time to demand another reorganization of our army, in which that branch of its service that grappled with the foe that caused 80 per cent. of its mortality should have equal recognition with other branches which, combined, fight the enemy which destroys but 20 per cent. The State deprived the soldier of his liberty, prescribed his dress, diet, exercise, etc., and expected him, if necessary, to lay down his life; it should therefore give him the best sanitation and the best medical supervision that the science of the age could devise. An adequate medical and sanitary organization was more important to the United States than to any other nation, because of the smallness of its regular army, and because in cases of emergency the vast majority of its medical officers must be drawn from civil life.

The Association of Military Surgeons had resolved that Congress be petitioned at its next session to reorganize the Medical Departments of the United States Army and Navy on a broad basis similar to that of the countries most advanced in military sanitation, giving to their officers equivalent rank, dignity, and power, and to their personnel ample members for the proper care of the sick and injured. The Association also recommended that the sale of beer be permitted at army post exchanges, subject to such regulations as should be determined by the General Staff of the Secretary of War; that an adequate knowledge of the care of troops was of such vital importance that it should be given recognition in our Army and Navy Schools, and especially in the Staff Colleges and War Colleges, and that the present course at West Point and Annapolis should count it in the requirements for graduation; it therefore respectfully petitioned the President to make this resolution effective.

The speaker said that the subject was a terribly live one, and that all he hoped for was that the man in the ranks and the medical profession might get their rights and due recognition.

This paper was discussed by Major John L. Phillips, U. S. A., Dr. Nathan S. Jarvis, Captain A. E. Piorkowski, Imperial German Army, Colonel W. E. Church, U. S. A., Major J. F. Powell, U. S. A., and Dr. Andrew H. Smith, and was closed by Dr. Seaman.

Chicago Medical Society.

At a meeting held November 16, 1904, Dr. Martin B. Tinker of Ithaca, New York, contributed a paper by invitation, on "The Advantage of Muscle-Splitting and Muscle-Retraction Incisions in the Prevention of Ventral Hernia." To avoid the disadvantages of the rectus incision, particularly the paralyzing of the median side of the muscle, he said that Lennander in 1898 introduced the rectus retraction incision; while in 1900 Pfannenstiel introduced his supra-symphyseal cross incision. The speaker usually employed the former incision in opening the abdomen for pelvic operations, although if freer exposure was desirable, the Lennander incision was preferable. The Pfannenstiel incision was found satisfactory for myomectomy; for operations on the tubes or ovaries; advancement of the round ligaments for backward displacement, or other operations near the median line of the lower part of the abdomen. For abdominal hysterectomy the Lennander incision gave better exposure. For exploration of the right iliac fossa, when some involvement of the pelvic organs was suspected, he also preferred the Lennander incision. When simple appendectomy was to be done, he thought nearly all surgeons agreed that the McBurney muscle-splitting incision was preferable, but when appendectomy was combined with pelvic work, the Lennander incision was preferable. As features of great importance in the prevention of ventral hernia, he mentioned healing by first intention; careful arrest of hemorrhage to prevent the accumulation of blood in the wound; the prevention of strain on the wound after operation by distention, etc. The possibility of getting a patient out of bed at an early date after operation with a feeling of real security from hernia, and without the need for wearing the binder, was a great satisfaction, and sufficient reward for the extra pains and few additional minutes of time taken to open and close the abdomen by any one of these methods. Dr. L. L. Mc Arthur was very much surprised that as large a proportion as one in five, or 20 per cent., of hernias should occur. It might be explained on the basis that patients did not return to the surgeon who had been the cause of the hernia. Dr. Arthur Dean Bevan mentioned a number of factors which must be considered in planning an abdominal incision. One should plan the incision (1) so as to give free and sufficient exposure to do the operation, (2) so as to give the least possible danger of a resulting hernia. One could not employ the Pfannenstiel incision in opening the abdomen to remove a large fibroid of the uterus. He could not employ the muscle-splitting incision in opening the abdomen to remove a large spleen. If one opened the abdomen posteriorly, to remove a large tumor of the kidney, the muscle-splitting incision was out of question. A muscle-splitting incision had little value in operations on the kidney. There was very little danger of hernia following a properly planned kidney incision, which divided the external oblique, the internal oblique, the transversalis fascia, but which did not interfere with the nerve or arterial supply of the abdominal wall posteriorly. Dr. E. Wyllys Andrews thought the Pfannenstiel incision was a skin incision only until he had heard differently. He

had only used it a few times, and believed it was employed almost entirely in the case of young or generally unmarried women, so as to be covered by the pubic hair afterwards. Personally, his inclination was to make a one-half or three-quarters of an inch incision out from the median line and secure the muscular wall for the incision. In ordinary laparotomy he attached considerable importance to the imbrication method. Dr. A. J. Ochsner had followed many hundreds of his cases, and in those in which there was no drainage or suppuration there was no ventral hernia. He placed a silkworm gut suture down through the transversalis fascia as an emergency suture, so that if the patient should sneeze severely at the time when the catgut became softened, there would be a safety suture on the outside to hold it. He sutured the peritoneum and transversalis fascia together; he passed a second catgut suture through the muscle, a third catgut suture through the aponeurosis of the external and internal oblique, and after all tied the silkworm gut sutures sufficiently loosely to guard against pressure necrosis. Furthermore, he applied, for emergency's sake, broad adhesive strips, so that if a patient should strain, vomit severely, or sneeze, the soft tissues would not be torn. Dr. E. C. Dudley made his so-called median incision through the right rectus muscle, parallel with the fibers of the muscle, somewhere near the inner margin of the muscle, to avoid ventral hernia, and to get a more accurate closure. Dr. William Cuthbertson spoke in reference to the after-treatment, saying that some practitioners lost sight of an important point, namely, the complete wound healing after operation in the abdominal cavity. Dr. Carl Beck had removed large tumors through a small transverse incision which one could stretch. The muscles were not split, but simply the fascia. Dr. Albert Goldspohn said the cardinal principles of closure of wounds must be carried out or there would be a hernia. He described a technique similar to that of Dr. Ochsner. Dr Tinker, in closing, would not have the members believe that he advocated these incisions for all kinds of surgical work, as no one recognized their limitations more clearly than he did.

Medical Society of City Hospital Alumni, St. Louis.

At a stated meeting held October 2, Dr. Geo. Gellhorn read a paper entitled "The Early Diagnosis of Uterine Cancer." He stated that cancer is on the increase, it being, according to the statement of Roger Williams, four times as common as it was fifty years ago. Only about 30 per cent. of the cases of uterine cancer which come under medical observation are operable at the time of first examination, and of these not more than one-fourth remain free from recurrence, so that only about 10 per cent. of the patients are saved from death. Each should consider it his duty to emphasize the points bearing on uterine cancer, and constantly study the means to arrive at an early recognition of the disease. The responsibility for the timely diagnosis of cancer rests with the family physician. Without his assistance the gynecologist will almost invariably see the case only when the disease is too far advanced to permit of a complete removal of the morbid growth. The speaker presented several specimens with the histories of the cases. The first case was that of a lady of fifty years, and the condition had been diagnosed submucous myoma. The only complaint was hemorrhage at the menstrual period. Examination showed a small tumor within the external os, and an attempt was made to enucleate it; only after microscopical examination of sections was it discovered that cancer existed. The uterus was removed and the disease was found to have spread to the left tube and involved the entire mucous membrane. Four and one-half years later the patient was still free from recurrence. Another case was that of a woman of thirty-eight years, whose mother and two aunts died of carcinoma. She had been treated for "ulceration of the uterus" for about one year. She had few symptoms, but following a slight, offensive discharge, a physician pronounced the case cancer, and this was confirmed later by the microscope. The speaker extirpated the uterus and found the growth had already invaded the deep tissues of the cervix. Speaking of the statement often made that the microscope sometimes fails to reveal the presence of the carcinomatous process, he mentions a case of a woman of fifty-three years, already in her menopause, who had been treated for several months for ulceration of the womb. The speaker was asked to examine her, but found no suspicious symptoms, and the patient was sent back to her physician with instructions to report to him in case any irregular hemorrhages occurred. This complication occurred two and one-half months later, and the patient was greatly weakened. She was transferred to a hospital at once, and the uterus curetted, but the microscope failed to demonstrate the presence of cancer though the macroscopical appearance very much resembled that of carcinoma. Numerous sections were made from all the pieces removed, but no malignancy was detected, yet the clinical observations concurred in establishing a diagnosis which the microscope could not verify. After long and careful consideration, the negative result of the microscopical examination was disregarded and the uterus was removed. The specimen showed a uterus considerably enlarged and thickened, but there was no sign of cancer anywhere. Dr. Carl Fisch said it was impossible positively to diagnose cancer in the very early stages by the microscope, because we do not know the appearance of the tissue in this stage of the disease. When a case presents suspicious symptoms and the microscope is unable to verify the diagnosis of cancer, the patient should be operated upon.

Dr. Fred J. Taussig read a paper entitled "The Etiology and Management of Brow Presentation," and reported a case. The case threw an interesting light upon the etiology of brow presentations. Owing to the fact that the umbilical cord was tightly wound twice around the child's neck, together with a condition of hydramnion, deflection of the occiput occurred. A sudden and complete rupture of the bag of waters served to fix the head in this position. The speaker agreed with the view that conditions of the soft parts and accidents affecting the attitude of the child are more often responsible for the occurrence of brow presentations than anomalies of the bony pelvis. In the management he suggested that when the head had already entered the pelvis, and when Thorn's method of correcting the position could not be applied, the following procedure be tried: One blade of the forceps is passed around the occiput; two or three fingers of the opposite side are introduced to exert pressure upward on the brow, while, at the same time, traction is made downward with the forceps blade; in order to prevent the forceps blade from slipping, a certain amount of counter pressure must be made between the blade and the fingers; an assistant simultaneously exerts pressure on the abdomen, with one hand pushing the chest of the child backward, and with the other hand pushing the breech forward. In this way pressure is exerted upon the child's body at four points, all tending to restore to the normal attitude. The procedure was tried in the case reported, and, although not successful, owing to the extremely critical condition of the child, it was shown that a very considerable amount of flexing power was obtained. The patient should be under an anæsthetic. If the procedure is unsuccessful, it can be followed immediately by the application of forceps.

Oriental Drugs.—The United States General Appraisers have recognized, officially, the medicinal virtures of dried lizards, which are in high repute among many Celestial residents of this country. Hing Lum Chon imported some of the lizards, and Collector Stranahan classified them as a medicinal preparation. Hing Lum Chon protested, and carried the case to the Board of General Appraisers. They confirmed the classification, and thus upheld Mr. Stranahan's title as an expert in the Chinese pharmacopœia.—*The Sun.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 26, 1904:

	Cases.	Deaths.
Measels	98	9
Diphtheria and Croup	376	40
Scarlet Fever	184	9
Small Pox	3	..
Chicken Pox	136	.
Tuberculosis	324	166
Typhoid Fever	89	12
Cerebro-Spinal Meningitis		14
Typhus Fever	.	.
Yellow Fever	.	.
Cholera	.	.
Totals	1,210	250

The Heart and Circulation in Pregnancy and the Puerperium.—Alfred Stengel and W. B. Stanton conclude that there is not, during pregnancy, any hypertrophy of the left ventricle, nor any special increase in its work. The increase of dulness toward the left is due to the upward displacement of the diaphragm and the consequent displacement of the heart in an upward and outward direction. The comparative outlines before and after labor show a rapid return to the normal position. Besides the frequency of an increase in the extension of dulness toward the left in the second and third interspaces, there is noted a distinct pulsation in the same area. This condition is evidently ascribable to distention of the conus arteriosus and root of the pulmonary artery. A systolic murmur is often heard in the same area. The writers believe that during the later months of pregnancy there exists some continuous dilatation of the right ventricle. This, however, seems to be of very moderate degree. As to the condition of the abdominal recti, in multiparæ separation of the recti materially lessens the tendency to displacement of the diaphragm, and diminishes in a corresponding degree the displacement of the heart during pregnancy. After delivery, this diastasis of the recti, however, may occasion a downward displacement of the cardiac apex, and the contrast before and after labor may be quite as pronounced as in primiparæ, though the first position occupied may not have been far from the normal. Later, if the separation of the muscles is not considerable and the normal tonus of the abdominal walls is regained, a restitution to the normal of the heart and its apex occurs. The writers have proved conclusively that there is no material increase of blood pressure before or after labor. During labor, there is sometimes observed a notable increase in the blood pressure. In comparing figures, the difficulties due to the imperfections of apparatus and the personal equation of the observer become apparent.—*University of Pennsylvania Medical Bulletin.*

Disinfections for Diphtheria and Scarlet Fever in Baltimore, with an Account of Reinfections.—Wilbur P. Stubbs describes the method of disinfection used by the Health Department of Baltimore, in relation to diphtheria, especially. When the presence of diphtheria is reported, the house is placarded at once and remains so till the throat cultures taken from all the inmates of the infected house are declared by the Health Department to be free from the presence of diphtheria bacilli. All inmates of a house placarded "Diphtheria" are supposed to be under quarantine. The increase in the work of throat inspection has been enormous, about 2½ times as many cultures having been taken in 1903 as in 1902. The largest number of cultures were taken during October, November, and December, while the smallest number were taken during the summer months. The opening of the public schools is doubtless the main factor in bringing about this relation. When negative cultures have been obtained from all of the inmates of an infected house, all of the infected rooms are disinfected by means of formaldehyde gas, and test cultures are placed in the rooms and returned to the Health Department by mail after fumigation. If it is seen by these cultures that all the germs have been destroyed, the disinfection is considered effective. If, however, germs are found, the fumigator repeats his work until a negative culture is obtained. The writer gives a table which shows how few reinfections have occurred. He includes in this table scarlet fever reinfections. The number of disinfections for 1903 in cases of scarlet fever was 957; in cases of diphtheria, 1,168; the number of reinfections, respectively, 18 and 34; the percentage of reinfections being, therefore, 1.8 per cent and 2.9 per cent. A case of reinfection occurring under one month after the room is disinfected appears to be dependent upon the original infection. This may happen even with the most stringent fumigation, for bits of membrane may be coughed up and deposited upon the nurse's dress, and if she goes to another part of the house this membrane may be deposited in various places. Considering the common obstacles to ideal disinfection, of which this is an example, the number of reinfections is small. In the case of scarlet fever, the period of time before reinfections occur is longer than in the case of diphtheria. But the period of incubation is generally longer in scarlet fever than in diphtheria. And again, the period of infectiousness in the case of scarlet fever is on the average about six weeks, and may be much longer. The scarlet fever organism seems to be even less resistant to formaldehyde than is the diphtheria bacillus, to judge from the smaller percentage of reinfections. The writer, in conclusion, emphasizes the importance of throat inspection and of thorough disinfection.—*Maryland Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the period from November 19 to November 25, 1904:

PROBLEMS IN DIETETICS.*

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE IN THE CORNELL UNIVERSITY MEDICAL COLLEGE IN NEW YORK CITY.

IN the dietetic treatment of disease, it not rarely happens that a combination of conditions is present in the same patient which appear to demand almost diametrically opposite systems of feeding. It often happens, also, that a diet which serves good purpose for a time, subsequently becomes harmful through causing anæmia and debility, if too long continued in a very chronic disease, and not a few patients become gradually starved by adherence to a régime which has become monotonous and distasteful. Again, there are certain recurrent diseases, like rheumatism, for example, which demand a special diet in the acute stage, but in the intervals between such attacks the question arises as to how far dietetic treatment may be made prophylactic. There are, moreover, a number of nutritional disorders, the etiology of which is still so obscure that the formulation of proper dietetic principles becomes unusually difficult. It is to the solution of some of these complex dietetic problems that the present discussion is directed.

Typhoid Fever.—One of the most practical of dietetic problems is the determination of the proper time at which to feed the typhoid fever patient with other foods than milk. Twenty years ago it was the common practice to continue the exclusive milk diet of the febrile stage for at least ten days after the body temperature had reached the normal, and remained normal or subnormal. I have seen such treatment produce a condition of scurvy, with swollen hemorrhagic gums, and I have long been convinced that in many cases it not only protracts convalescence, but, by impoverishing the nutrition, makes the patient far more liable to serious complications, such as thrombo-phlebitis, neuritis, general furuncolosis, etc. It is my present rule to commence the feeding of semisolid food, in ordinary cases, on the day when the body temperature first reaches the normal. Such articles of diet may then be given as soft-cooked eggs, baked custard, junket, milk toast, mutton or chicken broth thickened with rice or crackers, plain gelatin foods like blanc mange and wine jelly, and light farinaceous foods such as farina and boiled rice with beef juice. On the third day, if convalescence be uninterrupted, a scraped beef sandwich is given. I have never seen harm from such early feeding, and in support of this statement I might present several hundred temperature charts from cases thus treated at the Presbyterian Hospital by my colleagues and myself, during some years past.

Early increase in the dietary (*i.e.* as soon as the temperature first becomes normal) is recommended in all such cases as the following; very mild cases in general: any case in which the patient has a fairly clean, moist tongue, a soft abdomen, stools which are nearly normal in consistency, a clear mind and eye, and no serious complication. I should avoid it if there be much tympanites, diarrhœal stools, or recent severe hemorrhage. One is liable to forget that milk must be solidified by coagulation before it can be digested, and moreover, there are not a few persons who cannot digest milk at any time in health, or who cannot take it continuously for a week or ten days without serious biliousness. Such persons are surely no more likely to assimilate it when the digestive fluids are impaired by a long-continued fever. The objection that particles of solid food may act as mechanical irritants, erode a partially or recently healed ulcer, and thereby induce relapse, is hardly consistent with the modern view of typhoid fever, as a disease in which the germs are by no means confined to the alimentary canal, but are widely distributed throughout the body. Many so-called "relapses" are not relapses at all, in the ordinary sense, but are cases of mixed infection or some form of autointoxication. Of course, it would not be maintained that a diet of corned beef and cabbage may not produce great intestinal havoc and perhaps induce fatal hemorrhage, but I do maintain that a carefully increased dietary such as that described, is not a *cause* of relapse. This statement is emphasized for the reason that I so often find the friends or nurses of patients, as well as their physicians, censuring themselves or each other because the patient, having been given one egg, for example, has begun a relapse the next day, whereas he is in reality better prepared to endure the relapse, having had the food when he could digest it.

Typhoid fever is essentially a disease of so-called "relapses." About ten per cent. of all cases are followed by relapse, no matter what the treatment. I have witnessed many relapses among those who had taken nothing but milk, and had not raised the head from the pillow, and, on the other hand, have met with many dietetic misfits, which were not followed by relapse—even the eating of an entire bouquet by a ravenous child, upon whose pillow a zealous "flower missionary" had placed it. It fell to my lot to treat some two hundred cases of typhoid fever among the soldiers who returned from the Spanish War, and I was much impressed by the comparatively slight effect which a perfectly irrational diet had had upon them—relapses were not more common among them than the average, and although the cases were severe the mortality was not excessive. This merely shows that the ulcerated intestine may be more tolerant of food than is generally supposed.

There is a class of cases, much to be dreaded, in which the main danger lies in the rapid loss of nutrition. The temperature often remains low (101°-102° F.), but the loss in weight may exceed a pound a day; emaciation thus becomes extreme, and asthenia is pronounced. These cases are prone to serious complications, and the maintenance of a better nutrition is imperative. Evidently the milk

* A paper read before the Practitioners' Society in New York and the Section in Medicine of the Buffalo Academy of Medicine.

given during the fever is not digested or assimilated, curds are often to be observed in the stools, and meteorism is common. It is my custom in such cases either to abandon the milk diet altogether, or to give milk only which has been predigested and to reinforce it with beef juice, the white of egg, milk sugar, orange juice, and light farinaceous gruels. In such cases also, semisolid food may be given before the temperature is actually normal. In another group of cases, after a febrile course of considerable severity, the temperature remains normal for an hour or two in the day during the fourth week, but rises again each day to 100°-101° F. It may indeed be subnormal part of the time, thus presenting diurnal fluctuations of two or three degrees, and this condition may continue into the fortieth or perhaps fiftieth day, without discoverable complications. This type of patient almost always needs semisolid or solid food: I have a number of very striking charts of such cases, in which the temperature became normal and uniform within twenty-four hours of increased feeding. It is important to remember how little the thermometer really teaches in fever. It gives the balance, to be sure, between heat gain and loss, but if the loss be increased *pari passu* with the gain, the thermometric record is low, although metabolism is active and emaciation extreme. I would insist that the proper guide for feeding the typhoid patient is not the thermometric record alone, but rather the state of the digestion and the patient's general condition, as evidenced by the appearance of the tongue, the abdomen, the stools, by the appetite and the facies.

When, during the course of the fever, the patient being upon a milk diet, tympanites ensues, or any other evidence of marked indigestion, the milk should be withheld entirely for two or three days, beef juice and egg albumen or broths being substituted. With malfermentation, lactic acid and milk sugar are capable of evolving quantities of CO_2 gas, and not even hæmorrhage is to be more dreaded than excessive distention of the intestinal wall, weakened as it is by ulcers which may be on the verge of perforation.

Arthritis deformans, which is exciting so much renewed interest at present, is a disease of undetermined etiology, and it is very doubtful whether any form of food is especially harmful in this affection, in the sense in which it may be injurious in diabetes or gout. One meets with cases (not a few of which have been mistaken for rheumatism) in which the patients have been starving themselves in the belief that one or another article of diet is injurious, just as they believe it is in gout or rheumatic fever. As arthritis deformans, excepting in a few rare acute cases, is an exceedingly chronic and disabling disease, those afflicted with it tend to emaciate, owing to suffering from pain, lack of exercise, etc. Whether the disease be due to some perverted function of the trophic nerves, to an infection, or to spinal cord lesion, it is certainly best combated, in the present state of knowledge, by maintaining general nutrition at as high a level as possible. For this reason I am in the habit of treating these patients dietetically very much as if they had chronic phthisis, or chronic sepsis, *i.e.* by forced feeding, using largely fat foods —butter, cream, eggs, oils, bone marrow, bacon, etc. To combat the anæmia, they need also to eat abundantly of meats. Hence, in the main, these patients thrive best with a full diet of animal food, with predominance of fats. Digestion is not usually impaired, so that with a little care this dietary is well tolerated.

The ordinary meals should be supplemented by two or three luncheons during the day, at which milk and eggs, nutritious meat broths, meat sandwiches, or the like, are given. A heavy diet in one unable to exercise may be rendered less liable to produce biliousness by the following means: the use of simple bitters before meals, of dilute hydrochloric acid with nux vomica after meals, and the promotion of elimination of waste by use of an occasional cathartic and by the drinking of water in large quantity.

Nephritis.—It is a curious fact that in nephritis, as in diabetes, the organic substance which is chiefly at fault, being eliminated in excess, is the one which is most injurious when supplied to the organism in excess as a food, namely albumen or proteid in the one case, sugar in the other. It might be supposed that when proteid waste becomes abnormal, proteid food should be increased to supply the deficiency, yet so complex is the metabolism of such food that the appearance of albumen in the urine is regarded as a sign that proteid food cannot be completely assimilated, and to add it to the dietary is to add to the proteid waste direct and endanger the system through toxæmia. It is my belief, however, that in certain classes of cases this danger may be exaggerated. There seems in all cases to be a decided difference in the potential toxicity of the various proteids; thus, the proteid of red meats is the most deleterious, that of chicken and fish less so, and that of eggs and milk (casein) is still less, or not at all toxic.

As it is desirable to discriminate clinically and pathologically between different varieties of nephritis, so it is advantageous to modify the diet in the several types of this disease. The acute forms of nephritis may here be eliminated from further reference, for it is universally agreed that they demand an exclusive milk diet, or diet of bread or crackers and milk with farinaceous gruels, and the same statement applies to serious acute exacerbations of chronic forms. With regard to the chronic types, it is necessary to be more specific, for I would not be misunderstood in stating that the danger of eating meats in chronic nephritis is considerably overrated, and that there are some cases in which their moderate use is positively demanded. Such cases are (1) those of very long standing, in which the chief symptom is a moderate albuminuria, (2) those in which anæmia and loss of strength and weight are the prominent features, and (3) those in which some associated disease makes the use of animal food desirable.

(1) Cases with moderate albuminuria as the chief symptom. There are many cases in which the presence of alubumin is discovered in routine examination, as for example, for life insurance. If the patient be actively employed in business, or otherwise, and if he feels perfectly well, he is likely to become anæmic and lose strength if meat be withheld entirely. My practice is, in such instances, to permit the use of red meat sparingly, never more than once a day, or every other day. The urine, meanwhile, is systematically examined once in two or three weeks, and any increase in albumin or casts, or marked alteration in quantity or specific gravity, calls for a total abstinence from meat for a fortnight, when if improvement follows, it is again eaten. I have in mind four cases in which this plan has been followed for from five to six years, without any ill effects whatever. Two of these patients are middle-aged men, active in business pursuits, yet taking much exercise. They are allowed to eat bacon, ham, chicken, turkey, game, eggs and fish almost without restriction, and further to eat a small portion of steak, rare roast beef, mutton or a chop every other day. Originally, when their diet was restricted to vegetable foods and milk, they were losing in

strength, but on a more liberal diet, they tell me, they should not be aware of any ailment, but for the frequent urinalysis which is insisted upon. The albumin averages one or two per cent. by volume, and the specific gravity 1,020-1,025. I am confident that if they had been frightened out of all meat eating through so many years, they would be in far worse condition.

In cases of so-called functional or physiological albuminuria, or albuminosuria, a vegetarian or milk diet of ten days or a fortnight usually produces marked improvement in the urine, after which the patients are treated upon the same plan as above outlined.

(2) The second group of cases comprises those patients who through chronic nephritis, and, perhaps, accompanying arteriosclerosis, have become very anæmic and weak. It is not possible always to give such patients meat, and it is certainly undesirable if there be any uræmic symptoms, yet among them are not a few who become prematurely starved. With them periods of vegetarianism or of the diet of infancy may be made to alternate with periods of allowance of proteid foods. I will cite a single illustrative case, among many that I have seen. During the past summer a man sixty years of age was sent to the country, where I was residing, to be under my care. He arrived cyanosed, dyspnœic, and with a feeble, quick, intermittent pulse. His anasarca was so great that his features were almost unrecognizable, and he could wear none of his ordinary clothing, and the scrotum was so large that he could no longer contain it within a nightcap with which he had devised a temporary suspensory bandage. The left pleural cavity was more than half full of fluid. The urine was reduced to 20 ounces per diem, and contained from 5 to 7 per cent. of albumin by volume, many casts, and an average of only 15 grains of urea per diem. In a word, he presented a typical case of chronic parenchymatous nephritis, in the terminal stage, with a dilated heart and marked arteriosclerosis. He had for months past been allowed nothing but "slops" to eat, as he said, and his consumption of water had been reduced so much that he complained bitterly of thirst. He was very anæmic and, naturally, too feeble to walk. He was at once required to drink abundantly of water and vichy, and his diet was increased by addition of eggs, chicken, ham, and later a small portion of red meat once a day. He soon improved; within three weeks his anasarca completely disappeared, his pleuritic transudate was absorbed, his dyspnœa left him, his color and strength improved, and he was able to walk about on a level and take a daily drive. He received, of course, appropriate medicinal treatment also. He is phenomenally tall, —six feet four inches in height—and I am confident that he had been starved by the previous rigor of a diet too long enforced. His urine increased to 70 or 80 ounces per diem, with slight improvement as to the abnormal ingredients. It would be unwise to assert that the more liberal proteid diet caused all the improvement, but I am confident that without it improvement would have been much less in degree and promptness.

In cases such as this, in which there is a complicating endocarditis, and possibly myocardial degeneration, it is a mistake to allow the heart muscle to become still more feeble through inanition from lack of proteid food.

This case recalls the important dietetic question of how much fluid to allow patients with general anasarca, due to any cause. I think the only safe guide is the ratio between the fluid ingested and that which is voided. If the fluid ingested be restricted to, say, 30 ounces per diem, and the quantity of urine falls correspondingly, it is dangerous to withhold fluid longer, for uræmia is liable to develop. In a few cases, temporary restriction of ingested fluid causes reabsorption of the fluid which has passed into the tissues and serous cavities. The osmotic currents are reversed, and the quantity of urine is not diminished, or may possibly be increased. Unfortunately, this favorable result is seldom attained, but the experiment is worth trying in a given case. Should it not succeed, however, within forty-eight hours, *i.e.* should the quantity of urine still further diminish, there is danger that the excretion of urinary solids will be lessened, and possibly the reduction in intrarenal pressure which ensues may increase the accumulation of casts, which plug the renal tubules. It would seem best, therefore, in such cases not to restrict the fluid ingested below 50 or 60 ounces.

In the dietetic treatment of serous accumulations in the pleura, pericardium, or peritoneum, due to other causes than nephritis, the restriction of fluid ingested is often disappointing in its results. It influences reabsorption of transudates upon the whole less than does active catharsis.

(3) Chronic nephritis complicated with other diseases. What treatment should be given the patient whose nephritis demands no meat, yet whose complicating diabetes requires chiefly meat, or whose complicating gastric catarrh or phthisis requires chiefly animal food? The common refuge in all these cases is an exclusive milk diet, as it is the recourse of all those who are unwilling to bestow either time or interest upon dietetic problems. It is astonishing in how many hospitals there is no mean between the full "house diet" for the hearty day laborer with a broken leg, the "half diet," which is more often a mere reduction in quantity than an intelligent modification in quality, and the "milk diet," which is given indiscriminately in all doubtful cases, no matter what perils of biliousness, constipation, and tympanites may ensue. In dealing with nephritis complicated by other serious disease, if the patient be only ill enough, it may be granted that a milk diet may serve him best, but what directions are to be given the patient whose symptoms are as yet slight, and whose expectation of life may be several years? I think the only rational method is to determine which disease threatens the patient more severely, and diet that condition. For example, in a man of fifty years or more, who is not losing weight, complaining of thirst or other diabetic symptoms, a moderate glycosuria may be disregarded in the presence of the greater danger of thickened arteries, very high pulse tension, with moderate albuminuria and casts. Suppose a patient with a mild grade of chronic nephritis to have also a chronic gastritis, or a dilated stomach, which makes the digestion of other than proteid food impossible, it becomes a necessity to largely disregard the nephritis if nutrition and a fair degree of strength are to be sustained.

In all these complicated chronic cases the maintenance of nutrition is the all-important factor, and the effect of any system of diet should be checked by frequent examination of the stools, the urine, the body weight, and the condition of the blood as to anæmia.

The dietetic treatment of advanced cases of endocarditis involves two important factors. First, it is most undesirable to allow the heart muscle to become anæmic through insufficient nourishment, and, secondly, it is undesirable to overload the system with fluid which, when added to the volume of the blood by absorption, overtaxes the work of the heart and induces dilatation, or failure of compensation.

Hence it is that many cases of advanced mitral regurgitation, for example, do much better upon a solid or semi-solid diet than with milk and broths alone, and the diet should comprise a fair proportion of proteid.

Diabetes.—In the dietetic treatment of diabetes, I have come to disregard, almost entirely, the use of the much exploited gluten substitutes for bread. A diabetic patient who took a very intelligent interest in her symptoms and treatment had a large number of these preparations analyzed by expert chemists, both in this country and abroad. The gluten flours, biscuits, etc., were purchased in open market, and it was surprising how unreliable they were, many of them being found to contain a large proportion of starch or sugar, or both. Not only are such preparations uncertain in composition, but they fail to satisfy the craving which the diabetic has for bread, and he is apt to make too free use of them. Bread made from almonds, peanut flour, or the soya bean may be used for short periods of time, but is open to similar objections. For these reasons it is often best to allow the patient one or two very thin slices of thoroughly toasted bread once or twice a day, or a small baked potato. (The potato contains bulk for bulk less carbohydrates than bread by nearly 50 per cent.) A very good plan is to order the potato in the form of "Saratoga chips." In this manner a potato is divided into so large a surface that it seems to last longer and give more satisfaction in the eating; moreover, it is thoroughly cooked in fat. By these means it is possible to know with fair accuracy how much starchy food the patient is able to assimilate, and the quantity can be increased or reduced in accordance with that of glucose in the urine, and if fair equilibrium be established the patient retains weight, strength, and temper much better with a definitely prescribed modicum of starchy food. I think it is the general practice at the present time to order a less rigorous diet than formerly.

In fact, I am inclined to concur with the statement of Robert Hutchison, that "there is no such thing as a 'diabetic diet.'" In other words, a routine dietary for this disease may beget more harm than good, and each case constitutes a separate dietetic study.

In dealing with a well-developed case, it may be best to prescribe total abstinence from starch and, of course, from sugar for a week or two, with the promise that as the glycosuria abates and other symptoms improve, a measured quantity of bread or potato will be again allowed. Otherwise, the patient is apt to rebel against the hardship and help himself indiscriminately.

If the result of the carbohydrate elimination is a total disappearance of glycosuria, the patient can probably still assimilate small quantities of carbohydrate food, and very often the temporary rigid diet will the better enable him to do so by "re-educating the tissues in their power of dealing with sugar," as Hutchison expresses it.

It is a curious fact that certain tribes of man, like the Esquimau, live contentedly without ever knowing the taste of carbohydrate food, yet those accustomed to it, through heredity and life-long habit, find it impossible to do without it, and diabetics often appear to develop an abnormal craving for it.

Mild cases of diabetes will do well upon a diet chiefly proteid, to which a moderate quantity of carbohydrates and fats is added.

In more serious cases the fat should be still further increased, and in those most serious cases of all, in which upon an exclusive test diet of proteids, glucose continues to be excreted in the urine, both proteids and carbohydrates should be reduced below the normal, and the patient should take as much fat as he can possibly assimilate.

Among the fat foods which should enter largely into such a dietary are the following: Butter (¼ lb. per diem, or more), cream diluted with water and drank as a beverage (one pint or more per diem), the fats of Russell's Emulsion, cod-liver oil, olive oil upon salads, sardines, etc.; olives, oily nuts, such as fresh English walnuts, pecan and Brazil nuts; filberts, peanuts, eggs, bacon and fat ham; bone marrow, suet and lard (used freely in cooking); rich cheese, soups enriched with "dripping," and such fat fish as mackerel and salmon; fat meats, such as goose and duck, and the tender fat of corned beef.

Lithæmia.—The condition known as "lithæmia" is much benefited by dietetic treatment. I shall not here discuss the merits of the term, as to whether it be a definite scientific classification, or merely one of the medical scrap-baskets to which it is often convenient to relegate indeterminate diagnoses. I refer to that very common complex of symptoms briefly described as follows: The patient, usually in middle life, after leading an indoor or sedentary life, or after passing through a period of excessive mental strain and anxiety (especially of "worry"), complains of headache, insomnia, vertigo, "nervousness," irritability, and lassitude. Constipation and a furred tongue are observed, the pulse is often small and hard, and the urine, somewhat diminished in quantity, is overloaded with proteid waste. In a word, the balance between the intake of food, its oxidation, and the output of waste is disturbed, and nerve energy, which should be devoted to digestion, is diverted into other channels. Inquiry develops the fact that these patients usually have been eating meats at least twice and, sometimes, three times a day. The treatment is very simple, and the results are most satisfactory. For a week or ten days the patient should turn vegetarian, subsisting upon cereals, fresh green vegetables and fruits, and should drink 60 or 70 ounces of water per diem. Two glasses on rising, on retiring, and before each meal will account for ten tumblerfuls a day (about 65 ounces). Taken into an empty stomach water is promptly absorbed, and is more promptly diuretic than if drank with meals. If the patient, who usually has been taking less than half this quantity of water, needs coaxing to make him drink more, let him take it from a bottle with the label of some noted spa upon it—it makes no difference whence it comes—the water is the need. A less expensive and equally serviceable method is to add an effervescing lithium carbonate tablet to each tumberful—they are perfectly inocuous, and the visible effervescence is a great solace to the lay mind. Directions should be added to spend more time in the open air, to eat slowly, and, when feasible, to lie down and rest for half an hour before the principal meal of the day.

Occasionally this type of patient attempts his own cure by walking five or ten miles a day. He makes a great mistake by adding physical to mental exhaustion, sitting down to a hurried meal, and having no nerve force left to control the physiological functions of digestion and assimilation. Half an hour of vigorous exertion that calls into play a variety of muscles, and especially if it can be made to induce perspiration, is far more beneficial than tramping for miles the pavements of a crowded thoroughfare. A typically lithæmic man recently complained to me that although he walked fifteen miles a day he could not feel well. He was thin, and gaunt, and a nervous wreck. I told him to walk two miles only, and spend the balance of the time in proper rest in relation to his meals, and the effect was magical. As improve-

ment follows the patient may gradually resume the eating of animal food, commencing with eggs and fish. Bacon or ham, liver, and chicken may be added, and finally red meats may be eaten again sparingly once a day.

Arteriosclerosis.—The question whether the lithæmic condition long continued favors the early development of arteriosclerosis is very important, but it cannot be fully entered upon within the limits of this discussion. It is certainly not the sole cause, for there is much arteriosclerosis without lithæmic symptoms, as, for instance, that observed in tertiary syphilis, chronic lead poisoning, hepatic cirrhosis, and chronic nephritis. In my wards in Bellevue Hospital it is comparatively rare to find a man of thirty years or more who does not present an advanced grade of it. The most striking cases are among manual laborers, longshoremen, diggers, and the like, who have done much heavy lifting and drank much liquor of inferior quality, yet they rarely present the symptoms of lithæmia. Nevertheless, it seems reasonable to believe that lithæmia, like any form of autointoxication, may be at least one underlying factor in giving rise to arteriosclerosis, and it is certainly a highly undesirable condition to permit. The detetic treatment of arteriosclerosis should be substantially the same as that of lithæmia, with such common-sense modifications as the patient's social position may dictate. It is futile to tell a day laborer to lie down and rest before or after his meals, but it is possible to keep his elimination of waste products active through catharsis and diuresis, and to regulate his diet, while it may be possible to induce him to drink water occasionally, in lieu of poor beer and worse whiskey.

The quantity of fluid ingested is of importance in arteriosclerosis. In cases complicated with cardiac dilatation or myocarditis, it is desirable to restrict fluids as much as possible in order to lessen the weight of fluid that an enfeebled heart, already working against great arterial resistance, is obliged to pump through the circulation. It may be desirable to restrict it as a means of reducing intra-arterial pressure, thereby lessening the progress of cardiac hypertrophy. In many cases, however, there is a complicating nephritis, and it may be then undesirable to restrict fluid ingestion on account of the danger of renal inadequacy and consequent accumulation of proteid waste in the system. Such accumulation may be one of the factors in producing arteriosclerosis. The problem thus becomes so complicated that each case should be governed by the peculiar combination of conditions which it presents, rather than by set rules.

Gout.—There is no disease amenable to dietetic treatment in regard to which so many "fads" exist as gout. Many a patient who has, or thinks he has, it has received dietetic maxims from scores of friends, and firmly believes that "tomatoes cause gout," that "coffee is bad for gout," that "potatoes are the worst thing he can eat," and "apples are poison," and so on down the entire dietetic gamut, until, if he followed all the gratuitous advice he accumulates, he would go hungry indeed. As a rule, he contents himself with leaving alone a few articles of diet which he does not especially care for, and continues to eat and drink more than he needs, and fails to oxidize his food and eliminate his waste products.

Yet typical gout, the old-fashioned gout of Sydenham, whose personal experience with it has furnished a medical classic, is becoming less and less common in this country. "High living" is by no means the only cause of it, and by far the larger number of cases that I meet with to-day are observed among the laboring classes in the wards of Bellevue Hospital, among whom the consumption of cheap liquors, especially malt liquors, appears to be a more potent etiological factor than the quality of their food.

What one does encounter very often among the well-to-do, on the contrary, is the condition which William Ewart has so admirably dealt with under the title of "Goutiness" ("Gout and Goutiness"). For the acute attack a dietary of milk and vichy with simple gruels best suffices; but for the interim, as prophylaxis, and for the treatment of the lesser and chronic manifestations of gout, it is well to formulate a definite regimen. Of far more importance than the giving up of occasional articles of food in a long dietetic list are the following general principles—first, to reduce the consumption of food as a whole; second, to increase the consumption of water; third, to eliminate entirely sugars and sweets of every kind, as well as alcohol, and, fourthly, to reduce the consumption of red meats to a minimum. Almost any fresh vegetables may be eaten, and cereals also, provided the patient will take them without sugar; eggs, foods made with milk and eggs, fish and white meats (chicken, turkey, etc.), may be allowed. I am accustomed also to permit the eating of many fruits, such as oranges, grape fruit, melons, and the juice of pineapples, which contains a natural digestive ferment. A rigid diet, chiefly vegetarian, may be advised for periods of two or three weeks, but if too long continued it is liable to produce anæmia and weakness, and if the patient will follow proper hygienic rules they may be made the condition of greater latitude at the table.

Of recent years there is a prevalent fad among adults who are gouty or rheumatic for the use of Scotch whiskey. In so far as this form of drink is made to exclude other beverages, especially both sweet and sour wines, it may have advantage, but much of the so-called "Scotch" sold in this country is an artificial and injurious compound of rectified spirit flavored with creosote, which certainly never emanated from Scotland, and it is quite as harmful as any other form of alcohol in this type of disease. It favors dyspepsia, and any food or drink which does so is liable to provoke an attack of gout, less because of its own peculiar composition than because of the autotoxic influences which arise from dyspeptic fermentation.

Rheumatism.—The dietetic treatment of rheumatism is a disappointment. In general it should be similar to that of gout, *i.e.* a milk diet when acute attacks occur, and restriction of meats and sweets in the interim. But dieting as a prophylactic measure is far less satisfactory than in gout, and if rheumatism be regarded as an infection, as it appears to be, there is no apparent reason that it should be prevented by dieting. A child of eleven was brought to me a few days ago who had recovered from her first attack of acute articular rheumatism, which had left a serious mitral lesion. Her mother insisted that I prescribe a prophylactic dietary, and I frankly confessed my inability to do so. The child must still grow, and to check nutrition by a rigid regimen would perhaps result in anæmia and retarded development, without any influence upon a possible future attack beyond making the system less strong to resist it. Careful regulation of the mode of life and attention to general hygiene seemed a much more promising method of treatment.

I have purposely omitted consideration of the dietetic principles governing the treatment of gastric disorders, as this field is so extensive that to engage upon it would lead into too wide an excursion for the present time. I would, however, enter a word

of protest against the common practice of basing dietetic and other treatment of stomachic disease upon the results of a *single* gastric analysis. To this subject I have given much attention. In not a few instances I have known a patient whose gastric juice was reported by the hospital pathologists as containing no hydrochloric acid to eat and digest the full ward diet and grow stout upon it. The common test meal (a roll and glass of water) is by no means so appetizing as always to stimulate gastric secretion; the dread of the passage of the stomach tube may in a sensitive person inhibit or modify normal secretion, and there are other fallacies in the single test depending upon intermittent causes. Dr. William Armstrong has furnished me with a series of most instructive records of analyses of stomach contents made upon patients at my clinic at the Cornell Medical College Dispensary which show in the same person variations in successive days between extreme hyperacidity and total anacidity. Such results force the conclusion that in a given case, as deciding, for instance, between gastric ulcer or carcinoma and simple gastralgia or neurasthenia, at least half a dozen tests should be made before any definite conclusions are justifiable, dietetic or otherwise.

I have endeavored to confine this discussion to a review of a few of the many dietetic problems of disease, selecting those which come within the range of most common experience. I would disclaim any special dietetic system or "fad." No one food is curative in itself. I am not among those who believe in the cure-all system of meat and hot water, of vegetarianism, or of any cast-iron rules of eating, but the subject which I have outlined in this brief review is one which is still strangely neglected in comparison with the other branches of treatment, and is worthy of closer study. Authorities differ much in the details of dietetic regimen, but no more than they do in those of medicinal treatment, yet there are surely fundamental principles which, if properly mastered, should make the art of dietetics of at least equal value with the art of prescription.

RHEUMATISM.*

By GEORGE E. MALSBARY, M.D.,

CINCINNATI, OHIO.

ASSISTANT TO THE CHAIR OF THEORY AND PRACTICE OF MEDICINE, MEDICAL COLLEGE OF OHIO; MEDICAL DEPARTMENT UNIVERSITY OF CINCINNATI.

THE term "rheumatism" is used to cover a multitude of diagnostic sins. As a dumping-ground for imperfect diagnoses, "rheumatism" vies with "catarrh." Indeed, these two terms have the same derivation, from a word meaning "to flow," and they were used synonymously by the humoral pathologists to cover a large number of diseases, which they attributed to a peccant humor flowing through the body. About the time of Ballonius (1600) "catarrh" became confined to affections of the mucous membranes, and "rheumatism" became limited to diseases characterized by pain about the bones, joints, and other structures than mucous membranes, which are not attributed to any special or specific cause. Later investigations have isolated gout (Sydenham), arthritis (Senator), trichinosis (Zenker), syphilis, tuberculosis, rickets, osteomalacia, and diffuse sarcomatosis and carcinosis.

The term "rheumatism" is now used to cover at least five distinct affections: (1) Acute articular rheumatism, (2) Chronic articular rheumatism, (3) Gonorrhœal rheumatism, (4) Muscular rheumatism, and (5) Nodular rheumatism (arthritis deformans).

This does not include the almost inexhaustible list of so-called "rheumatic" affections. Thus, the older writers described visceral, gastric, cerebral, cardiac, vesical, etc., rheumatism, and some writers still refer to rheumatic pleurisy, peritonitis, etc., and the oculists still report cases of rheumatic iritis, in describing cases not attributed to a specific cause, or the cause of which remains unknown.

At the present time our knowledge of the causes of the rheumatisms is so limited that it is not practicable to formulate anything like a complete classification based upon eitology. It is pretty generally recognized that the rheumatisms are toxic affections, and that in some instances the causal toxic substances are due to bacterial activity. Often the diet seems to play a prominent rôle in etiology. Not infrequently the essayist has apparently produced rheumatic pains in tubercular patients by placing them upon a diet in the treatment of tuberculosis. The apparent influence of the weather is a matter of common observation. Damp weather seems to aggravate rather than produce the disease. Let us consider briefly the various clinical forms of the disease:

Acute Articular Rheumatism.—This is an acute infectious disease, characterized by multiple arthritis. The affection flies from joint to joint. The disease is almost limited to the period of adolescence, fifteen to thirty-five years, and prefers fall and winter, when the weather is most changeable; but no season is exempt. The disease is comparatively rare before four or after forty years. Individuals most frequently affected are those exposed to changes of temperature—drivers, washerwomen, servants, bakers, sailors, and laborers. The disease is frequently ascribed to "taking cold." Acute articular rheumatism often occurs in the course of the infections, especially scarlet fever, dysentery, and puerperal fever (septicæmia). The disease is supposed to be due to some infectious agent, probably closely related to the streptococcus pyogenes. Often the infectious agent seems to gain entrance to the body through the tonsils.

The onset of the symptoms of acute articular rheumatism is often preceded by angina, especially tonsillitis, and malaise. Usually the disease begins suddenly, with a chill and fever, reaching 102° to 105° F. within a day. The pulse is usually above 100. There are more or less malaise and general distress. Affection of the joints is usually observed within the first 24 hours. The disease shows a preference for the medium-sized joints, especially the knee, ankle and wrist; later the shoulder and elbow, and still later the fingers, and the vertebral and streno-clavicular joints. Rarely there may be involvement of the articulations of the maxilla, larynx, pelvis and ribs. The joints become red and swollen. There may be subcutaneous œdema. The disease, as stated, flits from joint to joint, often to return again to a joint previously affected.

There is often profuse sweating, which lowers the temperature for a time. The perspiration is acid in reaction and sour-smelling. Often there are sudamina, especially in the absence of cleanliness. Examination of the blood shows marked anæmia and hyperleucocytosis. The urine is usually reduced in quantity, concentrated, of high color, acid in reaction, and loaded with urates. The chlorides are diminished, and sometimes absent. The saliva may show an acid reaction and an excess of sulphocyanides.

The chief complications of acute articular rheumatism are affections of the heart: pericarditis, en-

*Read by invitation before the Highland County Medical Society, Hillsboro, Ohio, July 6, 1904.

docarditis, and myocarditis. Some cases show hyperpyrexia, the temperature reaching 110° to 118° F. Upon the part of the lungs, there may be pneumonia or pleurisy. Some cases show delirium and coma; less frequently convulsions, rarely meningitis. Often there is chorea. The presence of sudamina has been mentioned. There may be a red miliary rash, scarlatiniform eruptions, purpura, often urticaria, and erythema. Rheumatic nodules are sometimes found upon the tendons and fasciæ.

In the diagnosis of acute articular rheumatism, the affection of medium-sized joints, and especially the flitting from joint to joint, are characteristic points. Atypical cases and cases that do not respond readily to treatment should arouse the suspicion that they are not cases of rheumatism. Acute articular rheumatism must be separated from other forms of rheumatism, involvement of the joints in septicæmia, and gout and sarcoma.

Rheumatism has in itself a mortality of about three per cent. The remote effects are more dangerous. From one-third to one-half of the cases have permanent heart-lesions. Sometimes the heart-lesions entirely disappear.

Chronic Articular Rheumatism.—Exceptionally chronic articular rheumatism may result from acute rheumatism. As a rule, chronic rheumatism comes on insidiously, after the meridian of life, and remains confined to the joint or joints first affected. The disease shows an unwelcome preference for the poor—those most exposed to cold and damp. The affected joint is somewhat swollen, stiff, and painful. The pain is increased during damp weather or upon exposure to cold and damp. The joint may become ankylosed. Chronic rheumatism more frequently affects the larger joints—hip, shoulder, knee, wrist, and ankle. The age of the individual, the number of joints affected, the long duration despite medication, and the absence of sweating, high fever, or complications on the part of the heart, are important points in diagnosis, and serve to differentiate the chronic from acute rheumatism. In chronic articular rheumatism, usually life is not shortened; but the outlook as to cure is not good. The disease is obstinate to treatment.

Gonorrhœal Rheumatism.—Gonorrhœal rheumatism prefers the period of adolescence, the male sex, and the knee-joint. But the disease is not confined to these preferences. Females are not exempt, nor is immunity conferred by passing the meridian of life. There may be involvement of the ankle and joints of the foot. Usually the affection of the joints is observed within three months after the gonorrhœal infection. This period may appear to be exceeded in cases of latent chronic gonorrhœa. The joints are greatly swollen. The specific cause is the gonococcus, or the pyogenic micro-organisms as a secondary infection. The latter are really cases of septic rheumatism. Gonorrhœal rheumatism runs a chronic course, does not show sweating or involvement of the heart, and when finally cured does not return, and usually leaves no deformity.

Muscular Rheumatism.—Myalgia is a better term. Many cases of "muscular rheumatism" are caused by trauma, whereby muscular fibres are ruptured. Other cases are attributed to cold and exposure, which probably act by localizing some infection or poison. At least one infection, that by the trichina spiralis, is now recognized as a separate affection, trichinosis. The only characteristic symptom of myalgia is pain, which may vary in all degrees of severity, and is confined to the voluntary muscles. The pain is usually relieved by pressure.

The chief varieties of muscular rheumatism are: occipitofrontal rheumatism; torticollis, cervical rheumatism, stiff neck; pleurodynia, which is chiefly an intercostal rheumatism, and lumbago, one of the most frequent and painful forms. Affection of the muscles of the head is sometimes known as cephalodynia. The pain may be localized in the muscles about the shoulder and upper part of the back—scapulodynia, omodynia and dorsodynia. Myalgia must be differentiated from the infections, especially smallpox, tuberculosis, syphilis and septicæmia; and aneurism, caries of bone, and tumors must be excluded. The separation from neuralgia is sometimes difficult. The prognosis of muscular rheumatism is usually good.

Nodular rheumatism, arthritis deformans, is a chronic disease of obscure etiology, characterized by progressive, symmetrical deformity of the joints. Many observers believe the disease to be a chronic infection; others that it is of nervous origin. Most cases are found between thirty and fifty years. The great majority of cases occur in women. Heredity sometimes seems to play a rôle. There is a history of gout oftener than of true rheumatism. Exposure to cold, wet, damp, errors in diet, depressing mental emotions, grief or dejection, are prominent factors in causation.

Usually the onset of arthritis deformans is insidious. The affected joints first become stiff, especially in the morning, and tender, and later show characteristic deformity. The joints of the hands and fingers are usually first attacked. The fingers are flexed upon the hand and point toward the ulna; the thumb is not affected. When the disease attacks the foot, the big toe is first involved. The joints become locked, so that in cases of extensive involvement of the joints the patient may become immovably fixed in the position usually occupied. The disease is marked by great deformity. With exacerbations and abatements the disease is progressive. There are impairment of the appetite and digestion, and constipation, largely due to lack of exercise. The patients become irritable and hypochondriacal. The muscles undergo atrophy.

Diagnosis may be difficult only early in the course of the disease. Arthritis deformans prefers the female sex, and is comparatively rare under twenty. Permanent deformities are produced in the joints affected. Fever is usually absent. The disease is polyarticular and shows preference for the small joints. The hands and fingers, but not the thumbs, are usually first involved. Arthritis deformans does not seem to shorten life. The disease may be relieved, but the outlook as to cure is not good.

In conclusion, we may offer a few practical deductions. In the first place, it is important that we study our cases. It is a good practice to follow a scheme something like the following:

First, determine whether the disease is a rheumatism or some simulating affection, such as gout, arthritis, trichinosis, syphilis, tuberculosis, rickets, osteomalacia, or diffuse sarcomatosis or carcinosis.

Second, classify the case among the recognized clinical forms of rheumatism.

Third, if possible, find the cause or causes operative in the individual case, in order that the treatment may be rational.

Fourth, watch the heart.

In illustration, it may be interesting to record a case that came under my observation something over a year ago. The case was readily recognized and classified as one of acute articular rheumatism. Almost all the joints of the body, including even the sutures of the skull and some of the pelvic joints, were or had been affected by the disease. Upon examination of the urine, streptococci were found in

pure culture and in large numbers. The patient showed some improvement under salicylate of sodium. The injection of the streptococci into guinea-pigs did not produce pus.

After the patient had been under observation five months, the use of the antistreptococcus serum was begun. The result was striking. After the injection of the serum, the symptoms abated and there has been no return of the disease after a lapse of something over a year. In that case, the search for the cause was rewarded by finding the streptococcus, and we were able to institute rational treatment, the use of the antistreptococcus serum, which was followed by a cure in a most pronounced case of years' duration. There is always a peculiar satisfaction in solving a difficult case, in succeeding where others have failed.

Nothing could be farther from the purpose of this paper than to indicate that the antistreptococcus serum will cure every case of rheumatism. But we must study our cases, and we will find that many of the cases of rheumatism that are apparently most intractible are amenable to treatment.

In closing, we may review briefly the treatment of the various clinical forms of rheumatism, that has proven of most value in my practice.

In acute articular rheumatism, the patients should wear flannel and sleep between blankets. The best single article of diet is milk, which may be diluted with an alkaline mineral water. Thirst should be relieved by the free ingestion of fluid. Often relief may be obtained by fixing the joint—sometimes simply by wrapping the affected joint in cotton or hot cloths. Various liniments may be used, which are of value chiefly through massage and the application of heat.

For this purpose I have found a good application, and one that has the advantage of comparative cheapness, in an ointment composed of equal parts of salicylate of sodium, lanolin, and lard, to be applied hot twice a day.

It has been recommended that we wrap the affected joints in salicylated cotton, but I have not been able to see that this gives any better results than the use of ordinary cotton or flannel. Pain may sometimes be relieved by the use of a blister or a light application of the Paquelin thermocautery. Salicin, salicylic acid, and the salicylates, for a time regarded as specifics, often suffice to relieve pain and probably neutralize toxins. The oil of wintergreen, m.xx in milk every two hours, often gives good results. The salicylates are probably best given with alkalies, in sufficient dosage to keep the urine alkaline in reaction. Severe pain may demand opium, best in the form of Dover's powder, or morphine. As a rule, one of the coal-tar analgesics will suffice. Excessive fever may be controlled best by bathing. Tumultuous action of the heart may be relieved by the application of the ice-bag. The heart must be watched and any affection of that organ must be properly treated.

Finally, both as a curative and prophylactic measure, the throat should be carefully inspected, and any angina, especially tonsilitis, should receive the proper treatment.

In chronic articular rheumatism, iodine in the form of iodide of potassium or Lugol's solution, is probably the best internal remedy. Next to this I would place the tincture of colchicum, gtt.x ter in die. The salicylates may relieve the acute pain or exacerbations. Much may be accomplished by Swedish movements and the local application of heat and friction. All sorts of liniments are recommended, and are chiefly of value as affording massage and the application of heat. The Scandinavian fishermen introduced the use of cod liver oil as a liniment. The use of this remedy in private practice is not satisfactory, because of its odor. Ointments of potassium iodide and of ichthyol and iodine have been used.

In some cases I have secured rather striking improvement through the intramuscular injection of a solution of iodine in sesame oil. For this purpose I use a 25 per cent. solution, and inject 1.0—4.0 c.c. deep into the gluteal muscles, repeating the injection every second day. It is better to begin with the smaller dose, and make sure that there is no idiosyncrasy against the drug. This method of administration has proven of value in some cases in which the internal use of iodine and the iodides was not satisfactory.

Often relief may be secured by painting the part with pure guaiacol. The chloride of ethyl guaiacol spray is a useful preparation for this purpose. The oil of wintergreen, or menthol in a 25 per cent. solution in alcohol, is also useful as a topical application. The value of hot fomentations to the joints in these cases is well recognized even by the laity.

The local application of heat in rheumatism has long been recognized as a valuable adjunct in treatment. But from the exclusive use of hot air or "baking" in chronic rheumatism, I have observed only two cases that were permanently cured. In both of these cases the rheumatism affected the knees and was of the gonorrhœal form. In many cases of chronic rheumatism, the use of hot air gave very great relief, in some cases amounting to an absolute temporary cessation of symptoms on the part of the joint treated, but only in the two cases mentioned was the cure permanent, and therefore worthy the name of "cure." In some other cases of gonorrhœal rheumatism the use of hot air failed to cure the disease. The explanation for this diversity of results in gonorrhœal rheumatism may be found in the recognized fact that some cases of so-called gonorrhœal rheumatism are due to the presence of the gonococcus in the joint, while in other cases the cause is the ordinary septic organisms that find entrance as a secondary infection. Sometimes the application of blisters gives relief.

Often the best results may be obtained by climatotherapy, especially by prolonged residence in a warm climate, or at least by wintering in such a climate, to avoid cold, damp weather.

Unfortunately, comparatively few patients can afford such treatment. Hydrotherapy is sometimes successful. One of the best remedies for sleeplessness is the hot bath at night. Tonics and general hygienic regulations should not be neglected, especially in the after-treatment.

In gonorrhœal rheumatism, most may be accomplished by the use of heat, electricity, friction and massage. Further treatment is the same as for chronic rheumatism. It is important that chronic gonorrhœa should receive attention, to prevent continuous infection. Not infrequently an appeal to surgery must be made.

In muscular rheumatism, myalgia, the muscle should be put to rest, *e. g.*, by strapping the chest with adhesive plaster in cases of pleurodynia. Heat, friction, and electricity are probably the best remedies. Pain may demand one of the synthetic analeptics, aquapuncture, or morphine. Lumbago is sometimes relieved by aquapuncture. Some cases may be cut short by a hot bath early in the course of the disease. In chronic cases, iodide of potassium is the best single remedy. In all cases a careful search should be made for the cause, which should be removed or properly treated.

In nodular rheumatism, arthritis deformans, the

pain may be relieved by hydrotherapy and massage, which also assist the nutrition of the muscles. Electricity is sometimes of value. Arsenic probably does good as a tonic. Iron may be indicated by anæmia. Iodine best in the tincture, gtt.x, or the iodide of potassium or sodium, given in milk, is worthy a trial. The salicylates or salol may be advantageously used during the acute exacerbations. Massage and the local application of hot air sometimes produce good results. Blisters are of value, especially in chronic cases. Often a change of climate is advisable.

I cannot close without a word as to the diathesis. In tuberculosis, it is pretty generally recognized that individuals with the so-called tuberculous diathesis already have the disease, though it may be quiescent or latent. Indeed, it was the observation of this fact that led me to take up the study of the diatheses, and incidentally to pay attention to rheumatism. Suffice it to say that we shall succeed better if we consider all cases of the rheumatic diathesis as we would rheumatism, and try to study and classify them and find their cause. If this is done, we shall have fewer cases of rheumatism, and we shall not hear so much of the rheumatic diathesis.

14 East Seventh Street.

TREATMENT OF PNEUMONIA IN ADULTS.*

By MORRIS MANGES, M.D.,
NEW YORK.
PROFESSOR OF CLINICAL MEDICINE, NEW YORK POLYCLINIC MEDICAL SCHOOL; VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL.

Before discussing the treatment of pneumonia in adults, it might possibly not be amiss to present a few general considerations. First of all, I would draw attention to the fact that in no other disease is there greater contradiction between theory and practice than in pneumonia. Theoretically everyone agrees in regarding pneumonia as an acute general disease with lung phenomena as a local lesion; and yet in practice, the assiduous attention which is paid to the physical examination of the lungs alone, and the whole plan of treatment adopted by so many practitioners, would lead one to believe that they were dealing with a local pulmorary condition.

I would remind you of several important facts to emphasize the general nature of pneumonia. The first is that in nearly all cases bacteriologists have found the diplococcus of pneumonia in the circulating blood, provided a sufficiently large amount of blood was taken for culture. The second fact is that after the crisis the lung is just as consolidated and the alveoli contain just as much fibrin, cellular elements and diplococci as they did a few hours before the advent of the favorable turn.

The corollary of the above is that in pneumonia we have a general disease, the tendency of which is to recovery after the lapse of sufficient time for the body to produce its own antitoxin. A case that was recently under my care may be cited to emphasize this. A robust girl of twelve years was ill for about ten days with fever and a group of symptoms which suggested pneumonia as the only explanation. Careful examinations of the lungs yielded only evidences of bronchitis. On examining the child on the third day after the temperature had remained normal, to determine whether she should be allowed to leave her bed, I was very much surprised to find the signs of fully developed pneumonia at the left base, reaching from the spine to the anterior axillary line. For the three following days these signs persisted without any rise of temperature or any change in the pulse condition. On the fourth day redux râles appeared and the lungs resolved in the ordinary fashion. It might be said that this was a central pneumonia which had "worked" toward the surface, to which I can only assent. The case, however, shows most beautifully the absolute lack of relation of local physical signs to the general condition which is so often manifest in pneumonia. How many patients have succumbed with very small patches of pneumonia; how many have survived enormous consolidations! In other words, it is not the quantity of consolidation, but the quality of the infection, that is of importance.

Another important fact which must be borne in mind, especially now, is that pneumonia has become an entirely different disease since the advent of the grippe. It is true that we still see classical cases of acute lobar pneumonia; yet the prevailing form of the disease in recent years and in the epidemic that is prevailing now is one the clinical features of which are not those of acute lobar pneumonia, but rather a mixture of catarrhal and fibrinous pneumonia. The amount of consolidation bears no relation to the severity of the infection. Complete involvement of lobes is less frequently found than the successive involvement of portions of lobes, and the clinical course is marked by irregularities which are due to the infection of fresh areas, or by pseudo-crises which accompany the resolution of only portions of the areas involved.

With reference to the mortality, we have unfortunately been deluding ourselves and have regarded pneumonia as a less formidable foe than it really is. The worship of statistics and the misleading reports of physicians which have been based upon too limited a number of cases are largely responsible for this.

We are fond of quoting the statistics of Townsend and Coolidge,[1] and I will admit that I myself did the same in a former paper on the treatment of lobar pneumonia.[2] These give the record of 1,000 cases consecutively treated for this disease at the Massachusetts General Hospital from 1822 to 1889. The mortality of these cases was reckoned according to decades and presented on a chart. The result was almost a straight line, the rate varying between nine and fourteen per cent., showing that in spite of all the changes in treatment ranging from the bleeding, purging, salivation and blistering of 1822 to the symptomatic treatment of our own time, the death-rate at this hospital was practically unchanged.

These figures are certainly instructive, but they lose their force when we recall that they do not include patients "who were over fifty years of age, were intemperate, delicate or had complications."

Of far greater value are the statistics collected by Wells[3] of Chicago, which show a mortality rate of 18.1 per cent. for pneumonia of all ages as based upon the collection of 233,730 cases. (Since this paper was read, Wells has presented the mortality rate of a much greater number of cases, 465,020, the death rate of which was 20.1 per cent. for all ages.[4])

Many text-books have fostered this error as to the relatively low mortality of pneumonia. It is therefore well to quote the mortality rate given in Fraenkel's recently issued "Diseases of the Lung,"[5] a book which is destined to be a classic. For large cities the rate is between 20 and 35 per cent. In the patients under his care at the Urban Hospital in Berlin the rate varied in different years from 16.6 to 30 per cent., the average for adults being 22.6 per cent.

As regards mortality rate at the bedside, we are concerned, not with the question of average mor-

*Read at a meeting of the Bronx Medical Society, March, 1904.

tality, but the individual chances of the case under treatment, in estimating the prognosis of which we should not be misled by delusive statistics, but should bear in mind the individual characteristics of the patient, the method of his infection, the length of time which elapsed before he went to bed, his surroundings, the methods of treatment and nursing, his general constitution and the presence of complications. These are our guides in estimating the prognosis. Let text-books and insurance actuaries use statistics.

In discussing the treatment of pneumonia this evening, I propose to restrict myself to the disease as it occurs in adults and a consideration of the general indications of the treatment, rather than any attempt to include everything. What may we expect from a specific treatment for the disease? The answer to this question is to my mind a very simple one—nothing. What has been accomplished is so contradictory, is based upon so small a number of cases, the bacteriochemical principles are so ill understood, that the future holds little in store for us in this direction. All pneumococci are not the same. That there are variations in them bacteriologists are realizing more and more. Morphologically all diplococci may appear to be alike, or may present only minor variations, but as regards infectiousness and virulence the greatest degrees of difference have been observed. It is from these variations in virulence and the cultural difficulties which are encountered that the failure of any specific plan of treatment may be predicated. The possibilities in this direction become less and less as the difficulties and complexities of this problem are gradually becoming more and more evident. The obstacles which must be surmounted are very similar to those encountered in the manufacture of streptococcus antitoxin. It must also be borne in mind that all pneumonias are not caused by the pneumococcus, but that several other microorganisms may be present as mixed infections, of which we must never forget the important relations of the influenza bacillus in the disease as we now encounter it.

Somewhat allied to the subject of antitoxin is the use of creosote and guaiacol, which for the past few years have been so extensively tried for their specific effects in the treatment of pneumonia. While most of us are agreed that neither of these drugs can in any way be considered a specific, yet no harm follows their use, provided, of course, the kidneys do not offer any contraindication. Good results can be obtained in cases where grip exists as a complication and where there is a marked bronchitis.

In the meantime, how shall we treat our patients with pneumonia? Let it be premised that not every case demands treatment; patients presenting the normal picture of the disease, with a not too severe infection and a proper reaction by the system to the infection require nothing more than observation and proper nursing. When treatment is instituted, let it be remembered that we are not treating the pneumonia, but a patient with pneumonia. Also, that some will die in spite of all treatment, and that not a few perish as the result of it. The difference between the cases seen in the hospital ward and in private practice is most striking. It would aid many a general practitioner to see patient after patient, some with large areas of consolidation, progress nicely on very simple treatment in the wards. To many the diagnosis, pneumonia, *eo ipso*, seems to demand the immediate exhibition of heroic remedies. Meddlesome relations of the patient are bad; meddlesome nurses are worse; but in pneumonia the worst feature of all is the meddlesome doctor. When treatment is required it must be directed against the toxæmia. Its object is five-fold: (1) To maintain life; (2) to support the heart; (3) to control undue fever; (4) to relieve suffering; (5) to control complications.

(1) *To Maintain Life.*—This includes the nursing and diet which are too familiar to require any details. I wish, however, to emphasize the importance of watching the stomach, for not enough attention is paid to ascertain whether it be unduly distended with gas or partly digested food; even liquids may be improperly disposed of by the stomach. Routine percussion of the abdomen is far more important than routine examination of the lungs. The heart must be spared in every way; let its burdens not be unnecessarily increased by upward displacement from the unduly distended stomach and intestines. All articles of diet which may produce flatulence must be rigidly excluded, and the milk must be adapted to the patient both in quantity and in preparation. Do not overfeed these patients; the disease is a short one and the patient's surplus fat and tissues will supply any deficit in the diet. Spare the stomach from undue medication as much as possible and use the hypodermic method in preference. Give water freely, either cold or hot, for it allays the thirst, reduces the fever and increases the elimination of toxins by promoting free diuresis. For the latter purpose the combination of a light Moselle wine with an alkaline mineral water is exceedingly useful. The use of carbonated beverages in pneumonia is a danger which deserves attention. In the first place, it is impossible to drink large quantities of a charged water, and, after all, the object of the drinking of water is free flushing. Secondly, the patient already suffers from an excess of carbonic acid gas in the system—why needlessly increase it? Hence all charged waters, koumiss and champagne are to be avoided, the only exception being the occasional use of very small quantities of champagne where the condition of the stomach prevents the use of other means.

(2) *To Support the Heart.*—This very important indication can best be understood by considering that the dangers to the heart are fivefold: to (1) the medullary center, (2) the heart muscle, (3) the right ventricle, (4) the left ventricle, and (5) the vasomotor system. (1) Damage to the medullary center will result from the toxæmia and possibly the fever. (2) The effects upon the heart muscle are now very well understood since so much work has been done by Krehl, Romberg and others in showing the insular areas of infiltration and degeneration about the smaller vessels which are so characteristic of acute infections. Supplementing this are, of course, the well known effects of the hyperpyrexia. (3) The right ventricle: That the work of the right ventricle is very materially increased by the obstruction to the pulmonary circulation which is offered by the hepatized area of the lungs is well known. But Fraenkel has called attention to the fact that dilatation of the right heart has not been demonstrated in all severe cases and urges that we must look for more than local changes in the pulmonary circulation to explain this part of the matter. It is to be noted that the danger to the right heart is more serious in all cases where its work has already been materially increased by emphysema and old mitral lesions. (4) The left ventricle: The left ventricle plays a less important rôle and usually suffers as a result of the textural changes above noted. The gravity of an existing arteriosclerosis and old renal disease, which have already altered the left ventricle, becomes self-evident; hence the ominous prognostic significance of those

cases where the specific gravity of the urine remains low throughout the disease. (5) The vasomotor system: The work of Romberg and the careful measurement of blood pressure during the course of the disease have not alone cleared up many dark places, but have materially modified our therapeutic indications. The blood pressure is not high, as is usually supposed; on the contrary, it is diminished in the majority of cases, the lowest pressure being observed at the time of the crisis or shortly after. Increase of pressure is relatively infrequent and is only noted in the so-called sthenic cases. The rationale of the digititis treatment and of the ergot plan of treatment and all other methods by means of which smooth muscular fiber may be contracted is self-evident, and the fallacy of the use of nitroglycerin, which has been so indiscriminately employed, especially in this country, must be apparent. It is important to note also that this vasomotor paralysis is not confined to the blood vessels alone, but involves the intestines also, as the atonic distension of the abdomen, which constitutes so distressing a feature of severe cases, only too clearly attests.

The drugs which best meet the indications for the support of the heart are strychnine, caffeine, alcohol, camphor, and ergot. The caffeine is best given in solutions of the benzoate or salicylate; the ergot, according to the method which was described by Livingston, and later on employed by Lambert—aseptic ergot or the solution of the solid extract used hypodermically. If the results are not promptly obtained all the drugs should be administered hypodermically. Nor should we hesitate to use them freely, for the action of each is clean cut, and any overdosage can be recognized very readily. My own experience has convinced me of the value of very large doses of strychnine in tiding a heart through the crisis. For the same purpose we may also resort to the hypodermic injection of camphor in sweet almond oil. Many observers also report good results from hypodermoclysis and enemata of salt water. Elsner has recently called attention to the value of adrenalin for the same purpose (15 minims of the 1:1000 solution by mouth or subcutaneously). A struggling heart is often aided by an ice-bag over the præcordium. I would direct particular attention to the newer views as to the importance of the vasomotor paralysis since the rationale of the ergot plan of treatment finds much support. I might also again emphasize the need of greater caution in the use of nitroglycerin, which has been very indiscriminately used, especially in this country.

As to the use of digitalis in pneumonia, the extreme views of Petresco have not found favor. In answer to the low mortality of 2.06 per cent. reported by him and his school in 825 cases, most of these cases were in soldiers, his statistics being those of the military hospital at Bucharest, I may cite the extremely low mortality of 3.6 per cent. in 40,000 German soldiers. Fränkel's[6] mortality rate of 85,000 cases in the German army between 1878 and 1898 ranged between 3.1 and 4.3 per cent. Petresco has certainly demonstrated that the danger from these colossal doses of digitalis (12 grams or 180 grains daily) is small, but according to Reiner[7] they must not be continued more than two days at the utmost.

The only clinician of note who has recently advocated large doses of digitalis is A. Fränkel, who recommends the use of from 3 to 4 grams daily on three successive days, provided we see the patient during the first three days of the illness and provided there is no organic heart, vascular (arteriosclerosis) or renal disease.

Large doses of digitalis toward the end of the disease exercise an entirely different effect upon the heart than does its use in the early stages, since even the use of one gram may cause serious slowing and irregularity of the pulse in the latter period. Fränkel also avoids its use in patients over fifty years of age and in alcoholics. He never uses smaller doses than three grams a day because the shortness of the disease demands the speediest possible methods of administration. He has never exceeded the total dose of 12 grams. Fränkel claims to have observed shortening of the febrile period, but he has never observed any reduction of blood pressure. Unpleasant after-effects were seldom noted. It may be of interest to note that Leyden in his recently published views[8] does not share these opinions.

Another explanation of the tolerance of large doses may be found in the experiments of Brunton and Cash,[9] which clearly show that the action of digitalis is lessened in febrile conditions.

A safe guide for the use of this drug is that given by Von Juergensen:[10] "Digitalis is indicated as soon as the pulse rises in frequency and at the same time becomes irregular without any demonstrable cause in patients whose hearts were weak before the attack, or in patients whose hearts have weakened during the course of the disease. The fulness or emptiness of the pulse is important in determining this; if it is still full we can afford to wait a little, especially toward the end of the disease, when not infrequently one of the indications of an impending favorable turn is slight irregularity of the pulse."

There are also other indications for the relief of the struggling heart to be found in the lung itself. I refer to the treatment of marked congestion or edema in the unaffected areas. Timely action demands timely recognition of this complication and bubbling râles and the first sign of edema are danger signals of the gravest significance. Repeated dry cupping is a powerful method, if properly done. It is surprising how much dry cupping can be done over the back if only a little care is taken in the application of the cups. The hypodermic injection of atropine (1-100 of a grain) is of signal value, not alone in lessening the outpouring of secretion, but also in stimulating the respiratory center.

Venesection may also be considered in this connection. In the case of young, robust adults, venesection and the withdrawal of 12 to 15 ounces of blood is often followed by marked relief of the distended and over-active right heart, and in this class of cases I have no hesitancy in using it. In elderly or feeble persons, however, or in those trying cases of grippe-pneumonia of irregular course, where the fresh inflammation of new areas may be marked by edema, or where a pseudo-crisis may occur with the resolution of a small patch, venesection is not indicated.

Before leaving this topic a bit of advice will not be out of place, and that is to leave with the nurse a written list of directions as to what course is to be followed by her should heart failure, crisis or untoward complications occur during the absence of the physician. Such scheduled directions add not a little to the nurse's usefulness and the peace of mind of the physician during his absence from the case.

(3). *To Control Hyperpyrexia.*—In considering this indication it should always be borne in mind that temperatures ranging up to 104° F. are as normal a feature of pneumonia as dyspnœa and rusty sputum. The view which is now generally accepted is that fevers up to this point are the normal reaction of the organism to the pneumococci. The fever and the associated leucocytosis may have important relations in nature's defense against the disease;

hence, as in all symptoms of pneumonia, we must individualize, for in some patients a fever of 102° F. may inflict more damage than 105° may in others. The thermometer, then, is not the only gauge as to the question of the fever being unduly high; the true guide is the patient's general condition.

The use of large, flat ice-bags is a convenient method for the reduction of undue fever, two or three being applied to the affected area. They are usually well borne and may add to the patient's comfort. The ice-bag, however, is no specific against pneumonia, as Mays would have us believe. I would warn against the possibility of intercostal neuritis from carelessness in the use of ice-bags, which I have noted in two cases.

Cold baths are absolutely contraindicated. Cold sponging and cold packs are often useful, but very cold packs are to be used with caution, since the shock of carelessly applied cold may inflict damage upon the heart. Properly applied moist compresses which envelope the entire chest, and are changed every hour or two without disturbing the patient too much are of use; their antipyretic effect is not very marked, but they often comfort the patient, and they, at least, constitute a local treatment which does no harm.

Concerning the use of quinine I would state that the hopes of Aufrecht, that the systematic hypodermic use of quinine would act specifically, have not been realized. I have used quinine where the leucocyte count was low in the hope of stimulating leucocytosis.

As regards the use of the coal-tar preparations a more rational view is now taken than formerly. First over-used and then under-used, it is now generally conceded that the rational use of small doses of any of the coal-tar products may add not a little to the patient's comfort in the reduction of undue fevers and in a general soothing effect.

In all antipyretic efforts it must be remembered that the bad effects upon the heart are not due to the temperature alone, but to the effect of the toxins upon the myocardium and vasomotor system, and that when we reduce the temperature we do not influence the latter at all.

(4) *To Relieve Suffering.*—The most striking indication under this head is the relief of the pleuritic stitches and the distressing cough which wear out the patients and rob them of their much needed sleep. These are best relieved by the hypodermic injection of small doses of morphine (gr. 1-10 to 1-8) or heroine hydrochlorate (gr. 1-8 to 1-6) which may be resorted to as soon as possible without unnecessarily weakening the patient by temporizing with other means. The Paquelin cautery often acts magically in quieting pleuritic irritation; no one who has ever used it will temporize with sinapisms, blisters, leeches, poultices, etc. The ice-bag is valuable, but does not act as promptly as either of the above. Large moist compresses, changed every two hours, may also be used.

The undue distention of the stomach and bowels in some of the cases during the past few years has been a most distressing complication. This is not necessarily due to any error in diet or any fermentation in the stomach or intestines, but may be the manifestation of a severe general toxæmia showing itself in a vasomotor paralysis or atonic distention of the gut. An interesting point may be mentioned concerning the treatment of this distention, that while it is of enormous value to give calomel or other cathartics early in the disease, yet the temptation to use calomel or cathartics of any kind in the later stages of the disease to reduce this undue distention must be carefully considered. Personally I am afraid to use them, as I recall two melancholy cases in which their use was followed by most disastrous results. Lambert has strongly recommended hypodermic injections of large doses of ergot for the control of this distention, and although I have thus far had no personal experience with this method of treatment, yet I believe its recommendation most valuable.

The perusal of the nurse's notes will include a most careful study of the temperature variations; the rate of the pulse and respiration are carefully noted; possibly a summary of the quantity of food which has been taken and the urine passed may be included; but how few are the physicians who inquire about the number of hours of sleep! A moment's reflection must make it evident to every one that the securing of sleep is to this class of patients not alone desirable, but imperative. No class of patients is more over-worked and no system cries for sleep more urgently than does that of the patient with pneumonia. W. G. Thompson has happily called attention to the advisability of procuring sleep, not alone at night, but in the daytime. All administration of drugs, of food, of hydrotherapy should be done at stated times; during the intervals between them rest or sleep should be procured. At all events the attempt should be made to secure an uninterrupted sleep of some hours several times during the day. Leyden and others have no hesitancy in using small doses of morphine hypodermically (Gr. 1-10 to 1-8) for this purpose. Personally, I prefer to produce sleep by less powerful means, and I have not been disappointed in the judicious selection and variation of the newer hypnotics. With them, I have found chloral, the bromides, and even morphine unnecessary in the vast majority of cases. Should these drugs fail, I would not hesitate to resort to the hypodermic use of even morphine to secure the much needed sleep.

Fränkel forcibly states that the securing of sleep has a favorable influence upon the course of the disease, and may even avert heart failure. He also emphasizes the necessity of sleep in the delirious patient whose very delirium is an indication for the need of such sleep. Sleep is also procured by efforts directed to meet the third indication—the relief of suffering.

Of the value of oxygen in the relief of dyspnœa and cyanosis it is difficult to give a final judgment. The opinion is slowly but surely gaining ground among the great clinicians that oxygen has been much overrated in the treatment of pneumonia. Theoretically its employment seems to be so well founded, its application is so simple and the apparent relief so striking that the universality of its use is not at all strange. But does it really do any good in those cases in which we want its effects most? The primary effects soon wear off in serious cases and the dyspnœa and cyanosis increase in spite of its free use. Let the enthusiast for oxygen remember that the lung is just as consolidated immediately after the crisis as it was before it, and yet what a change there is in the patient's breathing. This proves that dyspnœa is not entirely mechanical in origin, as is generally thought, but is mainly the result of the pneumococcus toxemia. In tiding the patient over sudden attacks of dyspnœa and cyanosis oxygen is most useful, and there is no objection to its brief use at short, regular intervals after the dyspnœa has become more or less pronounced.

(5) *To Control Complications.*—Of these the most important are pleurisy with diffusion, empyema, pericarditis and endocarditis. The treatment of these conditions in pneumonia differs in no wise

from that ordinarily pursued, and hence requires no special discussion.

The recognition of effusions in pneumonia is often difficult, since the flat note and other signs which would indicate the presence of an effusion may be due to the presence of very thick layers of fibrin. To determine this point I have aspirated a large number of these cases and have been surprised at the relative frequency of this as a cause of undue flatness at the base of the lung. It may be added that effusions into the chest, either serous or purulent, ought to be removed as soon as the amount of fluid becomes large enough to seriously interfere with the lung. In delayed resolution one should never fail to look for an empyema.

In conclusion, I would once more warn against routine or scheduled plans of treatment. The successful outcome of a case of pneumonia is sometimes a matter of luck, but more often a matter of judgment. In few diseases are the therapeutic indications more sharply outlined; in no other is the practice of therapeutics so great an art.

A QUESTION IN GALL-BLADDER SURGERY.*

CHOLECYSTOTOMY OR CHOLECYSTECTOMY?

By HARRIS F. BROWNLEE, M.D.,
DANBURY, CONN.
SURGEON TO THE DANBURY HOSPITAL.

It is worthy of comment that most of the advances of surgery in recent years have been made so rapidly that they have often exceeded the bounds of good judgment before finally settling down to a recognized moderate and sane procedure beyond which good surgeons do not usually go. A few years ago the ablation of ovaries was so common that a woman was hardly safe within sight of a surgeon; to-day, conservative surgery removes but few, and restores many to normal function. It was demonstrated that the appendix could be safely removed when diseased, and in condition which previously had been fatal. Soon we heard men advocating operation for every intestinal colic, and advising the removal of the appendix from babies at birth, to be sure that they should never have appendicitis. But to-day the boundaries between when to operate and when not are more nearly set, between which there is ample room for the exercise of good judgment and special knowledge of the conditions.

This is largely due to excessive zeal of some earnest men, striving to arrive quickly at the end of the subject, and in some measure, by the endeavor of some men to outdo everybody else in the field, regardless of what the ultimate consensus of opinion may be.

In surgery, as well as in political life, there is usually an energetic constructive party whose efforts are always in advance; there is also an opposition party, who are never leaders; always followers, and follow only after a period of intense opposition. They can not create or advance alone, and are loth to acknowledge the creations or advances of others.

It is not my desire to be classed with the opposition party, but most decidedly with the progressive element. However, a degree of conservatism is necessary in any party, surgical or political, if it is to predominate and remain a leader.

My paper to-day is not so much a contribution to surgical literature, but rather a protest against a procedure which is just now enjoying the approval of many progressive surgeons, namely, the indiscriminate removal of the gall-bladder, cholecystectomy, as if it were an unnecessary appendage similar to the vermiform appendix, and useful only to afford lodgment for stones.

It is now the custom of many surgeons, and at a recent meeting of the New York Surgical Society it was endorsed by a majority present as good judgment, to remove the gall-bladder in all cases in which an operation is necessary for stones, or for any other morbid condition, no matter what the state of the viscus might be. The gentleman presenting the subject claimed for the procedure an equal degree of safety with other primary operations, naming appendicectomy; greater safety than secondary operations on the gall-bladder; greater surety in preventing reformation of stones, and a greater degree of neatness and thoroughness of operation.

Admitting that this is not only a justifiable but advisable procedure in all cases in which the gall-bladder is from any source atrophied or diseased beyond repair, it is not in my opinion justifiable when the viscus can be preserved and restored to its normal function, and I maintain here that it has a well-defined function which can not with impunity be ignored or dispensed with. The results of ruthless excision of the gall-bladder are not evident immediately after operation, and will be proved only by a gradual development of evils beginning at this time.

Bile is formed in the liver without interruption, while it is allowed to flow into the intestine only after food has been taken into the stomach. The common duct is closed at its distal or intestinal end by a sphincter of muscle fibers, and the presence of food in the stomach acts as a stimulus, which causes peristalsis of the gall-bladder and ducts with relaxation of the sphincter. The surplus of bile formed in the liver is stored in the bladder until needed, and thrown into the duodenum in large quantities during the process of digestion, so we see that the bile-ducts do not act simply as a drain from the liver; or if they do, it is a necessary provision that there should not be a free communication at all times between the ducts and the intestine, the sphincter being opened only when the intestinal peristalsis is actively passing things along. Perhaps here is a provision against infection from stagnant gases contained in a quiet intestine.

Unfortunately the viscus has a bad habit of accumulating deposits of bile salts known as stones. Usually they form in the gall-bladder, which is natural, as the bladder is dependent, the fundus being the lowest portion when a person is standing, and the bile is in a condition of stasis. However, they may form in any part of the biliary tract, even in the inner recesses of the liver.

Without going exhaustively into the theories as to the causes of cholelithiasis, we will accept the consensus of opinion that stones are largely due to a catarrhal condition of the biliary passages, caused by the invasion of bacteria from the intestinal tract;

*Read before Fairfield County, Conn., Medical Society, Oct. 11, 1904, at Stamford, Ct.

mainly *Bacterium coli* and frequently the typhoid bacillus. Their formation is favored by anything which contributes to stasis of the biliary flow.

We will assume that we have the stones for the present all in the gall-bladder, and their removal is indicated, or assume that the gall-bladder is the seat of an acute infection, cholecystitis requiring opening. The usual operation is cholecystotomy; the bladder is opened, emptied, and, if the cystic duct is patent, is stitched into the abdominal wound, where it is allowed to drain and cleanse itself, after which it returns to its natural function as a reservoir for bile.

But instead of this, suppose we do a cholecystectomy, simply ligate the cystic duct with its arteries, and remove the gall-bladder entirely, which is just as easy—in fact, I think a quicker and an easier procedure than stitching it into the wound. Our reasons for this are to prevent a similar occurrence in the future, to avoid the necessity of a fistula, and to accomplish a neater operation, reasons which certainly sound plausible. However, when you take away the gall-bladder you take away the safety valve of the liver. Bile to the amount of about 15 to 18 ounces, and frequently more, is formed in the liver during the day, and, as I have said, is only discharged into the intestine during the period of digestion, though the production is uninterrupted. Now if there is no storage place for the surplus produced between meals, it must be retained in the common and hepatic ducts until their capacity is reached, then retained in the liver spaces until the pressure is reversed, and a certain amount of absorption takes place into the general circulation. This also produces a form of hepatitis similar to cirrhosis. In course of time the gall-ducts become dilated to a considerable extent so as to contain a large amount of bile. Then another danger intervenes. This large still column of bile is, through stasis, more liable to infection, and on account also of the stasis the infection is carried upward into the liver. It has been shown by experiment that bile in the ampulla is always infected from the intestine, and if the common duct be tied higher up the bile contained in the portion below the ligature will also become infected, at least the walls of the duct will become infected. The bile does not act as an antiseptic, as has been stated, at least only mildly so, and it is the moving current which keeps the ducts healthy, by carrying away the dead epithelium from their walls, the surplus bile being regurgitated into the gall-bladder, where it is stored, until at the proper time it is thrown out with considerable force.

The strength of the gall-blader is not generally appreciated. A sound bladder removed and filled with air while fresh will sustain the weight of a heavy man without rupture. Many a smoker will tell you that a tobacco pouch made from a beef gall will outwear anything else of its kind.

Now suppose the common duct is occluded by a stone washed down into it, which may have formed in the liver itself or in the ducts; the gall-bladder then acts as a receptacle into which the bile is forced, and it is often found enormously distended, and while there is necessarily considerable back pressure into the liver cells, it is lessened for a space of time until the full limit of the distended bladder is reached, and while a patient soon shows signs of jaundice, he is not at once overwhelmed with sepsis from absorption. Of course, this comes sooner or later, but some time is gained during which the peristaltic endeavors of the duct, aided by the contraction of the bladder, may serve to dislodge the stone, by pressing it into the intestine, after which recovery is speedy, even when jaundice is very marked. The same rapid recovery takes place when the stone is removed by the surgeon.

However, when there is no gall-bladder into which the bile may for a time be forced, the bile is at once backed up into the liver, causing an acute hepatitis which interferes with its normal functions, and a double process begins at once. The organ ceases to remove the bile from the blood, or does so only in part; that removed begins immediately to be reabsorbed, and the patient is rapidly overwhelmed with sepsis.

The assistance of the normal contractile force of the gall-bladder in expelling the stone is also absent. When these patients, after becoming thoroughly poisoned, are relieved by removal of the obstruction, they do not recover as surely and rapidly as those in whom the main pressure was received by the gall-bladder; the liver is not able to recover from its violently congested condition and the patient dies from that cause.

I have observed a number of cases in which at the time of operation the patient was markedly jaundiced, and the gall-bladder enormously distended, which, however, made rapid recovery after removal of the obstruction; and recently I encountered one of the other class, which served to crystallize my opinions in regard to the advisability of having a gall-bladder if possible, and retaining it as long as it remains, or can be made, capable of its normal function.

Patient, male, 52 years, had complained at times for past year of an uncomfortable feeling about the region of the stomach near the pylorus. Usually this pain or bad feeling followed soon after eating, but was not closely associated with his meals, and would disappear for weeks, then recur. At no time was it really a pain, and there was no history of colic. I examined him carefully twice, and concluded it was some error in digestion, and treatment with that in view seemed always to relieve him. However, he came to my office a short time ago on a Saturday, complaining of more marked distress in the same region, not a colic, but more of a feeling of weight. On examination I could make out only a marked rigidity of the right rectus muscle over the pylorus. He said he had not felt well for several weeks—in fact, all summer. I asked him to return the following day, an hour after eating a prescribed test meal, for examination of the stomach contents. He did not return, and I did not see him until Wednesday evening, when I found him at home suffering from marked biliary colic which had persisted during the day. He looked haggard and was jaundiced to some extent. I sent him to the hospital with instructions for relief of pain, etc.

The following day he was markedly jaundiced, the skin being deeply stained, the tongue was dry, and his whole appearance bad; pain had ceased. Consent for operation could not be obtained, though it was urged. The following day, Friday, his appearance was worse, and consent for operation was obtained. Exploration through the usual opening disclosed a liver distended in all directions, the gall-bladder atrophied to size of one joint of a man's thumb, containing neither bile nor stone. In the common duct very near to the gut, just above the ampulla, I found a small stone, the cause of the obstruction. I could not dislodge it, though I tried hard to push it through into the intestine. Finally, I crushed it and then worked it through into the bowel.

Hemorrhage was profuse from everywhere, a continual oozing, which made careful manipulation dif-

ficult because I could not see well, and in crushing the stone I opened the duct. A small amount of very thick viscid matter appeared on the wipe, but there was no free escape of fluid, and I thought at the time only small damage was done to the duct wall. No other stones could be felt between that point and the liver.

The hemorrhage was so persistent that I was forced to pack some gauze into the bottom of the wound. The incision was then closed, excepting the space required for gauze. The patient did not improve after the operation, and died during the night of the following day.

Examination after death revealed only a small amount of bile in the ducts and no evidence of any quantity having passed into the duodenum, though the duct was patent. Had this man been possessed of a competent gall-bladder the back pressure would have been in a considerable measure mitigated, his consequent hepatitis at least postponed, and his chance of recovery after operation materially increased. Of course he could not have waited forever, but a little aid would have proven of great service.

If the cystic duct is closed permanently the bladder is of course useless, and should be removed. In one case I left it, hoping it might finally reopen, but a troublesome fistula resulted through which discharged a quantity of glary mucus, and was only stopped after repeated injections of a solution of corrosive sublimate in caustic strength.

The same indications exist when the gall-bladder has become permanently diseased from any cause, but there is no justifiable reason for removing every gall-bladder which has become infected, or has afforded lodgment to stones. The mere fact that a man may live without it is not sufficient. We are not at all sure that his liver functions are not materially embarrassed, which in the end will aid in the downfall of his general health. Nature may offer compensation in some way, but why should it be necessary?

I doubt if the number of recurrences of stones in the gall-bladder after cystotomy is greater than the number of cases of stone lodged in the common duct after the bladder has been removed, and the danger of reinfection is less.

It is a fact that infection of the gall-bladder a second time is an exception to the prevailing rule, as is also a second accumulation of stones; whether an immunity is developed, or an insufficient number of years have elapsed to prove the frequency of second accumulations, I cannot say.

Cholecystectomy is still too young for us to predict what will follow, but I believe stones will form more readily in a distended common duct where the gall-bladder is absent, and that infection leading direct to the liver, will have easier access, which, with the evil of the liver having to store a quantity of its own production within itself for variable lengths of time, will ultimately lead to the downfall of the patients' health.

Milk Baths.—A dairymaid has been arrested at Cologne for bathing herself daily in the milk before it was sold, because she had read that milk baths were good for the complexion.

A SERIES OF FOREIGN BODIES IN THE VERMIFORM APPENDIX MET WITH IN 1,600 NECROPSIES.

By LOUIS J. MITCHELL, M.D.,
CHICAGO.

The "foreign bodies" referred to here are those properly so-called, not fecal concretions, and they were found during the writer's service as Coroner's Physician.

The points of interest concerning them are as follows:

Grape Seeds.

1. Male, 43 years, September 20, appendix 3½ inches long, below cecum, hanging down, contained 3 grape seeds and semisolid feces. Cause of death, fracture of skull.

2. Male, 42 years, September 30, appendix 4½ inches long, pointing to left, contained 1 grape seed. Cause of death, pulmonary tuberculosis.

3. Male, 33 years, November 7, appendix 2 inches long, very wide (3-8 inch) retrocecal, contained 2 grape seeds and semisolid feces. Cause of death, bullet wound of chest.

4. Female, 27 years, January 15, appendix 3½ inches long, below cecum hanging down, contained 1 grape seed and 2 fecal concretions. Cause of death, bullet wound of abdomen.

5. Male, 26 years, September 29, appendix 4½ inches long, hanging down into pelvis, contained 1 grape seed and numerous fecal masses. Cause of death, bullet wound of abdomen.

6. Female, 52 years, August 6, appendix 4 inches long, hanging into pelvis, contained 3 grape seeds and semisolid feces. Cause of death, enteritis.

7. Male, 35 years, December 29, appendix 4½ inches long, pointing to left, contained 1 grape seed and soft feces. Cause of death, alcoholism.

8. Male, 23 years, January 2, appendix 4 inches long, hanging into pelvis, contained 2 grape seeds and semisolid feces. Cause of death, bullet wound of brain.

Metallic Objects.

9. Male, 22 years, April 4, appendix 6½ inches long, contained 1 shot. Cause of death, pulmonary tuberculosis.

10. Male, 22 years, April 4, appendix 6 inches long, hanging into pelvis, contained 1 shot and mucus. Cause of death, chronic pleuritis.

11. Male, 44 years, March 24, appendix 4 inches long, hanging into pelvis, contained 3 shot. Cause of death, chronic nephritis.

12. Male, 23 years, September 3, appendix 4 inches long, curled on itself, contained a fragment of shingle nail (about half the length from point) and 1 husk. Cause of death, stab wound of neck.

13. Male, 37 years, July 17, appendix 3½ inches long, hanging into pelvis, contained a globule of solder weighing 14½ grains. Cause of death, alcoholism.

Miscellaneous.

14. Male, 27 years, November 13, appendix 5 inches long, hanging into pelvis, contained piece of nut shell and soft feces. Cause of death, fracture of skull.

15. Male, 40 years, January 14, appendix 5½ inches long, retrocecal, contained centrum of vertebra of small fish, with part of vertebral arch attached. Cause of death, alcoholism.

16. Male, 40 years, April 16, appendix 5 inches long, tip resting on bladder, contained 2 fragments of bone and soft feces. Cause of death, typhoid fever.

17. Male, 47 years, July 11, appendix 3½ inches

long, hanging into pelvis, contained a very sharp fragment of bone. Cause of death, mercurial poisoning.

18. Male, 50 years, November 27, appendix 4½ inches long, very wide (3-8 inch), hanging into pelvis, contained 3 hard fragments apparently ash or stone, and soft feces. Cause of death, morphine poisoning.

Of late years the tendency to regard foreign bodies as the cause of appendicitis has become less, and the pendulum has now swung to the other extreme—many writers believing true foreign bodies to be of unusual occurrence, and that fecal calculi are generally mistaken for them. Thus Berry[1] states: "The literature of the subject reveals a most extraordinary collection of substances which are stated to have been found in the cavity of the appendix. Thus fruit seeds, cherry stones, hairs, bristles, shot, pins, have all at times been recorded as having been found in the appendix. Without challenging the good faith of the observers who have recorded the above examples, I venture to assert that many of them are inaccurate. From their similarity in size, shape, and appearance, so-called fecal concretions have frequently been mistaken for foreign bodies. It may be said, in fact, that the occurrence of foreign bodies in the appendix is exceedingly rare," etc.

J. F. Mitchell[2] also regards them as uncommon: "Those foreign bodies of light weight like grape seeds and cherry stones, so popularly assigned as causes of appendicitis, are in reality exceptional, and their frequency is much overestimated, on account of the close resemblance of fecal concretions, and the lack of careful examination of the foreign bodies."

In the majority of cases of foreign bodies here reported the appendix was either empty save for the foreign body, or contained only soft feces. The resemblance of fecal concretions to orange or lemon pips is at times remarkably close. On one occasion, even after a somewhat extensive experience with these concretions, one was found by the writer which simulated an orange or lemon seed so closely that it was about to be noted as a "find," but on crushing it with the handle of the post-mortem knife its true nature was finally revealed. This occurred in a youth of 17, the appendix was 5 inches long, hanging down, and contained 2 very hard concretions, one round, the other of the shape described. Death resulted from a bullet wound of the abdomen. In this connection it may be of interest to state that the youngest age at which concretions were found was 8 years. This occurred in a little girl, who died from a bullet wound of the abdomen; the appendix was 3 inches long, hanging below the cecum, and contained soft feces in addition to a single concretion.

It will be seen that grape seeds were found in the months when grapes are in season, or about the holidays, incident to the consumption of the festive plum pudding, etc. So, too, the shot occurred during the game season.

In conclusion it may be noted that none of the appendices containing these bodies showed any signs of inflammation, either past or present.

A New Cause of Appendicitis.—Some imaginative Swedish doctors having found minute pieces of enamel from "granite" ware in cases of appendicitis, have suggested that the common use of this ware may have something to do with the prevalence of this disease.

A CASE OF CRYPTORCHIDISM.

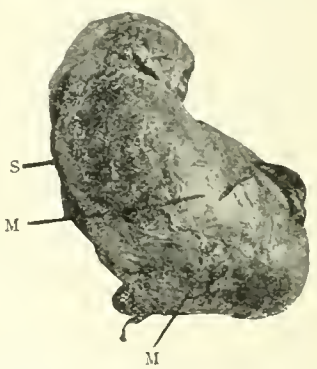
By JOHN M. FRANCE, M.D.,
RIVERSIDE, CALIFORNIA.

My only excuse for reporting this case is the very meager manner in which the subject is treated in the pages of our standard literature, and to urge surgical interference in early life for the relief of the condition.

J. E. M., aged 27, native of Kentucky, married, and the father of one child, presented himself at my office on June 1, 1904, and asked relief for a distressing pain in his bowels, which was now always present, and for the past three months had incapacitated him from performing any labor whatever.

Previous to my examination he gave the following history. Testicles had never descended, but were retained within the abdomen. He began suffering with vague pain in his left side, low down, about three years ago, not very severe. About one year ago he was in an electric car that had become unmanageable, and in his efforts to escape was severely bruised on his left side. Since then the pain had gradually grown worse. Now it was always present, and at times unendurable. He also informed me that his sexual desire was strong, and his ability to gratify it unimpaired.

The penis was normal in its development, but the scrotum was merely a small rudimentary sack



From a photograph of the tumor; S, spermatic artery; M, M, branches from the mesenteric arteries.

of skin. The left inguinal canal was totally obliterated; the right inguinal canal was obliterated to within one inch of the right internal ring. At a point one inch above where the left internal ring should have been, a round nodular body could be felt. This was very sensitive to the touch. Both rectus muscles were intensely rigid.

My diagnosis at that time was an incarcerated testicle that had taken on malignant growth. I advised an immediate operation for the extirpation of the diseased gland.

This he consented to, and the next evening entered the Riverside Hospital, where, on Friday, June 3, I operated.

After the patient was under the anæsthetic I could better outline the tumor, as the rigidity of the recti muscles had disappeared. I found what I had supposed to be simply an incarcerated testis to be a tumor of considerable size, filling the lower part of the pelvis. This determined me to ignore the rule to cut down directly on the neoplasm, so I made my incision in the medium line, three inches in length, between the umbilicus and pubes.

The digital examination revealed the fact that the tumor was adherent all around, above to the omentum and peritoneum, behind to the mesentery and small intestines, and in front to the bladder, the base resting on the right psoas magnus muscle. The

time occupied in enucleating this neoplasm was about three hours. The tumor, immediately after removal, weighed twenty-eight ounces.

The blood supply was from several arteries, entering its back, base, and side; in the illustration the points are marked where the vessels entered, the spermatic artery was one of them, the others were evidently derived from the mesenteric arteries.

The tumor, when cut, exhibited a white glistening surface which exuded a milk-like fluid; the histological examination showed it to be a large spindle-celled sarcoma. The patient's convalescence was devoid of any special interest, the only interruption being a slight infection from a stitch abscess in lower angle of skin wound on the eighth day. He left the hospital on the twentieth day.

In closing the abdominal wound, the peritoneum was separately closed by an uninterrupted cat gut suture, the deep fascia likewise, the coaptation of the skin was by interrupted sutures of chromatized catgut.

This method of closing an abdominal wound commends itself very highly, as in this instance, we had an infection in skin wound, where it was necessarily confined, the closing of the peritoneum and fascia by separate sutures protected the peritoneum from infection by either capillary attraction or direct contact with septic material. This case from a medico-legal aspect is not without interest. In searching the literature of the subject at my command I find that all authorities agree that cryptochids are sterile. Dr. Curling[3] has narrated nine cases in which the ejaculated semen of men with retained testes, or with a single testis, the other having been removed, or its duct obstructed, was destitute of spermatozoa. The history of the case certainly contradicts the foregoing, for the patient is the father of a child whose resemblance to him is marked.

Dr. Beigel[2] holds that when both testicles are absent the individual does not eliminate any semen, and when both are hidden the person is sterile. I could furnish other testimony similar to this above would space permit me.

The absence of the testes from the scrotum is usually discovered very soon after birth by either the mother or nurse, and as a measure of protection in after life from malignant disease it is suggested to search for incarcerated testicles, find them, and place them in the proper receptacle, or remove them.

Dr. Geo. Johnson[3] has reported a case of encephaloid cancer affecting a testicle retained within the abdomen. C. D., aged 27, was attacked after a hard day's shooting with a pain which appeared to be near the bladder, on the right side. From being a muscular and athletic man he became bent and haggard, and died in one year from the beginning of his illness. At the autopsy a mass weighing sixteen pounds was found in the abdomen. This specimen is preserved in the Anatomical Museum of Kings College.

Sir Spencer Wells[4] removed a cancerous testicle which was retained within the abdomen. The removal of the gland was safely accomplished, but the patient died in one week from sepsis.

In closing this paper I desire to mention the very skillful and valuable assistance afforded me in this operation by Major and Surgeon W. W. Roblee, N.G.C. Also to thank Dr. J. I. Clark of Santa Ana for the skill exhibited in maintaining complete anæsthesia with a minimum amount of chloroform in this very prolonged operation.

Chronic Intestinal Dyspepsia of Children.—J. Brunton Blaikie describes a typical case of what he calls the chronic intestinal dyspepsia of children. A child of eight has a headache in the morning, has no life in him, suffers from pain in the chest, has a bad cough, has always been weekly, is very thin, but not emaciated, has a sallow complexion, and dark rings around the eyes. The chest is found to be healthy, but badly developed, on account of the presence of adenoids and enlarged tonsils. The child is said to be very nervous. The chest pains are found to proceed from the epigastric region. The tongue is furred, and there are several carious teeth. The child suffers from night terrors. His appetite is poor and capricious. Thread worms have been noted in the stools. This condition is exceedingly common. When the correct diagnosis is made the child, instead of being stuffed with food and cod-liver oil and syrup of hypophosphites, will receive rational treatment. The writer has investigated fifty cases. The children are often members of poor families, although they are by no means limited to these classes. It is certain that the disease affects special families. All types were seen among these children. The disease generally occurs during the school age. Three-fifths of the cases were between the ages of five and eight. Thirty-four were in boys, and sixteen in girls. It is not possible to obtain any very definite information as to the duration of the disease. Constipation seemed to have a definite influence on the production of night terrors. The malady is often mistaken for tuberculosis. The disease is of itself probably never fatal. As to treatment, the most powerful remedy for the treatment of the immediate condition is change of air. Till the symptoms are greatly improved, it is well to allow the child no sugar, sweets, jam, potatoes, new bread, sago, tapioca, arrowroot, Indian corn, flour, turnips, or carrots. A sufficiency of fresh air is most important. The child should be kept from undue excitement. Among drugs, the most beneficial are the alkalies, oleoresins, and bitter tonics. Bicarbonate of potassium or sodium and citrate of potassium, especially when combined with nux vomica and myrrh, are very beneficial. Rhubarb and soda with a little grey powder are excellent. Aloes is also useful. The special symptoms require the usual treatment. The writer believes that this disease causes much needless suffering among children. By combating it the physical standard of coming generations will be raised.—*The Edinburgh Medical Journal.*

Meteorism Following Abdominal Operations.—A. P. Condon believes that of all the causative factors, the injury to the abdominal wall is the most important, for the meteorism seems to bear no relation to the amount of manipulation of the intestines, hemorrhage, etc., as he has seen the worst cases follow a simple section, with little hemorrhage and no handling of the intestines. Recently the writer has worked on the hypothesis that tympanites is due to lessened muscular tone following vasomotor paresis, in fact, a general and local condition of shock. He began to use ergot, hypodermically, knowing that this drug is one of the best remedies to overcome decreased contractility of involuntary muscles and flaccid condition of blood-vessels. He has used it now in forty-three abdominal operations, and has had no meteorism in any of these cases. There was less post-operative nausea and vomiting also, and less general shock. In every case in which it is possible he gives 30 minims of ergot hypodermically twenty-four hours before the operation. This dose is repeated every eight hours for four days, when it is discontinued. He also gives intestinal antiseptics the night before operating, to prevent excessive fermentation. When meteorism has developed, the writer has used with success physostigmine salicylate, hypodermically, in doses of 1-60 of a grain. Moskowicz has used this drug with magical effect in the relief of post-operative paralytic ileus. He emphasizes the danger of this pseudo-ileus, which is one cause of death after laparotomies, and has also been observed after vaginal operations.—*The Therapeutic Gazette.*

MEDICAL RECORD.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 10, 1904.

THE OPIUM QUESTION IN THE PHILIPPINES.

THE report of the committee appointed by the United States government to investigate the regulations controlling the opium traffic in the various countries throughout the Far East has recently been issued. After an exhaustive study of the conditions prevailing in all the lands in which the question presents itself, the members of the committee report in favor of the establishment of a rigid government monopoly of the sale of the drug in the Philippine Islands.

It is somewhat unfortunate that the Philippine Commission has been compelled so early to assume the responsibility of official action in this matter. The inherent difficulties of the question are much enhanced by the fact that the members of the commission are struggling with a complex problem in trying to conform to public opinion at home by establishing a form of government fit only for the highest types of men, yet compelled to modify it so that the childish Malay can take some part in it without injuring himself. Very few of the Filipinos have sufficient intelligence to understand Aryan ways or Aryan democracy, and this compels the commission to assume a paternal attitude, wholly at variance with the political ideas of the mass of the American people. Some combination of events unknown to us has induced the commissioners to take up the regulation of the opium traffic to protect the native. They have no doubt been influenced by exaggerated statements of the harmfulness of the use of the drug, and do not seem to be aware of the fact that the Asiatic nervous system is vastly different from that of the European. Unfortunately, the medical profession cannot enlighten them as it should. On the one hand we have the English reports from India to the effect that opium is quite harmless to the Asiatic, if not actually beneficial, and that it occupies the same place in his life that tea or coffee does in ours, with our more delicate and more unstable nervous tissue. On the other hand, we have the sensational reports of the missionaries in China, who think that opium is the cause of the dreadful condition of some members of that race, particularly of the inhabitants of certain interior villages which are said to have been practically destroyed. A middle position is taken by one writer, who apparently proves that the drug is invariably destructive to the peoples newly introduced to it, as in Farther India and China, but that by a process of elimination of the most susceptible, the race in time becomes composed only of those who can use it safely, and who become actually dependent upon it, as in India. The truth will probably be found midway, for the extreme views can safely be accused of bias. It is quite likely that the drug is harmful, but not nearly to the extent asserted by those who think it has the same effect on Asiatics as upon Europeans. So it might perhaps have been wiser to ignore the matter in the Philippines. In addition, the Malay uses the betel nut for the same purpose, and will probably not abandon it. It seems harmless to him, though it might not be so to us.

When the matter of regulation of the opium traffic was brought up it encountered violent opposition from the clergy and the Chinese, the former demanding absolute prohibition, on moral grounds, and the latter clamoring for no interference with a drug which they claim is as harmless and necessary to them as coffee is to us, and these two joined forces. It was like the combination of the whiskey interests and the temperance advocates to destroy the beer feature of the Army canteen, one fighting to increase the sales of whiskey, and the other endeavoring to prohibit all traffic. The commission was compelled to appoint a committee which, composed of a clergyman, a physician, and a Filipino, would naturally bring in a compromise report. As compromises with facts are notoriously unstable, we can expect difficulty in carrying out the recommendations, if not complete failure and renewed opposition from the extremists.

The Japanese Government has established a rigid monopoly in the drug in Formosa, but on such liberal terms that it is easy for the habitual user to obtain it. But the Chinese have developed the same sensitiveness to government control as the American colonists showed to the English monopoly of the tea trade. In Formosa it is an open secret that there is much opium smuggling, and the Chinese obtain it in as great quantities as ever, though they could buy it as cheaply, if not more cheaply, from the Government. As they are experts in smuggling, we can presume that in the Philippines they will obtain what they desire, irrespective of any system of laws which we can devise to regulate them. The wily Oriental is more than a match in subterfuge and underground work for Europeans, as he is the result of the survival of those who for many centuries could live only by such means.

THE MEDICAL RELATIONS OF LIFE INSURANCE.

ON the occasion of the Congress of Arts and Science, recently held in St. Louis, Mo., Mr. Frederick L. Hoffman read a very interesting and important address on "Life Insurance as a Science," in which he dwelt upon the relation of this branch of human activity to economics, on the one side, and to medicine on the other. The essay, instructive as it is in its entirety, is nevertheless of too great length to review in full, and we can only touch upon certain aspects of the question which intimately concern medicine. Mr. Hoffman points out that biological science rests in a larger measure than is commonly assumed upon a statistical foundation. Much, if not most, of what life insurance officials require to know of biology for the medical selection of risks relates to normal and abnormal man from the viewpoint of anatomy and physiology. The problems of human multiplication and normal increase, the mar-

riage rate, fecundity and sterility, consanguinity, race mixture, and intermarriage are all, as Mr. Hoffman shows, pending questions, toward the solution of which life insurance contributes much information and expert talent. The importance of the relationship of life insurance to pathology is sufficiently obvious to require no lengthy discussion. The medical director is an absolutely essential part of life insurance organization, and upon him depends to a very considerable extent the success of the company.

Neurology, the writer is of the opinion, will in the future render even greater service to insurance science than has been possible in the past. Brain diseases are increasing in all parts of the world, and statistics on the matter are to a great extent unreliable and undeterminate for a variety of reasons. In this connection actuarial skill can be of great value to the medical profession in assisting to clear up many obscure points. Suicide which may be termed one of the problems of neurology and of great importance to insurance companies, is briefly dealt with. In American cities the rate per 100,000 of population has changed from 12.0 during 1890 to 18.4 during 1903. This again is a question, the thorough investigation of which would be of the utmost service to insurance companies.

The psychology of life insurance is touched upon by the writer, and the psychology of suggestion in its special relation to the occurrence of mental epidemics is referred to. It goes without saying that the influence of suggestion in causing small epidemics of suicide of a local character is a source of considerable anxiety to the management of conservative insurance companies. As bearing upon this phase of the subject Mr. Hoffman quotes from Mackay's "Memoirs of Popular Delusions," as follows: "From time to time the infatuation to acquire wealth speedily by an illegitimate shuffling of the cards rather than by safe and equitable methods in the employment of capital and labor, seizes the people, and thus probably it will ever be until those who possess property shall be acquainted with the principles and laws of trade and shall at the same time be desirous to restore to the commercial character generally an inviolate and inflexible spirit of single-minded honesty." There is no doubt that the spirit of wild speculation so greatly in evidence in these days, and the unseemly haste to get rich, with the attendant nerve-racking tension, have much to answer for as causes of insanity and suicide.

Referring to gynecology in relation to life insurance, the author draws attention to the fact that woman as an insurance risk is one of the most perplexing problems with which insurance practice has to contend. Mortality tables go to show that the death rate of women at all ages is less than that of men. Nevertheless insured women frequently prove a loss to companies. One reason for this seeming anomaly is that for reasons of modesty the physical examination of women is less carefully carried out than is that of men, and consequently obscure pelvic diseases and diseases of the ovaries and uterus are often overlooked.

The improvement wrought by hygiene generally and by more careful feeding and care in particular, in lowering the mortality rates of the young, has materially affected insurance companies. On the whole, the general benefits accruing to such companies from the gradual diminution of a needless waste of infant life, has counterbalanced the loss of profits occasioned by the general decline in the birth rate. The perfection of the official registration of deaths and the medical or legal certification of their causes has been an agent in the improvement of the life expectancy, the value of which can hardly be overestimated. It may, however, be said that there is still room for further advance in many parts of the world, not excepting the United States, in the branch of vital statistics.

The effect of climate and weather is necessarily of the first importance with regard to life insurance, and the writer points out that tropical climates are losing much of their terror for white men. In India, for instance, the mortality of European troops since the days of the great East India Company has been reduced from 76 to 16 per 1,000. Meteorology has as yet not progressed so far that the effects of temperature, barometric pressure, humidity, rainfall, prevailing winds, etc., on human health can be accurately determined under the varying conditions met with in different portions of the globe. But our knowledge as to the manner of life best suited to various climates, and of the most efficient sanitary and preventive measures has immensely increased.

The article by Mr. Hoffman is both interesting and instructive, and is a notable addition to the literature of life insurance. It is well that a definite place should be accorded to life insurance among the sciences, and it is eminently fitting that so important a paper under the new classification should have been read in St. Louis, and by an American statistician. The United States is the country in which the principle of life insurance has reached its highest development, and this honorable altitude is due to the brains and energy of the men in charge.

THE CHANNELS FOR INFECTION WITH TUBERCULOSIS IN CHILDHOOD.

Infection with tuberculosis may take place through the inhalation of air containing tubercle bacilli, through the ingestion of food similarly contaminated, by direct inoculation, and by way of the placenta. In the first instance, which is naturally the most common, the air-passages, including especially the tracheal and bronchial glands and the lungs, become the seat of disease, although the bacilli may lodge in parts common to the alimentary and respiratory tracts, and thus eventually be swallowed. In the second instance, which comes next in frequency, the mesenteric glands and the intestines suffer most, while in the remaining instances the localization of the disease will vary in individual cases.

While probably the infection is acquired less commonly through the medium of contaminated milk than was at one time supposed, there is good reason for believing that this channel of communication can by no means be ignored, particularly in early life. Having in mind the importance as well as the difficulties of the subject, Dr. L. Kingsford (*Lancet*, September 24, 1904) undertook an analysis of the post-mortem records in 339 cases of tuberculosis in children at all ages up to 14 years observed at the East London Hospital for Children. As a result of this investigation it was found that 162, or 48 per cent. of the cases occurred during the first two years of life and 270 or 80 per cent. during the first five years of life, while there was a steady decline among

the older children. In 49 per cent. of the cases infection apparently took place through the mucous membrane of the trachea or the large bronchi. In more than 90 per cent. of the cases the lymphatic glands were obviously tuberculous, while in 68 per cent. they were the primary foci. Of 64 cases in which the origin of the disease was obviously abdominal, only 18 exhibited tuberculosis in any of the glands of the thorax, whilst the mesenteric glands were caseous in 62. Of the entire number of cases 212 or 62.5 per cent. were thoracic (167 primarily glandular, 34 primarily pulmonary, 11 both), 64 or 18.8 per cent. were abdominal (29 primarily glandular, 26 primarily intestinal, 9 both), 13 were pharyngeal, and 50 were doubtful.

If infection is considered to have taken place by inhalation in the middle-ear cases, of which there were four, to have been alimentary in the tonsillar case, of which there was but one, and of doubtful origin in the remaining pharyngeal cases, inhalation would account for 216 of the cases of 63.7 per cent., and ingestion for 65 or 19 per cent., while the remaining 17 per cent. are of doubtful origin. It will thus be seen that while the danger from inhalation is far greater than from ingestion of tuberculous material, the latter is far from insignificant, and cannot in practice be ignored. Differences in this connection in different countries are probably due to differences in the prevalence of tuberculosis in cattle and in the infectivity of the milk supply. Accordingly, in order to bring about a diminution in the prevalence of tuberculosis in children, measures must be enforced looking to prohibition of the sale of tuberculous milk, while at the same time attention should be directed toward improving the conditions of life through cleanliness, ventilation, disinfection, and better housing.

Exercise in Heart Disease.

At one time it was a canon of medical practice that exercise of any kind was contraindicated in cases of permanent anatomical defect of the heart. It is true that "old beliefs die hard," and even now the prevailing view among laymen is that physical exertion is dangerous, if not fatal, in heart disease. Stokes was one of the first to combat this view, and between 1862 and 1872 Sutorburg of Stockholm and Zander described the successful results obtained by them in the treatment of heart disease by gymnastics. In 1884 Oertel initiated the mode of treatment, which bears his name, consisting, among other means, of fairly vigorous exercise. Schott of Nauheim then made public his methods of treating heart disease by "resistance gymnastics" and the carbonated saline baths. Dr. N. S. Davis of Chicago, writing on the subject in the *Journal of the American Medical Association*, November 14, 1903, tabulated the following four forms of exercise, gathered from the history of the exercise treatment of heart disease: (1) Massage, (2) Swedish gymnastics, (3) mountain climbing, and (4) resistance gymnastics.

Dr. Davis has a high opinion of exercise for heart affections, but states that the exercise taken must be slight, although numerous large muscles must be used. Respiration must be deepened, but not hurried. Exercise must be graduated, beginning with the lightest.

Those forms of heart disease which are accompanied by muscular weakness, with or without dilatation, can be treated with hopefulness by exercise. Dilatation due to high arterial pressure or physical exertion, and in which there is little, if any, degeneration, yields most easily to the treatment. Recovery can be effected in the early stage of muscular degeneration, but when there is much degeneration, or a cause for its increase, only temporary improvement must be anticipated. Gymnastics exert a favorable influence upon the mitral form of chronic valvular disease, but there are many cases of this description which are hopeless. Aortic valvular affections are less seldom benefited by exercise.

Dr. Davis concludes that although, when the heart degenerates or grows weak because of artheromatous arteries, a perfect recovery is rarely effected, a temporary improvement often is. Even angina pectoris is not always a contraindication to the use of graduated exercises.

The Circulation During Pregnancy.

As a result of systematic investigation into the circulatory conditions present in pregnant women with healthy hearts, undertaken for the purpose of ascertaining the changes that take place naturally, and thus explaining the manner in which such changes have a deleterious influence on pregnant women suffering from valvular disease, Dr. J. Mackenzie (*British Medical Journal*, October 8, 1904) found a series of changes that, though in one sense abnormal, may in another sense be considered as incidental to pregnancy. These include limitation of the field of cardiac response, changes in the rate and rhythm of the heart, dilatation of the right side of the heart, a tendency to œdema of the lungs and to overfilling of the veins of the legs, and the occurrence of marked pulsation in the veins of the neck.

With respect to the relations between valvular disease of the heart and pregnancy, the opinion is expressed that when distinct evidence is present of failure of compensation, or when the patient is subject to frequent attacks of failure of compensation, pregnancy should be forbidden. Similar advice should be given also if with fair compensation there should be paralysis of the auricle, as evidenced by the presence of a diastolic murmur and the absence of a presystolic murmur, or of continued irregularity of the pulse, or of a jugular pulse of ventricular type. If, however, in the presence of fair compensation, with mitral murmur systolic or presystolic in time, and the apex-beat within the nipple-line, the patient may undertake the burden of pregnancy.

Chloroformed Vaccine Pulp.

Emulsions of vaccine pulp exposed for a time to chloroform vapors after the method devised by Dr. Alan B. Green of London have been found by Dr. J. F. Biehn, Director of the Department Laboratory of the Chicago Health Department, uniformly free from all foreign organisms except those causing vaccina. This vaccine was used by a physician five days after it was removed from the calf. One day was required to prepare it, one day to ship it to Chicago, two days to test it bacteriologically, and one day to send it to the clinician who made the clinical test. Ten days after its receipt the clinician reported that the chloroformed vaccine had given 100 per cent. of successful primary vaccinations. The most important advantage of the chloroform process is the rapidity with which vaccine lymph may be purified. Purifying by the action of glycerin requires from forty to sixty days; by chloroform, four hours.

Dr. Green, who devised this method of purifying vaccine pulp as it is collected from the calf, says, in a recent report, that since April, 1903, the date of his preliminary note on this subject, a large number

of vaccines have been treated. These lymphs have been freed from their non-spore-bearing extraneous bacteria within a period ranging between one and eight hours after their collection from the calf, and have, subject to the usual tests, been issued for general vaccination purposes about two weeks after collection. Their use, he claims, has resulted in high "case" and "insertion" success.

News of the Week.

The Fourth Annual Conference of Sanitary Officers under the direction of the State Department of Health will be held in the Assembly Chamber of the Capitol at Albany, December 15 and 16, 1904. For the purpose of securing a uniform system of sanitation, and increasing the efficiency of local boards of health, the department is anxious to secure the attendance at the conference, of as many health officers and registrars as possible. All others interested in public health matters are invited to attend the conference.

National Mosquito Extermination Society.—The second annual convention of this society will be held in New York on Thursday and Friday, December 15 and 16. The first session will be held at the Aquarium, Manhattan, at 2.30 P. M., on Thursday. "The Criminal Indictment of the Mosquito" is the title of a paper to be submitted by Frank Moss, Esq. The second session will be held at 8 P. M. of the same day at the Art Rooms of the Brooklyn Institute of Arts and Sciences, 174 Montague street. A paper will be presented on "The Sanitation of the Panama Canal Zone" by Col. Wm. C. Gorgas, and an address will be delivered by Dr. E. Porter Felt on "Diversities Among New York Mosquitos." The third session will be held in the hall of the Brooklyn Institute, 502 Fulton street, at 2.30 P. M. on Friday. Surgeon-General Walter Wyman and Dr. M. J. Rosenau of the Public Health and Marine Hospital Service will present a communication on "Methods of Examination and Dissection of Mosquitos for Parasites," and Dr. Thomas Darlington, Health Commissioner of New York City, will deliver an address on "What New York City is Doing and Might Do Towards Mosquito Extermination." The fourth session will be held at 8 P. M., in the hall of the American Institute, Berkeley Lyceum, 19-21 West Forty-fourth street, Manhattan. There will be an address by Dr. Quitman Kohnke, President Board of Health, New Orleans, La., on "The Mosquito Question," and a paper by Cornelius C. Vermeule, C. E., Consulting Engineer of the New Jersey State Geological Survey, etc., on "The Relation of Mosquito Extermination to Engineering and Public Improvements."

The American White Cross First Aid Society, chartered by the State of Illinois, took definite form as a national organization December 2 at a meeting of the incorporators, held in the office of Dr. Charles Adams. Dr. Nicholas Senn acted as chairman. The organization being national in character, it was decided to ask President Roosevelt to name its President. Other officers who were selected and have accepted follow: *Vice-Presidents,* Mrs. Potter Palmer, Mrs. R. P. Crane, and Dr. J. B. D. Irwin; *Surgeon-in-Chief,* Dr. Nicholas Senn; *Chairman of the Board,* Dr. John B. Murphy; *Superintendent,* Edward Howe; *Treasurer,* F. T. Haskell; *Secretary,* Mrs. M. A. Hines.

For the Prevention of Epidemic Disease.—Dr. John H. Simon, Health Commissioner of St. Louis, has prepared an illustrated treatise on the "Suppression of Epidemic Diseases" which will appear in the next bulletin of the League of American Municipalities, an organization composed of the Mayors, Comptrollers, and health officers of all the large cities of the United States. Dr. Simon has been very successful in stamping out epidemic diseases, and St. Louis has been one of the healthiest cities in the world during the last twelve months. In the paper, statistics will be given which will prove of special importance to seaboard cities where foreign cargoes are unloaded, as the method of preventing diseases which may be communicated by rats is thoroughly discussed. He advocates a method, adapted from the German exhibits at the World's Fair, of pumping gases into the holds of all incoming ships for the purpose of exterminating rats and germs. The subject of vaccination is treated of at length and statistics given which show that smallpox has decreased about 90 per cent. in Germany since the introduction of vaccination.

Jubilee of Dr. John B. Chapin.—A dinner was given on December 1 to Dr. John B. Chapin Medical Superintendent of the Insane Department of the Pennsylvania Hospital, in celebration of the completion of half a century in hospitals for the insane. Dr. Chapin, after spending four years in the New York Hospital, from 1850 to 1854, meanwhile preparing for his degree in medicine, became a resident physician in the Utica Hospital. Subsequently he aided in the founding of Brigham Hall, where he remained for a number of years, later becoming medical superintendent of Willard Hospital. He assumed charge of the insane department of the Pennsylvania Hospital in 1884 on the death of the late Dr. Thomas S. Kirkbride, and he has since continued in that position. The dinner was participated in by nearly a hundred guests, a number from distant cities. Dr. Edward N. Brush acted as toastmaster and responses were made by Dr. Chapin, Dr. James C. Wilson, Rev. Dr. Stephen W. Dana, Mr. James M. Beck, Mr. James T. Shinn, Dr. Henry M. Hurd, who presented an oil portrait of Dr. Chapin to his family, and Rev. Wm. M. Gilbert, who accepted the portrait on behalf of the family.

Sanitary Improvements in St. Louis.—The City Council of St. Louis has passed a measure authorizing an issue of bonds to the amount of $9,000,000 for the erection of new public buildings, including a new insane asylum, for improving the sewer system, and for a park fund and other improvements. Of this amount $1,000,000 is to be expended in building the insane asylum and reconstruction of present buildings, and $2,000,000 for improving the sewer system.

Rockefeller Laboratory.—The cornerstone of the bacteriological laboratory for the Rockefeller Institute was laid on December 3, by Dr. Simon Flexner, aided by Profs. J. M. Prudden, L. E. Holt and C. A. Herter, of the College of Physicians and Surgeons. The original endowment of the Institute consisted of $200,000, but has since been increased to $1,200,000, by further gifts from the founder, John D. Rockefeller, Sr. While waiting for the completion of the new building, which is being erected on the site purchased by the trustees a year ago, in Sixty-fifth street near Avenue A, the Rockefeller Institute has temporary quarters at Fiftieth street and Lexington avenue. The laboratory will have a frontage of 100 feet and will be five stories high. It is to be of light brick with limestone trimmings and will cost $325,000.

Dentists Robbed.—The offices of thirteen dentists in one building in this city, were plundered on Thursday of last week by a thief who obtained gold plates, fillings, etc., to the amount of $1,500. Instruments

and other articles of value were left untouched and only the gold, which can readily be disposed of, was taken.

The Status of Hospital Ships.—An international conference concerning the status of hospital ships in war time will meet at The Hague, on December 13. A majority of the powers will be represented by their respective Ministers. Russia will send M. de Martens, who will be accompanied by a naval officer.

Dr. Frederick Holme Wiggin has been appointed a delegate to represent the New York State Medical Association at the coming meeting of the Pan-American Medical Congress to be held in Panama.

Seizure of Spurious Drugs in Chicago.—Several United States detectives, aided by the local police, made a number of raids last week upon places in Chicago where counterfeit and adulterated drugs were manufactured, and several wagon loads of the stuff were seized.

Tuberculosis in Hogs.—Apparently danger of the transmission of tuberculosis through food, is not confined to the use of beef and dairy products. Western pork breeders are uneasy over the increasing prevalence of swine tuberculosis, which is becoming a serious question for the farmers and packing houses. A hog expert has expressed the opinion that the animals receive the infection by being fed with skimmed milk from tuberculous cows, as during the months when there is most dairy food for hogs the disease is seen more frequently.

Lying-In Hospital Report.—The annual report of the society of the Lying-In Hospital directs attention to the institution's urgent need of funds. The society's entire income in the last twelve months has been $32,178.57, while the actual expenses were $119,535.74. According to the report the number of the society's cases has increased, and it now shows a larger service than ever before, the applicants being 6,085, an excess of 775 over the previous year. Of these the society admitted into its hospital building 1,735, exceeding the figures of last year by 603, and giving an average of 145 every month, the average for the period ending September 30, 1903, being 94. The number of days' treatment given was 31,532, some 8,000 more than the year before, while the medical visits to the outdoor patients exceeded 61,000. Two ward floors, containing 124 beds, could not be opened on account of the lack of money to run them.

Garbage Disposal.—The City of St. Louis has adopted a new method for disposing of garbage. The garbage is collected by wagons as formerly, but instead of being carried to a reduction works it is hauled to the river and dumped on barges; these barges are towed down the river to an island about twelve miles below the city and there the garbage is spread over the land. This is in the nature of an experiment, but up to the present time it has proved a very satisfactory means of disposing of the garbage collected each day. The island may be rented to hog raisers, who will feed the hogs on the garbage brought to the island.

To Prohibit the Wearing of Corsets.—A society of women in Berlin has recently presented a petition to the Prussian Minister of Education, praying for the prohibition of corsets in young ladies' schools on the ground that this garment is prejudicial to the health of the growing girl.

Smallpox in Pennsylvania.—The public schools, churches, and Sunday schools in Dover and Conewago townships have been closed by order of the State Board of Health on account of the prevalence of smallpox. The School Boards of these townships have been organized into township Boards of Health and they have quarantined the homes in which there are persons suffering from smallpox. The schoolhouses are to be fumigated and the books used by the children burned.

Difficulty Over Vaccination.—The Board of Health of the city of Altoona, Pa., has entered criminal suit against a number of directors and principals of the public schools for permitting children to attend school who has not been successfully vaccinated. More than 100 children were discovered as pupils who had not been vaccinated, and they were promptly sent to their homes. Besides, a number of fraudulent vaccination certificates were discovered. The principals permitted a number of the dismissed children to return to school, and hence the suit.

Suit for Salary.—Dr. Frank Boogher of St. Louis, has filed suit in the Circuit Court against the City of St. Louis, for $1,350 salary alleged to be due him as Deputy Coroner. Dr. Boogher served as Deputy Coroner for a considerable period but was dismissed on charges which were not sustained at his trial.

Dr. Martha Tracy, a graduate of the Women's Medical College of Pennsylvania, obtained the highest mark among the candidates for licenses at the recent State examination. She had a mark of 91.07, while the best average of the graduates of any men's college was but 80.39.

State Pharmacy Law.—A committee of sixteen representatives of the pharmaceutical associations of this State met in Albany on November 28, to discuss proposed changes in the pharmacy laws. The committee on legislation of the State association was instructed to advocate before the next Legislature a revision of the State Pharmacy Law, so as to make it uniform with the penal code in relation to the registry and sale of poisons. The association will also petition Congress to amend the Federal Liquor Law, so that druggists selling alcohol only may pay a tax of $5 a year instead of $25, which they are now forced to pay, and which covers the sale of pure alcohol and spirituous liquors.

Sidewalk Dentistry.—A Brooklyn Alderman has presented a resolution to the Board to restrain the practice of dentistry in the streets of the Borough of Brooklyn. The resolution was directed against certain notoriety seeking dentists who have been setting up stands on street corners and extracting teeth free of charge. The matter was referred to the Committee on Laws and Legislation.

Obituary Notes.—Dr. J. P. Willett, of Webb City, Mo., was shot and killed at his home on November 15, by a young man who had been placed on guard to protect the house from burglars. During the night the doctor got up and walked close to the window when the man fired. The doctor was killed instantly. He was graduated from the Ohio Medical College in 1885.

Dr. Joseph Rutter Draper of Westford, Mass., died October 30, of typhoid fever complicated with pneumonia and meningitis. He was born in Dedham, Mass., May 22, 1862, was educated at the Boston Latin School, was graduated in arts from Williams College in 1885 and in medicine from the Harvard Medical School in 1888.

Dr. Jacob P. Bixler died from paralysis at Carlisle, Pa., on December 3, at the age of 65 years. He was graduated from Jefferson Medical College in the class of 1866. He had been for many years president of the local school board.

Dr. Leonard F. Pitkin, of this city, surgeon to the Interborough Company, died on December 1. He was taken ill last spring and had to retire tem-

porarily from practice. Dr. Pitkin was born in Hartford in 1858. He came to New York twenty-five years ago and built up a large practice. He attended all subway cases since that work began. He was a member of the New York Athletic Club and the local medical societies. He was the physician for many of the prominent actors and managers.

Dr. William F. Cushman, a retired physician of this city, who had lived lately at Ridgefield, Conn., died of apoplexy there on December 2. He was born in the Chelsea village district of Manhattan sixty-six years ago, and was graduated from the College of Physicians and Surgeons. He was for many years treasurer of the New York Academy of Medicine.

Dr. William E. Carroll of Newark, N. J., died of pneumonia on December 3, at the age of fifty-seven years. He was gynecologist to St. Michael's Hospital, Newark, and to All Soul's Hospital, Morristown.

Occupation Neuroses.—L. Harrison Mettler defines the term occupation neurosis as a nervous trouble brought on by a monotonous, excessive, or faulty manner of using the muscles concerned in certain special, complicated and co-ordinated movements and shown by the inability to perform these movements without the loss of other movements involving the same muscles. An occupation neurosis is apparently nothing but a disturbed function. The writer has never seen a case in which he could not trace a neuropathic inheritance. Neurasthenia, hemicrania, epilepsy, neuralgia, convulsive tic, phobias, and tabes have been seen and recorded in association with it. Men are more often affected than women. They suffer especially from the motor form of the trouble. The exciting cause of the disease is the overuse of a particular set of muscles—that is, an excessive, monotonous employment of a particular form of complicated, coordinated movement. It is the overuse of a movement, not merely of the muscles, that is at the foundation of the trouble. Writing seems to provoke it more than anything else. The style of writing, the anxiety to get through, the instrument employed, all have a share in the etiology. What is true of writing is also applicable to all other occupation movements from which the disease has developed. Emotion is an etiological factor. In the few cases that have come to autopsy, no pathological changes have been found. It is preeminently a motor trouble. The onset of this affection is always gradual. There are three types of this disease: The spasmodic, the paralytic, and the tremulous. In writer's cramp an attempt to use the muscles immediately develops a spasm. The paralytic form is not so common as the spastic. The will seems to lose all power over the muscles concerned. In some cases an irregular tremulousness has been observed. In cases in which there is much pain, the type is called neuralgic. Its etiology and symptomatology both show that it is a disorder of the higher conscious or subconscious coordinating mechanism. Neuritis and this affection are often confused. Poliomyelitis has also given rise to some confusion. Neuritis suggests clearly an organic, well-defined, local lesion, while an occupation neurosis resembles somewhat neurasthenia or hysteria. Poliomyelitis manifests itself in the legs, the neurosis in the arms. In the former there is a febrile condition. In whatever occupation the trouble may be acquired, it is practically always of the same nature. Absolute cures have been noted, but they are rare. This affection never destroys life. Prophylaxis is most important. All stiff, cramped, and uncomfortable attitudes should be avoided. When the trouble is fully developed, absolute and prolonged rest is the only safe course to follow. There is no drug treatment for this neurosis. Massage and gymnastics give the best results. Electrical treatment is of no use. Suggestions and psychical treatment have some influence.—*The Clinical Review.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL COLLEGE OF SURGEONS—SUPERNUMERARY RIBS—ULCERATIVE ENDOCARDITIS — LIVERPOOL UNIVERSITY MEDICAL SCHOOL—AIR VS. SUNSHINE—POISON-EATER—LONDON HOSPITAL—A DOCTOR'S TRAVELS ON CYCLE—NOTES—DEATHS.

London, November 18, 1904.

Yesterday afternoon the annual meeting of the Royal College of Surgeons was held, with the usual result. The President, Mr. John Tweedy, occupied the chair, and "placed before" the meeting the Report of the Council for the year ending August 1. He stated that the council was the governing body, and that no criticism of the action or policy of that council, as exhibited in the Report, could be permitted. Was there ever such a farce as calling a meeting to receive a report on such conditions? And yet this farce has been annually enacted for about twenty years. The Fellows and Members are called together to be told the two dozen Fellows who form the council are there for no purpose whatever. They need not endorse, approve, or accept the Report. They are summoned merely to hear the President tell them they have no voice in their college and cannot offer any criticism on the action or policy exhibited in the Report.

At the Medico-Chi. Mr. Thorburn read a paper on supernumerary cervical ribs and their effects on the brachial plexus. These ribs he did not consider very rare, and were fairly well recognized, but he had found no full description of the clinical symptoms they produce. Gruber said the condition was frequent. When sufficient size is attained (often there is a mere rudiment) to project into the posterior triangle of the neck, there may be deformity or pressure on the brachial plexus or subclavian artery may set up symptoms. Four cases were detailed; in two only a little tingling or numbness was felt; in the others paralysis of the hand, pain and sensory loss in the territory of the first dorsal root. The muscles on the ulnar side tended toward spasm; on the radial side toward paralysis. The diagnosis was not difficult by palpation, and could be confirmed by *x*-rays. The rib could be removed without any particular danger or difficulty.

Mr. Keetley had a patient with this condition, who first noticed pain in the right arm fifteen years ago. There was marked pulsation above the clavicle. The pulse differed on the two sides. In some cases aneurysm, thrombosis, and gangrene had resulted, but usually no symptoms of consequence were produced.

Dr. F. Buzzard pointed out the difference between these cases and those of uniradicular brachial plexus paralysis which he and Dr. Bramwell had described.

Mr. Carless mentioned a case in which the condition led at first to a diagnosis of subclavian aneurysm. Though most frequent in females, as pointed out, the condition is also met with in males.

Dr. J. P. Stewart said the symptoms were often unilateral, though the supernumerary rib might be on one side only. If exertion produced symptoms, they should be more frequent among males—the reverse of the fact. He thought the existence of the condition did not account for the symptoms without additional factors.

Dr. Newton Pitt then gave an account of two remarkable cases of ulcerative endocarditis, both ending in recovery. One was in a boy of 13, the other in a boy of 11. In the former the mitral valve was affected a week after chorea attacked him, and he developed right hemiplegia, complete aphasia, albuminous urine with incontinence; he became very drowsy and very emaciated, and for two months seemed certain to die. Injections of antistreptococcus serum were given on alternate days. He improved at once and progressed to complete recovery in about three months. Went home in October and is now earning his living. The second case developed after apical pneumonia. The temperature oscillated for a month up to 100° F. Injections were used and the lad recovered, but a few months later the bruit was audible. In fact, in both cases the valves have been permanently damaged, otherwise they seem in good health.

Liverpool still keeps in the fore front. On Saturday the new medical buildings and the physics laboratory of the University were opened. Lord Kelvin, Lord Derby, Mr. Haldane, M.P., took part in the proceedings. Since 1898 some £100,000 has been raised for these purposes and further additions to the University are in progress. As Lord Derby in his speech remarked, probably no city in the Kingdom—certainly no university city—can claim such alliance as Liverpool with the wants of medical and scientific knowledge beyond seas.

Mr. Haldane, who led the battle for the creation of the university, was made an honorary doctor of Laws.

Dr. Heron, in a recent address insisting on the value of fresh air, remarked that even in Harley Street and Wimpole

Street, with doctors' plates on most of the doors, very few windows were open at night. On this one "old Barts' man in his ninety-second year" writes that he is glad they are wise enough to shut out the cold night air, and perhaps Dr. Heron thinks more of fresh air than sunlight. Many windows, he adds, are open all night, and the blinds down all day to keep out sunshine for the sake of paltry bits of furniture. "Heaven's light is a better health-giver than the air which we medicals prate so much about."

Two new Hebrew wards have been added to the London Hospital. They are the gift of the late Mr. E. L. Raphael, and his son has provided for lining the walls with opalite. The formal opening was made on Monday by Mr. Leopold de Rothschild as representing his brother, Lord Rothschild, who was prevented by an attack of sciatica. The London Hospital has had separate wards for Jewish patients with separate kitchen to meet their requirements for more than a generation. The addition raises the number of beds for Jews from 27 to 54.

The Cancer Hospital's new home for nurses, erected at a cost of £5,000, was opened on Monday. In addition, an anonymous lady donor has presented an electric lift to the hospital at a cost of £250.

A certain "Captain Vetrio" has come here from Chicago, and professes to be able to swallow poisonous alkalies and salts with impunity. He gave a demonstration the other day to some forty gentlemen, several of them doctors. He said he could not digest acids. He had managed atropine in the presence of doctors. He declared he took no antidotes, made no preparations in advance, and did not use a stomach pump afterwards, adding that at Detroit Medical College he was under observation thirty hours before and seven after his demonstration. Then he proceeded with his meal—first course, copperas mixed in water; second, a dose of strychnine; a doctor tested this, and said it was weak, whereupon the "Captain" showed him a bottle said to contain a grain, and that being approved drank it. The next course was a blue powder dissolved in water, and the last a bite off a stick of phosphorus taken fresh from its bottle of water. The demonstration lasted one-half an hour or more, and the "Captain" exhibited no symptoms of inconvenience.

"Through Town and Jungle: Fourteen Thousand Miles Awheel Among the Temples and Peoples of the Indian Plain" is a remarkable book published this week, a record by Dr. and Mrs. Workman, who cycled with a camera from temple to temple through the depths of many a jungle far from the beaten tracks of tourists and the present centres of population. The doctor and his wife are inveterate travelers, but in this they have eclipsed all their records.

The *Dental Surgeon* is the title of a new weekly journal which has just been issued. Previously our dental brethren were content with monthlies. Mr. Robert Manning is the editor, with a strong staff.

There is an outbreak of typhoid at the Cork Lunatic Asylum. Sixty-eight patients, of whom two have died, have been attacked and fifteen of the attendants. An analysis of the water and milk gave negative results, but the water from a well on the farm of one contractor is stated to be very bad. The milk from that farm has been discontinued.

The funeral of Dr. A. Vintras, whose death I mentioned in my last letter, took place on Tuesday at Brompton, where his wife was buried nine years ago. A number of distinguished persons were present, among them the French Ambassador and his staff, representatives of the Italian Embassy, the French Hospital, of which he was one of the founders, and other institutions with which he was connected. He was an officer of the Legion of Honor for many years, physician to the French Embassy here, and the trusted adviser of the most distinguished French residents. He had lived among us over half a century, and took part of his education at St. Mary's Hospital. He qualified M.R.C.S. Eng. 1858, and M.D. St. And. 1859.

Dr. C. D. F. Phillips died on Sunday after a short illness, aged 74. He was for some years lecturer on Materia Medica and Therapeutics at the Westminster Hospital, and subsequently examiner in those subjects in the universities of Aberdeen (his alma mater), Glasgow, and Edinburgh. His *magnum opus* in two volumes, Materia Medica and Therapeutics, will be well known to you. A third edition of the first volume appeared only a few months ago. The Vegetable Kingdom volume was the first issued, 1874, and the volume on the Inorganic Kingdom followed in 1882.

Dr. John Harker, J.P. for the County of Lancaster, died suddenly on Saturday at the age of 70. He was on the staff of the Royal Lancaster Infirmary for some 46 years, and had served as a president of the hospital. He had also been M.O.H. for the borough for many years.

Dr. G. E. Power, who died on the 29th ult., was one of the sons of the late Dr. Power, a private tutor who attained some repute many years ago. He was born in 1849 and qualified in 1873. He took much interest in natural history.

FACTITIOUS SCOTCH WHISKEY.

To the Editor of the Medical Record:

Sir: In the discussion of Dr. Wiley's recent paper at the Academy of Medicine, recorded in the current issue of the Medical Record, your reporter credits me with saying that methyl alcohol was used to adulterate some Scotch whiskey. This I did not say. In another journal of the same date, the reporter credits me with saying that the flavor of Scotch whiskey was due to amyl alcohol. This I did not say. What I did say, was that I believed that a considerable portion of the "Scotch" whiskey imported into this country was manufactured in England from cheap German potato spirit, which contains a larger proportion of amyl alcohol (fusel oil) than grain spirit, hence was objectionable. The smoky flavor of factitious "Scotch" whiskey is usually obtained by adding a small quantity of creosote.

H. G. Piffard, M.D.

New York, December 3, 1904.

THE OPTOMETRY BILL.

To the Editor of the Medical Record:

Sir: The letter in this issue of the Medical Record under the head of "The Optomery Bill" I have read with great interest. If we but look below the surface it will require but a slight effort to see that the whole scheme is pernicious from its very inception, notwithstanding the coat of plausibility with which its advocates attempt to gloss over it. These parties ask for simply the right to refract all cases that do not require the use of a cyclopegic, and such that do require drugs, in their estimation, they promise to send to the oculist. As many of these men are decrying the use of a cyclopegic and picture the dangers attendant on its use in such a way that even now a large part of the public are beginning to regard this procedure as something most hazardous, we can readily understand the worth of such a promise. Again, as they have been carrying on their work for so long without the protection of a law, what guarantee have we that with a law such as this enacted they will not go a step further and use these same cyclopegics themselves, after undergoing a change of heart regarding their safety(!).

This would be simply in conformity with the teachings of the leading oculists at the present time, who claim that to obtain satisfactory results in refraction a cyclopegic is nearly always essential. Refraction is too closely allied to the science of opthalmology to be separated from it or practised by any other than the oculist himself. If this subject should be given more publicity and the public, and the general practitioner as well, be educated to an appreciation of the fact that the prescribing of glasses is fully as scientific a procedure as the treatment of other diseases of the eye, it might tend to discourage such a scheme as now presented to us in this Optometry Bill. Could we but educate the above to an appreciation of the fact that refraction is a science, and not a trade, and that properly to prescribe glasses to correct an error of refraction, requies a considerable amount of brain work as a preliminary to the mere holding the lens before the patient's eye. The fact should be taught that badly fitting or wrongly prescribed glasses are in their way fully as injurious to the eyes as a poisonous drug wrongfully given is to any part of the body. It may at the present time seem a sweeping statement, but when this subject is better understood it will appear perfectly feasible, not only that glasses should be prescribed only by an oculist, but also that they should not be sold without the prescription of a physician, in the same manner as poisonons drugs are obtained. This might prove disastrous to the traffic in "bargain spectacles" in our department stores, but nevertheless it would be an effective measure for the preservation of many eyes.

Perry Dickie, M.D.

Brooklyn, N. Y.

Treatment of Aneurysms of Large Vessels by Gelatin Injections.—According to Lancereaux, the method of using gelatin injections in the treatment of aneurysms of the aorta, is never dangerous if care is taken to use solutions of gelatin which are of good quality and which are well sterilized. These injections favor the coagulation of blood in the aneurysmal sac, and in this way they aid in the cure of aneurysms of the large vessels, which are so alarming. Tetanic accidents or others, which have been noted as following this treatment, have been produced either by the employment of gelatin solutions of poor quality, or by the use of solutions insufficiently sterilized.—*Revue Française de Médecine et de Chirurgie*, October 17, 1904.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 1, 1904.

Mechanical Restraint and Seclusion of Insane Persons.—Charles W. Page in his interesting paper, says that it is only about 100 years since the propriety of controlling insane persons by the aid of manacles, shackles, chains, ropes, straps, etc., was especially called into question. He lauds the work of John Conolly, an Englishman, who in 1839, without previous experience in such work, assumed control of the lunatic asylum at Hanwell, containing about 800 patients. The various instruments of restraint which he found in use in that asylum, he collected in one room which was called the museum. From this time no patient in the institution was subjected to mechanical restraint. Under the influence of this example, the same spirit invaded other English asylums, and the fetters fell from the limbs of their inmates. In fact, Conolly revolutionized the management of the insane. He labored unceasingly to the end that the lunatic instead of being an object of dread, might be treated with pity and tenderness, and that insanity might be considered a disease of the body instead of a disease of the mind. He gave the most painstaking personal attention to detail in his wards. With the use of restraint, the spirit of coercion on the part of the nurses is fostered. Nurses will depend upon this treatment instead of relying upon their own tact. The general good of the inmates depends largely upon the nursing morale of the hospital. When mechanical restraint is abolished, nurses are considered incompetent if they cannot manage their patients without violence. Thus a kindly, humane spirit is advanced. The writer believes that mechanical restraint should be used only when there is no question but that its use or neglect would determine the life or death of the patient. Earnestness of purpose is the solution of the non-restraint problem. The objections to mechanical restraint apply in large measure also to seclusion of the insane.

New York Medical Journal, December 3, 1904.

Epilepsy Cured Without Drugs.—A. L. Ranney declares that eye-strain is responsible for many cases of epilepsy and refers to a previous publication of the notes of twenty-six cases. Four patients abandoned treatment from the beginning, but of the twenty-two remaining patients, ten, or forty-five per cent., may be considered to-day (nearly eight years since the aforesaid publication) as well (seven being completely cured and three being practically cured); amelioration of the attacks has been afforded by eye treatment in nine cases, or nearly forty-one per cent.; and no improvement has been observed in three cases, or about fourteen per cent. He gives the histories of six additional cases. His general conclusions are that a very large proportion of epileptics suffer from some reflex irritation, most commonly from eye trouble. The refraction of all patients should be determined under mydriasis. Glasses should be worn for a while before any attempt is made to adjust the eye muscles. The most serious refractive errors and muscular defects in the orbits do not necessarily create eye symptoms; even when reflex symptoms produced by existing eye defects are extremely severe. The percentage of cure of chronic epilepsy under skillful eye treatment will naturally be modified greatly by the abnormal eye conditions found, the physical condition of the patient, the amount of drugs that have been given to the patient, and the complications that may coexist with eye-strain. No one is ever justified in promising a cure of epilepsy by any plan of treatment, but examination of the eyes should be a preliminary to any other mode of treatment.

Should Pulmonary Tuberculosis Be Treated at Home?—R. W. Craig believes that the recent exploitation of "home" treatment of this disease is a step backward, especially in case of those who have means to secure proper climatic treatment. The conditions of the latter are sunshine, relative humidity, temperature, and altitude. The influence of the latter does not count for much in comparison with the others. No particular climate has a specific action on the disease, but in certain climates the best results can be obtained from an out-door life and the question is as to where the patient can spend the most time in the sunshine, equable temperature, least humidity and in air free from dust and bacteria. The author then goes on to extol the Arizona and Southern California regions, and makes a strong plea for tent life. Tent architecture is a very large factor in the success of tent life. The tent for one person should have a framework of lumber and should be about 15 by 18 feet in dimensions. An absolutely tight board floor is very essential, and a tight wall should be built around the side, about three feet from the floor. Over this the tent should be stretched, and a heavy fly should cover the entire tent. This gives enough space for two comfortable rooms. The upper part of the walls should be made detachable, so that they can be raised and lowered and converted into an awning, which changes the tent house into the best sort of pavilion.

Pregnancy and Successful Parturition in a Patient with Advanced Carcinoma of the Cervix.—C. A. L. Reed reports the history of a woman, aged 38 years, upon whom he performed the operation of removal of a portion of the anterior lip of the cervix. She soon became pregnant. Pregnancy went on in a normal manner, and it was decided to do at the proper time a cesarean or Porro operation. Labor came on, and while the posterior portion of the cervix dilated naturally, the anterior, in which the cancerous process had progressed, did not. Incision of the latter was proposed, but abandoned owing to the danger of wounding the bladder, so digital dilation of the os was practiced, and delivery accomplished by forceps. A severe hemorrhage followed, although the uterus was now well contracted. The flow was found to come from the offending growth, which had been torn in numerous directions, much after the order of old leather. Packing uterus and vagina firmly with iodoform gauze checked the bleeding. The patient got up in about the usual time. She lived about eighteen months, afterwards dying of an extension of the disease.

Medical News, December 3, 1904.

Diagnosis of Extrauterine Pregnancy.—Isaac Ivan Lemann believes that extrauterine pregnancy is far more frequent than is most generally supposed. By maintaining an attitude of alertness and by carefully investigating all conditions of menstrual irregularities and colicky pains, the writer feels assured that we shall find ourselves warranted in establishing an accurate diagnosis and saving the lives of some patients who would otherwise perish. When the diagnosis is obscure in the presence of a boggy or fluctuating mass to either side of the uterus, we are justified in doing an exploratory operation, either through the abdomen or the vaginal fornix.

Laundry Hygiene.—Ira S. Wile in his investigations has not been able to obtain statistics which afford any basis for medical reasoning. Until some other facts and figures are available it seems necessary to coincide with the opinions expressed by the laundrymen themselves. The writer formulated these five questions, which he sent to numerous laundries: (1) What precautions, if any, do you use to prevent infection of employees in handling soiled materials from time of collection to delivery? (2) Do you have much illness among employees? If so, of what character? (3) Do you know of any specific diseases which have been spread? If so, what ones? (4) What means do you have of protection of patrons from diseases of employees? (5) Is tuberculosis common among employees? Among diseases to be considered are typhoid, scarlet fever, smallpox, syphilis, diphtheria, gonorrhea, infected fingers, inflamed eyes, etc. The answers to these questions were practically uniform. (1) No especial precautions are taken to prevent infection of employees. Particularly filthy materials are not accepted. Linen is not received from places where contagious diseases are known to exist. The marking room is kept as clean as possible, and thoroughly scrubbed at least once a week. (2) Illness does not seem to be any more frequent than in any other business establishment employing large numbers of workers. The ailments are merely of ordinary types, and in no way dependent upon the vocation. (3) No specific cases of contagion have been found due to or even attributed to handling infected garments. These reports emphasize the comparative freedom from contagion of those handling the soiled clothes of a city. (4) No systematic, intentional protection to patrons is deemed necessary. Exposure to heat and chemicals, along with mechanical agitation, destroys the hardiest of bacteria. During the transition from soiled to clean clothes contagion is abolished. (5) Tuberculosis is no more common among laundry employees than among the workers in any modern, regularly inspected, hygienic, light, airy factory. The moist atmosphere, the frequent scrubbings, and lessened dust tend to keep the bacillus tuberculosis in marked subjection. One scientist wrote that "starching is the best employment for consumptives." These answers are all from public laundries. As far as can be judged, therefore, laundering appears to be an efficient hygienic method of promoting cleanliness, without marked danger to patron, and with comparative safety for the employee.

American Medicine, December 5, 1904.

Presence of Tubercle Bacilli in the Urine of Patients Suffering with Pulmonary Tuberculosis.—Rosenberger carefully studied 25 cases for the purpose of determining whether tubercle bacilli were present in the urine. The residual urine was obtained by means of a sterile catheter. Although the sputum in these cases uniformly showed the presence of tubercle bacilli, tuberculosis of the genito-urinary tract was neither diagnosed nor suspected. In five cases a few isolated tubercle bacilli were observed. But there were no clumps or groups, so common in tuberculous cystitis and nephritis. Guinea pigs were inoculated with

the sedimented urine. Three animals died, and in one case no tubercle bacilli had been found in the urine of the individual which had been used for injection. After three months the surviving animals were killed, and not one of them exhibited any tuberculous process. The writer believes that it is safe to say that in pulmonary tuberculosis the tubercle bacillus is found in the urine in only a very small percentage of cases.

A New Reflex: The Paradoxical Flexor; Its Diagnostic Value.—Gordon calls this reflex paradoxic, because excitation of the flexors gives extension instead of flexion. This reflex is elicited by pressing upon the flexors of the legs in a certain manner, which must be strictly observed, and for a description of which the reader is referred to the original article. The writer believes that this reflex ranks in value alongside of exaggerated knee-jerks or the phenomenon of extension of the toes, in the diagnosis of organic diseases of the nervous system. He has found it of especial worth in obscure cases, in which other symptoms are vague, and also in cases in which the diagnosis between organic and functional disease is doubtful. In his study of this subject Gordon has examined 30 cases of various organic diseases, and, for the purpose of control, several hundred normal individuals, and about 50 cases of various nervous diseases in which the new reflex could not be expected. He expresses his opinion concerning the relationship of this reflex to other reflexes, particularly to those which are manifestations of involvement of the motor tract.

Operative Technique in Stone in the Ureter.—Crawford describes in detail the anatomical arrangement of the ureter as to its reservoirs, sphincters, and flexures. In their relation to the retention of calculi. He emphasizes the fact that the ureter is not a passive organ from a physiological point of view, since the urine is transported from the kidney to the bladder by peristalsis. One dilatation and contraction, extending from the calices to the bladder—that is, a single rhythm—occupies about five minutes. Both in the normal, as well as in the pathological ureter, the irregular caliber and peristaltic force are important factors in determining the passage or retention of calculi. The writer describes a unique method of invading the distal extremity of the ureter for the release of calculi. In the particular case described, the stone had passed all barriers to this point, but remained here for years, increasing to large size. The mouth of the ureter was not forcibly dilated by instrumentation, but with the tip of the index finger introduced it was pulled and pushed to and fro, the sphincter being constantly teased for nearly an hour. After this manipulation the distal sphincter was sufficiently dilated to allow the delivery of the calculus, which was 1⅜ inches in diameter. The bladder wall was not lacerated.

Journal of the American Medical Association, Dec. 3, 1904.

The Etiology and Pathology of Gout.—T. B. Futcher concludes an elaborate paper in this issue. He summarizes by stating that heredity, overindulgence in malt liquors, poor food, with bad hygienic surroundings or overeating with insufficient exercise, and lead intoxication are undoubtedly important predisposing etiologic factors in the production of gout. An analysis of 54 cases treated in the medical wards of the Johns Hopkins Hospital shows that the overuse of fermented beverages seems to be the most potent factor in this country. Gout in the United States appears, therefore, in the majority of cases to be acquired or "free-hold," rather than "copy-hold" or inherited. Studies of the metabolism in gout have as yet afforded no satisfactory explanation for the causation of the disease. There seems very little doubt but that it is due to disturbance in the metabolism of the "endogenous" and "exogenous" purins. As yet there is not sufficient experimental evidence to warrant us in abandoning the theory that the manifestations are in large part due to disturbances in uric-acid metabolism. Practically all researches agree in showing that the blood in gout contains a marked excess in uric acid, and the balance of opinion is in favor of the view that this excess is due to deficient excretion on the part of the kidneys. The alkalinity of the blood is not diminished, as Garrod supposed. The joint manifestations are essentially due to the deposition of the uric acid combinations of the blood in the form of the crystalline sodium biurate. Whether a local tissue necrosis is primary or secondary to this deposition is a question still in dispute. Nephritis, usually of a chronic interstitial type, arteriosclerosis, myocarditis, pericarditis and emphysema are the other most frequent pathologic findings.

The Uric-Acid Delusion and the Prevention of Gout.—Woods Hutchinson claims that the researches of the last half century have conclusively proven that uric acid is *not* the cause of gout. Uric acid is not toxic, is in no sense a result of imperfect combustion of proteids of the urea series, is, as appearing in gout, a result of the destructive metabolism of the nucleins of the body tissues, and is in no way derived from the blood. Some of its antecedents, the so-called purin group, are more toxic than uric acid itself, but are probably a symptom, and not a cause of the toxemia of the disease. The author would define gout as "any form of mild chronic intoxication occurring in an individual of the medium grade of resistance, and resulting in the deposit of uric acid in the tissues or urine." It is a symptom rather than a disease *per se*. As to its prevention, the author relegates diet to the background, declaring that each patient should have such food as will, while reducing intestinal putrefaction to a minimum, abundantly support strength. He finds it practical to limit the consumption of potatoes, bread, pastry, and preserves. Vegetarian diet in the disease he considers a polite form of starvation, and, where indicated, it is of value. In the long run it will be preferable to increase the body oxidation rather than diminish the amount of food consumed. Large quantities of water should be consumed, because, first, our digestive processes are processes of hydration, and water is a valuable aid to digestion instead of a hindrance, according to the ridiculous old nursery superstition of the last generation; second, it is the finest eliminant, whether alimentary, renal, or cutaneous, that we possess; third, because 99 per cent. of the body cells are still aquatic organisms and marine at that, and must be kept flooded with water in order to live. What salts are dissolved in the water is purely a matter of taste.

The Lancet, November 26, 1904.

Red-Light Treatment of Smallpox.—The first paper on this subject is by J. T. C. Nash, who reports three cases treated in one family. Case 1 was that of a boy eight years old, of the unmodified discrete variety, and admitted to hospital on the eighth day of the disease when suppuration was imminent and the temperature showed evidence of slight secondary fever. He recovered without incident. The other two cases, one of a vaccinated patient and the other of a patient who was unvaccinated up to the date of invasion and admission to hospital, showed no secondary fever of suppuration. Nash fits red glass to the windows, so as not to interfere with ventilation, but the practice of hanging red curtains so as to exclude every possible ray of ordinary daylight he regards as both unhygienic and unnecessary. In the second case the temperature of the vaccination seemed to run an unmodified course concurrently with the variola. The third case was tabulated as discrete modified smallpox.

The second paper is by T. F. Ricketts and J. B. Byles, and is mainly a reply to a criticism of their previous article on the subject (*Lancet*, July 30, 1904) by the late Prof. Finsen, who was an advocate of the red-light treatment. These authors are loath to believe that there is anything of value in the red-light therapy, so far as preventing suppuration in variola is concerned. Not any of their cases showed any modification or improvement which could be attributed to this therapeutic agent.

Calomel as a Poison.—T. L. Bunting reports the case of a boy of three and one-half years who, obtaining possession of a bottle of calomel tablets, ate 110 of one grain each. In twenty minutes emesis was produced and the stomach washed out, a solution of sodium bicarbonate being used in order to neutralize the free hydrochloric acid and so prevent conversion of the calomel into the perchlorate of mercury. After the washing five ounces of milk were poured down the tube and left in the stomach. The patient immediately fell asleep. Half an hour later he vomited again and then slept undisturbed for nine hours. There was no further vomiting. The first motion of the bowels did not take place until twelve hours after the calomel was taken; it was copious and soft, but not liquid. A second motion, which consisted entirely of an almost gelatinous green mucus, occurred four hours later. After that the bowels were moved only normally. The patient never at any time showed any ill effects or any other symptoms than those recorded. The case is reported by the author to show the inconstancy of calomel as a poison.

A Case of Accidental Vaccination Inoculation Simulating Cutaneous Anthrax.—The patient of W. Sheen was a woman of thirty years who had on her left cheek a lesion consisting of a central depressed black slough, a quarter of an inch in diameter, with a ring of small, nearly confluent vesicles round, a few of which were broken and exuding a turbid fluid. Beyond this the whole of the cheek was swollen, red, slightly œdematous, and somewhat tender. The swelling extended round the eye, which was partially closed, and also below the jaw, where enlarged and tender submaxillary glands were to be felt. The patient's general health was unaffected and the temperature was normal. The woman volunteered the statement that she thought the condition was due to vaccination and said that her baby was done three weeks previously, "took" well, and the places were now drying up. Eight days before the mother's cheek had been scratched by the baby; on the following day a pimple appeared, which two days later became swollen and painful, and then gradually got

to the present condition. An examination of the fluid for anthrax bacilli gave a negative result. Boric acid fomentations were applied, and in a week the swelling had nearly subsided and the sore was scabbing.

British Medical Journal, November 26, 1904.

A Case of Tetanus Treated by Chloral Hydrate.—Alexander Binning treated this patient, who was suffering with well-marked symptoms of tetanus. His jaws were tightly closed, his head could not be moved on his body, there was marked arching of the back, the legs were rigid and widely separated, and he was seized with painful spasms every two or three minutes. The heart was normal and the pulse full and regular. Chloral hydrate, one drachm in water, was ordered. This lessened the number and severity of the spasms and made little change in the pulse. The drug was then given in gr.xx doses every four hours, with an occasional dose at the end of two hours, when the spasms were severe. Improvement continued, till by the ninth day the spasms had ceased. Relief from pain followed every dose. At about the end of ten days a scarlatiniform rash, due to the chloral, appeared on the back and front of the trunk, so this drug was ordered for every six hours. Several spasms then took place. The dose was then given every four hours, until the twelfth day, when it was stopped. But it had to be administered every morning for the next five days, as without it the patient was not able to open his mouth for food. This trouble did not occur in the latter part of the day. The treatment by chloral caused no bad symptoms except the rash, which disappeared in four days. The patient was not able to get out of bed before the end of a month. Convalescence was aided by massage of all the muscles.

The Protective Power of Vaccination.—J. T. C. Nash admitted a young woman to the hospital with smallpox, and as there was no place where her baby of six months could be taken care of outside of the hospital, and as the infant's arm revealed three typical full-sized vaccination scars of a satisfactory nature, it was taken into the hospital with its mother. In spite of its tender age, and the concentrated poison of smallpox in which it lived at the hospital, it remained perfectly well. The writer thinks that this case offers striking testimony to the efficacy of vaccination in affording protection against smallpox during a most susceptible time of life.

Colchicum Corm in Acute Gout.—D. Duncan advises that in case of dissatisfaction with the action of colchicum wine or tincture, the powdered corm be used; this will give far better results. Larger equivalent doses can be given without the undesirable effects, while with an equal amount the improvement in the condition will be greatly hastened.

Berliner klinische Wochenschrift, November 14, 1904.

Official Meat Inspection in Regard to Tuberculosis.—Westenhoeffer, as the result of experiments and theoretical considerations, does not believe that tuberculous meat is a frequent source of human infection. There are numerous instances on record in which large numbers of people have from motives of economy preferred to use meat from condemned animals, and during long periods of observation such communities have not suffered from tuberculosis to any greater degree than the rest of the population. The author considers that the flesh of cattle having a local lesion or a generalized tuberculosis which has subsided may be placed in the markets after removal of the diseased portions. Meat from animals with acute miliary tuberculosis or signs of a fresh generalization is dangerous to health and should be destroyed or devoted only to technical uses. In case the diseased portions cannot be removed without either infecting the healthy parts or injuring their appearance, such quarters should be condemned. If emaciation or changes in the character of the meat have taken place as a result of the tuberculosis, the entire carcass should be considered unfit for use, regardless of the general or local nature of the lesion. In other words, there is danger only in the meat coming from animals with acute miliary tuberculosis, and in all other cases of the disease the ingestion of the clean meat, after careful removal of all the affected portions, is without risk. The author also criticizes extensively the present laws of the German Empire controlling the inspection of meat, which he considers unnecessarily strict in some respects and dangerously lax in others.

Atropine Poisoning.—B. Holz was called to a patient supposed to be suffering from acute mania, and found a girl of seven in a state of wild delirium. Inquiry elicited the fact that the child was being treated at a dispensary for phlyctenular conjunctivitis, and had been given syrup of iodide of iron and atropine solution. By mistake the mother dropped the syrup into the eye and gave a teaspoonful of the atropine solution by mouth, which was equivalent to one-twelfth of a grain of the alkaloid. One-sixth of a grain of morphine in two injections was sufficient to control the symptoms, and the author reports the case to illustrate the completeness with which opium and belladonna neutralize each other's toxic effects, and further to emphasize the danger of ever giving atropine solutions to patients.

Deutsche medizinische Wochenschrift, November 17, 1904.

Trypanosomiasis.—R. Koch reviews the history of the development of our knowledge of trypanosome infections, and describes the varieties of the organism thus far recognized. He does not agree with those observers who attempt to subdivide the tsetse disease, and surra into several varieties of each, but considers the two as the same disease, and is inclined to add the mal de Caderas to the same group. Attempts to immunize cattle in Africa by treatment with trypanosomes that have been reduced in virulence by passage through dogs and rats have been very encouraging in so far as the morbidity of the animals treated is concerned, but the author calls attention to a serious danger attending this plan of procedure. The immunized animals are not rendered proof against trypanosome infection but simply lose their susceptibility to the effects of the presence of the organism and their blood continues to harbor the parasites. In other words, they are a perpetual source of infection for non-immunized animals and the wholesale adoption of the plan would serve only to perpetuate the disease and not to check it. The large game of Africa is a prolific source of infection, as the large antelopes, etc., nearly all serve as hosts to the trypanosome, and the choice for each district has to be made whether the game or the cattle are to be preferred. If the latter, then the wild animals must be exterminated, and the success of this measure in reducing the disease has already been seen in some regions. We are not yet in possession of any remedy which shall act against the trypanosome as quinine affects the malarial plasmodium, but it is likely that such an agent will soon be discovered, and perhaps also prove available for use in treating human trypanosomiasis, of which sleeping sickness is a late stage due to invasion of the cerebrospinal canal by the organisms.

The Action of Malachite-Green and Other Substances on the Nagana Trypanosome in White Rats.—H. Wendalstadt describes a series of experiments undertaken with a view of discovering some agent which should prove toxic for the trypanosome of nagana. A list of thirty-three agents experimented with is given, including Ehrlich's trypanred, which were without noteworthy effect in postponing the death of infected animals. Malachite-green, however, was found to have a markedly destructive action on the parasite though the substance suffers from the disadvantage of also being extremely toxic for the rats and of producing necrosis at the site of injection. Very small amounts are active, 1 c.c. of a 1-2000 solution being sufficient. After each injection the parasites disappear in about forty-eight hours but return again in several days, and finally the animal dies without showing more than the usual number of organisms in the blood, so that the author is not sure that perhaps the dye may not be the cause of death. The author has continued his observations by studying the action of malachite-green when used in combination with various other substances, and also the properties of other bodies chemically allied to this dye stuff and hopes to find some more satisfactory agent.

The Significance of Flagellates in the Human Stomach and Intestine.—A. Rosenfeld describes a series of cases in which a flagellate organism, probably the trichomonas intestinalis, was found in the gastric residue of patients having cancer of the stomach; the material being taken while fasting. Out of twelve cases only in a single instance did the organisms appear in a non-carcinomatous stomach and the author therefore believes that it affords good circumstantial evidence of the presence of malignant disease, though he does not go so far as Zabel, who considers the finding of flagellates an indication for operation. The frequent occurrence of such parasites in various forms of diarrhœa is probably not of very great importance, and such cases should always be studied carefully in order to determine the underlying etiological factor instead of being dismissed with the diagnosis of "flagellate diarrhœa."

Münchener medizinische Wochenschrift, November 15, 1904.

The Climatic Treatment of Asthma.—Avellis says that in spite of our efforts to discover the atmospheric conditions most suitable to the patient with nervous asthma, we must confess that success in these conditions is to be obtained only through the purest empiricism. Each case is different from every other, and more than this, conditions which at one time were favorable, after the lapse of a certain length of time may become just the reverse. In a case of the author's a boy of five found freedom from nocturnal attacks only after prolonged search in a certain country village. The effect of his sojourn there was so favorable that after his return to his city home he remained free from asthma for a year. His parents, wishing to do something further to strengthen him, took him back to the same village with the intention of spending some time there, but

the very first night the paroxysms returned and recurred every succeeding night of the visit. Apparently a very trifling change of air, such as is obtained by a one or two-hour drive, or even by removing from one part of a city to another, is sufficient in many cases to effect complete relief, and mountains and valleys, sea air and inland air all have special virtues for different patients. In general, it may be said that the patient should travel till he finds a place where he seems to be immune, and then stay there as long as possible.

Embolism of the Superior Mesenteric Artery in the Puerperium.—H. Cramer describes this unusual condition which occasioned the death of a woman of twenty-two, on the thirteenth day of her puerperium. She made a good recovery from the normal labor and was beginning to be out of bed, when on the eleventh day she had an involuntary defacation before arising, and abdominal pain followed by diarrhœa and vomiting. The next night was fairly comfortable, but the following day the symptoms became more severe, intestinal obstruction developed, the pulse and temperature rose, and the patient died during an exploratory laparotomy. Nearly the whole small intestine was found completely gangrenous and so friable that it tore repeatedly on handling with forceps. The author believes that the embolus probably originated in the pelvic veins and was short circuited into the arterial system through a patcht foramen ovale. The author reviews the fifty-one cases recorded in the literature and points out that in several the area of necrotic intestine was so small that a resection might have been attempted with good hope of success, and urges laparotomy with this end in view in all cases in which the diagnosis can be made.

Postdiphtheritic Nephritis.—A. Mayer says that it is usually accepted that the nephritis associated with diphtheria is an early lesion that it is rare to find it developing after the acute symptoms have subsided. Careful study of the urine, however, shows that there are opportunities for several fallacies which may give rise to inaccurate conclusions in this regard. One of these is the fact that the nephritis of diphtheria is peculiar in that there are often abnormal organized structures such as casts and epithelial cells to be found in the urine some time before the albumin can be recognized. It is therefore important to examine all specimens throughout the disease microscopically as well as chemically. The concentration of diphtheritic urine also causes spurious reactions for albumin to be simulated by precipitates of urates when tested by the acetic acid method, and in this way it may be thought that albumin not appearing till late was already present early in the disease. The author describes a case in which a sharp nephritis appeared on the thirteenth day when the child was about to leave the hospital. He concludes that the urine of diphtheritics should be examined for a considerable period after the disappearance of all symptoms, using the heat and nitric acid tests.

French and Italian Journals.

Treatment of Mosquito Bites.—Mosquitos, besides being the agents of propagation of certain infectious diseases, often produce local effects—for example, itching—which are extremely disagreeable to certain organisms. Physicians have for a long time been searching for a remedy which should not only do away with these distressing local effects, but which should also destroy to at least a certain extent any possible infectious agent at the portal of entry. Manquat advocates the use of several formulæ for this purpose. One is composed of 5 grammes of 40 per cent. formalin, 10 grammes of 90 per cent. alcohol, and 10 grammes of distilled water. This solution is to be applied repeatedly during fifteen minutes. This proceeding, although giving good results, is a little inconvenient on account of the length of time of its application. Another solution spoken of is mentholated cologne water, 5 per cent. The results from the application of this solution are more than doubtful. A third method praised especially by Capitan, is the application of the tincture of iodine as soon after the sting as possible.—*Revue Française de Médecine et de Chirurgie,* October 17, 1904.

Clinical and Anatomopathological Contribution to the Study of Cerebellar Atrophy in Man.—Giovanni Biancone has made a careful study of a case of cerebellar atrophy with epilepsy, in a girl fifteen years of age. The patient had rigidity of the muscles of the neck, tremor of the head, nystagmus, convergent strabismus, intention tremors of the upper extremities, oscillation of the trunk when standing, staggering gait with tremor, scanning speech, exaggerated reflexes, hypoalgia, and idiocy, associated with epilepsy. After admission to the hospital her condition grew gradually worse, and she died in a severe epileptic crisis. The autopsy and microscopical examination showed that she had chronic leptomeningitis of the cerebrospinal axis, marginal degeneration of the spinal medulla, symmetrical lack of development of the cerebellar hemispheres, and of some parts of the vermis, and decrease of the nervous elements of the cerebral cortex. A lack of development may be diagnosed from a sclerotic atrophy by the following considerations. If it has lasted from childhood without any evidences of fever or acute symptoms of an infective nature, it is congenital. If the condition is accompanied by ataxia, tremor and weakness, nystagmus, and scanning of words, it is associated with spinal lesions.—*Gazzetta Medica di Roma,* September, 1904.

Treatment of Echinococcus Cysts of the Liver by the Method of Baccelli.—Francesco Leto tells us that, in 1887, Baccelli, of Rome, brought forward a method for the treatment of echinococcus cysts in the liver at once simple, innocuous and efficacious; it consists of the puncture of the cyst with a small aspirating syringe, the removal of a small amount of liquid, and the injection of a small quantity of 1 per cent. corrosive sublimate solution. The amount injected should be 20 to 30 cm., about one-half of that withdrawn. The cyst is never infected, on account of the antiseptic action of the bichloride of mercury, and the echinococci are killed; the cyst gradually shrinks in size and a complete cure results, after the absorption of the fluid. More than one injection may be necessary, and the cure may require some months. Contraindications are suppuration of the cyst, and long continuance of the trouble. Several cysts may have to be injected at one or more sittings. The danger of hydatic fluid getting into the abdominal cavity and causing poisoning is small. After the operation, the patient should remain perfectly quiet for twenty-four hours, abstaining from food. The author publishes two successful cases treated by him after this method, and resulting in a perfect cure.—*Il Policlinico,* October, 1904.

The Otitis of Measles.—Le Marc, Hadour, and Bruder declare that the otitis of measles is closely associated with oculo-nasal catarrh and does not appear to be influenced either by the exanthem or by the angina. Just as it has been said that "scarlatina is angina," so it might be said that "measles are oculo-nasal catarrh." This predominance of naso-pharyngeal catarrh explains why measles affect the larynx while scarlatina is not apt to affect this part. The tonsil is an isolated territory without laryngeal repercussion; on the contrary, the least coryza often causes laryngitis and hoarseness. The writers have not made any bacteriological examinations of auricular suppurations because all of their cases were those of spontaneous perforations of the tympanum, and as these are already subject to secondary infections, the bacteriological examination would not be significant. The perforation most often occurred in the antero-inferior region, the otitis of measles following the general laws which regulate the escape of pus from the lowest point.—*Revue Française de Médecine et de Chirurgie,* October 3, 1904.

Treatment of Fracture of the Nose.—C. and F. Martin under general anæsthesia reduce fracture of the nose by means of their forceps which they introduce into the nasal fossæ. After the reduction is perfect the fragments are kept in position by the application of retention apparatus. Asepsis of the nasal cavity is assured by frequent and abundant lavage. Every five or six days the apparatus is removed and cleaned, and then replaced. This treatment is kept up for from four to six weeks. At the end of this period the consolidation is strong enough, so that the apparatus may be removed without danger of displacement of the fragments by cicatricial contraction. The results of this treatment are remarkable, and they are as good in old cases as they are in recent ones. Not one of the patients has had any mishap, no infection and no hemorrhage. In fact, in one of the cases, continuous epistaxis ceased after the reduction. In all cases, even when one is not absolutely sure of a fracture, reduction with these forceps should always be tried, for in this way the pain is overcome and consolidation is made more rapid.—*Le Bulletin Médical,* November 9, 1904.

Obesity.—Leven insists on the constancy of dyspeptic troubles in the obese. The author has observed a number of cases of obesity in which the patients suffered with diarrhœa, and whose weight increased in spite of the chronic diarrhœa. The cessation of the bowel disturbance after appropriate treatment was accompanied by loss in weight. These apparently paradoxical facts are explained on the ground that the weight is regulated by the nervous system whose mechanism may be disturbed by any diseased condition whatever. Leven insists on the necessity of decreasing the weight slowly since a rapid loss in weight depends more on dangerous dehydration of the tissues than on the loss of fat. Lorand thinks that there exists an obesity due to rich food and a sedentary life; and also an obesity due to morbid processes of certain glands whose internal secretions powerfully influence all of the processes of nutrition. The removal of the ovaries or of the thryoid is followed by a diminution of oxidation while the products of these glands increase it. The line between these cases of obesity and complete myxœdema is very narrow.—*La Tribune Médicale,* November 5, 1904.

Treatment of Congenital Dislocation of the Hip.—Calot presents a report of ten children who had been cured, some of single, some of double dislocation of the hip. The ease with which these children walked left nothing to be desired. He showed these children, two or three years of age, to prove that contrary to the generally accepted opinion it is easy to effect a cure in the very young. Though this treatment may necessitate extra attention at home, perhaps, the reduction is, notwithstanding, extremely easy; the treatment is very gentle and does not necessitate the use of an anæsthesia. And these anatomical and functional cures are generally more complete if they are undertaken before the development of serious osseous deformities which age induces. The writer questions why these children should not be promptly cured of these as well as other orthopædic congenital affections. Many of these cases have been cured in the space of four months with but a single application of apparatus.—*La Presse Médicale,* November 5, 1904.

Pustular Bromide Rash.—Vincenzo Chirivino publishes a case of bromide rash, with observations on the cause of such affections. The patient took each year a course of bromides for the relief of epilepsy, and he had usually no bad effects from the use of the drug. Finally, on one occasion of using the drug, he had a severe postular eruption appear nearly all over the body, lasting three months, without fever. Careful histological examinations of the skin and postular contents were made, which showed that the lesion was of the endothelium of the cutaneous vessels, and exclusively those of the rete subpapillare and of the papillæ; and that it was inflammatory in nature, and not functional or vasomotor. The author considers it of the greatest importance to note that before this attack the patient had marked gastric disturbances, characterized by hyperchlorhydria. He considers that this produced a chemical change in the bromides when taken into the stomach, chlorides of the sodium and potassium being formed in the stomach, and thus bromine set free to be eliminated by the skin and cause the pustulation. He advises that the gastric secretions be carefully examined before administering bromides in large amounts, and that in cases of hyperacidity they be not given; that acids be avoided while taking bromides; and that in cases of eruption the physician suspend at once the use of the drug, and treat the stomach. —*Giornale Internazionale delle Scienze Mediche,* October 31, 1904.

Post-Mortem Temperature in the Human Cadaver.—Ettore Greggio and Francesco Valtorta have made experiments as to the fall of temperature in the cadaver post mortem, which seem to be of considerable value medico-legally. They made observations on 100 bodies, beginning to take the temperature ten minutes after death, and repeating it at intervals during twenty-four or more hours. They found that there were considerable differences in the temperature, depending on the cause of death, the amount of fat on the body, etc., a fat body retaining heat longer than a lean one. Their conclusions are as follows: 1. Three periods may be distinguished; a short one of about three hours, in which little heat is lost; a longer one of six hours, in which the loss is greater, at least one degree per hour, and a third, longest of all, in which the loss becomes progressively less. 2. Reduction to the temperature of the surrounding air occurs in about 22 hours. 3. The temperature, after becoming that of the surroundings, rises again slightly. 4. A rise of temperature after death is more frequent than has been supposed. It was observed 25 times out of 40 in cases that had febrile diseases. The maximum rise was 45 minutes after death, and was in some cases more than a degree. 5. There is no great difference in the time of arrival of rigidity in different cases. Sometimes it comes sooner in certain parts than in others, as in a paralyzed portion of the body.—*Gazzetta Medica Lombarda,* October 17, 1904.

Rare Forms of Cardiorespiratory Murmurs of Double Rhythm.—Carlo Quadrone has observed, during his hospital experience, cases of cardiac murmurs of double rhythm, produced by the pressure of the ear or of the stethoscope on the chest wall. He accounts for them as follows: 1. There can be produced, by pressure over the precordial region, murmurs of definite tone and rhythm, which may be noticed for a long time and do not change their nature. 2. They are mostly mesosystolic, some synchronous with systole or presystolic. 3. They change their characteristics with the phases of the respiratory act. 4. They may be considered as cardio-pulmonary murmurs, produced by an aspirative and compressive action of the heart on the neighboring lung tissue, aided by the external pressure applied.—*Revista Critica di Clinica Medica,* October 15, 1904.

Annals of Surgery, October, 1904.

Some Studies in Asepsis.—C. Harrington calls attention to some of the fallacies attendant on modern surgical methods with reference to aseptic measures. Much stress is laid on certain pet procedures, while other matters of quite as much importance are neglected. Particular attention is called to the fact that many of the plans of washing the hands now followed do not produce asepsis. As the result of long-continued experimentation, the author is inclined to believe that the best results some from using as a solution for the hands the following mixture: Commercial alcohol (94 per cent.), 640 c.c.; hydrochloric acid, 60 c.c.; water, 300 c.c.; corrosive sublimate, 0.8 gram. This mixture contains 60 per cent. absolute alcohol, 6 per cent. commercial (strong) hydrochloric acid, and 1:1250 corrosive sublimate. Now, 60 per cent. alcohol will destroy *Staphylococcus aureus* in four minutes; 10 per cent. hydrochloric acid is equally effective; and 1:1000 corrosive sublimate will kill it in three minutes. Why a combination containing all three substances, but with lesser proportions of the acid and the salt, is so much quicker in its action than any one of them alone, is, says the author, an interesting question of physical chemistry. This mixture kills the *Staphylococcus aureus* in about ten seconds.

The Treatment of Hæmatemesis by Gastroenterostomy.—F. G. Connell reviews the literature and reports a personal case operated on in the manner indicated, with a fatal result on the fifth day. Autopsy revealed an ulcer on the anterior stomach wall, near the pylorus and lesser curvature, with an eroded artery at its base. An examination of the mucosa during the operation did not locate this point. From collective experience, the author believes that gastroenterostomy is but an indirect and unreliable method of dealing with gastric hemorrhage. While it has been followed, it is true, by a cessation of the bleeding, and the healing of the ulcer causing it, it cannot be depended on with any certainty. As to the indications for the operation, it may be said that it is indicated in hæmatemesis, first, after a thorough search has failed to reveal the source of the hemorrhage; second, when the source of the bleeding is located, but it is in such a condition as to make direct treatment impracticable or impossible.

Postoperative Intestinal Obstruction.—The histories of these cases are given by C. H. Peck, who notes that the possibility of postoperative obstruction should be borne in mind in all abdominal operations, especially in conditions likely to result in extensive adhesions, *e.g.* appendicitis with peritonitis, or pyosalpingitis with pelvic peritonitis. All raw surfaces should be covered as much as possible with normal peritoneum, or, when this is not practicable, perhaps with Cargile membrane, or carefully arranged omentum. Small incisions and the least possible manipulation and evisceration should be the rule. The cleansing of the peritoneum should be done rapidly and with the least possible trauma and handling of normal peritoneum. The smallest possible drains should be used, if any. Diet and regulation of the bowels should be watched with the greatest care during the first few weeks of convalescence; attacks of gaseous indigestion with colicky pain should be regarded with suspicion and treated promptly and vigorously. Determined effort should be made to relieve early attacks of obstruction by enemata, position, gastric lavage, etc., and if successful, the patient should be kept on a scanty fluid diet for some time, and watched most carefully for possible recurrence of symptoms. If palliative measures are unsuccessful after a few hours' trial, operation should be promptly resorted to. In cases occurring later than four to six weeks, palliative measures are less likely to be effective, and early operation is usually imperative. All patients who have been operated upon for intraabdominal inflammatory troubles should be warned of the possibility of the occurrence of obstruction before leaving the care of the surgeon, impressed with the importance of avoiding indiscretions in diet and attacks of indigestion, and of seeking advice promptly if such attacks should occur. The operative procedure must be adapted to each individual case; the right Kammerer incision for cases following appendicitis with complete healing is often useful. Resection and end-to-end anastomosis should be preferred to enterostomy in the majority of cases in which gangrene or sloughing of the bowel demands one or the other.

The Treatment of Fractured Patella.—J. A. Hutchinson reports seven personal cases, with excellent radiographic illustrations. He gives a general description of the deformity following the accident, and enumerates the various plans of treatment which have been and are now followed. He prefers the open operation, following the subsidence of inflammatory swelling (seven to ten days). He lays special stress on the following points of surgical technics: rapid operation, rubber gloves, packing of the joint cavity as soon as opened with sterile gauze in normal saline fluid, continuous irrigation with the latter during operation, keeping all instruments out of the joint cavity as far as possible, special care in adjusting the torn aponeurosis, particularly on the lateral aspects, elevation of the whole limb after operation, early massage and passive movement. Of six cases operated on according to this method, all are able to walk without lameness, and to go up and down stairs without difficulty.

Book Reviews.

The Medical Record Visiting List, or Physicians' Diary for 1905. New revised edition. New York: William Wood & Company.

This visiting list may now be assumed to represent the acme of convenience in pocket records. Thirty pages of printed matter contain information useful to have ready for consultation at any moment, such as a very ingenious obstetrical calendar; equivalents of temperature, weight, capacity, etc., in the metric and English systems; a table of solutions for hypodermic use; hints for the proper management of poisoning and other emergencies, etc. An unusually well arranged table gives the maximum doses of drugs in both the apothecaries' and decimal systems, and also indicates the remedies official in the pharmacopœia. The blank pages are designed for the daily record of visits made or to be made, together with details as to the charges, etc., consultation practice, obstetric engagements, and record of such cases, record of vaccinations, register of deaths, nurses' addresses, patients' addresses, and cash account. The binding is of the most durable type, the paper tough, and the volume of a size to slip easily into the pocket.

A Text-Book of Clinical Diagnosis by Laboratory Methods. For the Use of Students, Practitioners, and Laboratory Workers. By L. Napoleon Boston, A.M., M.D. Associate in Medicine and Director of the Clinical Laboratories, Medico-Chirurgical College, Philadelphia. Formerly Bacteriologist at the Philadelphia Hospital and at the Ayer Clinical Laboratory of the Pennsylvania Hospital. With 320 Illustrations, many of them in Colors. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

The author introduces his work by a concise description of the practical use of the microscope, and states that the ignorance of instrumental technique is largely responsible for unsatisfactory results in the laboratory. The first section deals with the examination of the blood, over one hundred pages being devoted to the most practical and recent methods, with plates such as are sufficient to make the subject matter intelligible. In this chapter the bacteriology and parasitic diseases are discussed in full and those protozoan parasites which invade animals are also included. Serum-diagnosis is given a fair amount of attention, and the text gives in a concise manner the latest decisions of what we know regarding this new but important branch. The portion on uranalysis is thoroughly up to date, giving methods of determining acidity, Bence-Jones albumin, etc. The gastric and intestinal contents are described and methods applicable to each are given in a manner such that the average man could perform them intelligently. The author also includes the examinations of the sputum, buccal secretion, nasal secretion, discharges from the ear and eye, together with the semen, vaginal secretion, and menstrual fluid. A short chapter on cerebrospinal fluid will be of interest, on account of the recent epidemic. Inoscopy and cytodiagnosis are briefly considered. The work as a whole fulfills the intention of the author and has the advantage of brevity without careless omission.

Kirkes' Handbook of Physiology. Revised by Frederick C. Busch, B.S., M.D. Professor of Physiology, Medical Department, University of Buffalo. Fifth American revision, with five hundred and thirty-five illustrations, including many in colors. New York: William Wood & Company, 1904.

Kirkes' Physiology is too well known as a reliable textbook to demand any extended notice. In this revision several changes have been made in order to keep the book abreast of the modern advances in physiological science. These changes and additions are particularly noticeable in the chapters on the Chemical Composition of the Body, the Blood (notably the paragraphs on the globulicidal properties of serum, agglutination, cytolysis, and precipitins), and the sections of the Hæmolymph Glands and the Internal Secretions. The chapter on Food and Digestion shows also considerable revision. The revision is well and thoroughly done, and the volume will be welcomed as an old friend by the very many who have used an earlier edition, while the medical student of to-day cannot do better than procure a book which has stood the test of long and critical service. We believe that it is more than fifty years since the first edition of Kirkes was published, and, judging from the rapidity with which successive editions appear, it is still able to hold its own.

Diseases of the Nose, Throat, and Ear, and Their Accessory Cavities. By Seth Scott Bishop, M.D., D.C.L., LL.D., Author of "The Ear and Its Diseases;" Honorary President of the Faculty and Professor of Diseases of the Nose, Throat, and Ear in the Illinois Medical College; Professor in the Chicago Post-Graduate Medical School and Hospital; Surgeon to the Post-Graduate Hospital and to the Illinois Hospital; Consulting Surgeon to the Mary Thompson Hospital, to the Illinois Masonic Orphans' Home, and to the Silver Cross Hospital of Joliet, etc. Third edition. Philadelphia: F. A. Davis Company, 1904.

The second edition of Dr. Bishop's book appeared in 1898. During the past six years much progress has been made in the fields indicated in the title, and the present edition incorporates into the original treatise all that recent years have shown to be of value. Full attention is given to recent discoveries, while many helpful quotations and references to current literature are added. We may particularly mention the closing chapter on Life Insurance, as affected by ear, nose, and throat diseases. Probably no one text book in use by American students and practitioners covers the general ground of ear, nose, and throat work better than does that of Dr. Bishop. This is not saying that one may not take exception to certain statements on various topics, but the book as a whole must be accepted as an interesting record of the experience of a long term of years spent in special practice.

The Medical News Visiting List. 1905. Thirty Patients per Week. Philadelphia and New York: Lea Brothers & Co.

The present handy little volume is in the nineteenth year of issue, and consequently is the product of years of experience and study. The text has been brought carefully up to date. Among other valuable features are a scheme of dentition, instructions for examining the urine, tables on eruptive fevers, of incompatibles, poisons, and antidotes. The paper is tough and fine, suitable for either pencil or pen and the binding is of leather.

Health and Disease in Relation to Marriage and the Married State. A Manual contributed to by Drs. G. Abelsdorff, L. Blumreich, R. Eberstadt, A. Eulenberg, C. A. Ewald, P. Fürbringer, M. Gruber, W. Havelburg, A. Hoffa, R. Kossmann, F. Kraus, R. Ledermann, A. Leppmann, E. v. Leyden, E. Mendel, A. Moll, A. Neiser, J. Orth, S. Placzek, C. Posner, P. F. Richter, H. Rosin, W. Wolff. Edited by Prof. Dr. H. Senator and Dr. S. Kaminer. The only authorized Translation from the German into the English language, by J. Dulberg, M.D., of Manchester, England. Vol. I. New York: Rebman Company; London: Rebman, Ltd., 1904.

The volume before us consists of an introductory chapter which points out the relation of Matrimony to Public Hygiene and to Preventive Medicine. This is followed by chapters on The Hygienic Significance of Marriage; Congenital and Inherited Diseases and Predispositions to Disease; Consanguinity in Marriage and its Effects on the Offspring; Climate, Race, and Nationality in Relation to Marriage; Sexual Hygiene in Married Life; Menstruation, Pregnancy, Child-bed, and Lactation in Relation to Marriage; Constitutional (Metabolic) Diseases in Relation to Marriage; Diseases of the Vascular System, of the Respiratory Organs, of the Organs of Digestion, of Diseases of the Kidneys in relation to marriage. The book is intended for the general practitioner, and differs very considerably from the works of Havelock Ellis, Krafft-Ebing, etc., in that here are no long histories of sexual degenerates, or, indeed, of any sexual abnormalities. The various subjects are carefully and thoroughly handled, and the reader will find here much information for which he will search in vain elsewhere. There is an ample bibliography (chiefly German), together with a good index.

Duality of Thought and Language. By Emil Sutro. New York: The Physio-Psychic Society, 1904.

We must confess that, while this work may prove of interest and profit to those who have a taste for metaphysics, it does not convey any very definite message to the physician. The author's main postulate is that "there is a correlation existing between the various phases of the human spirit and those constituting language, especially spoken language." Penetrating into the inner being of the latter, he finds that it owes its existence to a series of correlated physical and psychical factors constituting man. Language is a symbolical representation of human life.

Blakiston's Quiz-Compends. A Compend of Medical Latin, Designed Expressly for Elementary Training of Medical Students. By W. T. St. Clair, A.M. Professor of the Latin Language and Literature in the Male High School of Louisville, Kentucky; Author of "Cæsar for Beginners," "Notes to Cæsar's Gallic War, Book Three," etc. Second edition, revised. Philadelphia: P. Blakiston's Son & Company, 1904.

The most useful portions of this compend are the vocabulary and the few pages on prescriptions. The sentences given for translation into English are framed on the supposition that Latin words strung together constitute Latin. The grammatical slips are few, but the arrangement of the words in the (medical) Latin sentences is bad.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 28, 1904.

DR. HENRY S. STEARNS, PRESIDENT.

Address of the Retiring President.—Dr. WENDELL C. PHILLIPS took pleasure in saying a few words regarding the work of the past year. His work as president had been laborious, but the duties involved were pleasant. To be the presiding officer of a body numbering 2,000, with all the responsibilities and duties attached to the office, was no easy task. Among the greatest responsibilities had been the arranging of the programmes, which required a great deal of thought, knowing so well that upon the character of the scientific work depended the success of the society. Again the responsibilities were increased by the varying calls upon him by members for advice and counsel, sometimes calling his attention to irregularities in the profession requiring work of the legal department. Not a small responsibility was the work of the legal department, and it was necessary to exercise the greatest care; it was not merely the arrest and conviction of such men as Conrad and Blinn that called for great care, but in doing all they could without reflecting in any way upon the medical profession. He thanked the members of the society for their kindly support during the year past, as shown not only by the interest taken in the programmes but also in the attendance, which was unusually large. He then introduced the incoming president.

The President's Inaugural Address.—Dr. HENRY S. STEARNS thanked the society for the honor they had conferred upon him in electing him president of this time-honored society, which had many veterans of the medical profession in this city to-day. He said that no efforts would be spared to make the coming meetings interesting. He hoped that every respectable and licensed practitioner of medicine in the county would be enrolled among the list of members. Very important and valuable work had been done by the Comitia Minora during the past year, as well as by other committees. He urged that the members persuade other medical men to become members, as the success of the society depended upon its membership. On the 10th of last month the maximum penalty had been imposed upon fifty milk dealers, which was largely the result of the work of the Milk Commission, which had the backing of this society. He called attention to the enactment of a new statute in which should be clearly interpreted the term "practice of medicine," which would enable them to get rid of so-called "Faith Curists," and others of similar type. By increasing the membership, more funds could be had for the purpose of suppressing illegal practitioners. Every dollar of this fund had been spent for this end. The daily press had asked why the Society did not suppress illegal practitioners, and his only answer was lack of funds to obtain indictments. A larger fund was imperatively needed to carry on the work of the legal department. Not only did lack of funds stand in their way, but also the lack of a statute defining the term "practice of medicine" more exactly. Other States, especially Michigan, were ahead of New York in this particular. Certain changes should be made in the laws, such as giving the Registrars the power to revoke licenses if bad conduct was proven; also re-registration of medical men should be made imperative, because many quacks were to-day practising under dead men's diplomas; also better definition of the words "practice of medicine," following somewhat the Michigan law. At present fine and imprisonment could not be imposed upon an illegal practitioner at the same time; practising medicine illegally should be made a misdemeanor, with a fine of one hundred dollars and imprisonment for one year. After reviewing briefly the attempts made at amalgamation of the two State societies and the cause of failure, he closed his address by stating that the State Society and County Society would honor all pledges given in joint conference, and that he entered upon his duties as president with the fixed determination to foster kindly feelings and to have no internal dissensions. He then made his committee appointments for the coming year.

Dr. J. RIDDLE GOFFE, president of the Medical Society of the State of New York, stated that somehow the impression among a few was that he was against the amalgamation of the Medical Society of the State of New York and the New York State Medical Association, and he wished it to be understood, once and for all, that he was unqualifiedly in favor of it and would work to this end. He felt certain that this amalgamation would take place before another year.

Recent Clinical Studies of Uterine Fibroids; A Plea for Early Operative Intervention.—Dr. ARNOLD STURMDORF read this paper. He said that two decades ago eighty-five out of one hundred women died when operated upon for uterine fibroids, while to-day the results of the operative treatment constituted one of the most brilliant achievements of surgery, and no woman would lose her life if operated upon in time. It was unfortunate that some, even to-day, condemned operative intervention. These growths possessed a peculiar malignancy; they were not self-limited, and they could kill by inducing local and constitutional conditions. At present all palliative therapeutics had proven futile and sometimes even disastrous. The histological structures possessed malignant potentialities. The question arose, why and when to operate? The answer was based upon the following: (1) Was there a tendency in the disease in question to spontaneous cure? (2) What was the potency of theraupetic resources? (3) What were the immediate and remote results of radical intervention? He said that Dr. Noble, of Philadelphia, in his report on 1,188 fibroid tumors operated upon, called attention to the relative frequency of adenocarcinoma of the uterus and epithelioma of the cervix. Fibroid tumors were direct predisposing causes of cancer. It should not be understood that uterine fibroids were benign tumors. It was also erroneous to think that such tumors produced few symptoms, and that, after the menopause, retrograde changes would occur and the tumor disappear. An analysis of the 1,188 cases of fibroid tumors of the uterus showed that 16 per cent. of these patients would have died without operation, and that 18 per cent. would have died from complications. In addition a certain percentage of them would have died from conditions produced by chronic anæmia and from pressure effects upon the alimentary and urinary tracts. Direct and indirect deaths from uterine fibroids could be placed under five categories, as follows: (1) the pathological conditions induced in the adnexa; (2) structural changes or degenerations in the tumor; (3) compression on adjacent organs or viscera; (4) metabolic and cardiovascular changes not due to pressure and occurring frequently when the tumors were very small; (5) pregnancy. Inactivity condemned the patient to invalidism for years. This was the reverse of the optimism taken by many general practitioners. In many instances, what would have been the operation of choice soon would become an operation attended with great and grave responsibilities.

Recent Pathological Studies of Uterine Fibroids.—Dr. THOS. L. CULLEN, of Baltimore, said that he had made a study of between 1,200 and 1,300 cases of uterine fibroids with Dr. Howard Kelly. These cases had been studied microscopically, and the histological elements had been carefully studied as well. They had accepted the general classification of interstitial, subperitoneal, and submucous myomata. Whenever large myomata existed they invariably had found others, some as small as pin-points. In many cases subperitoneal fibroids were seen to be covered over by adhesions, and one of the most interesting was shown to be adhesions to the omentum; an atrophy of the omentum had been traced in these cases. Some were slightly adherent, while others were very firmly attached; sometimes the omentum had entirely disappeared. Parasitic myomata were shown in some cases to be entirely separated

from the uterus and lying perfectly free in the abdominal cavity. He called attention to sloughing of these growths. In many instances in which the growth projected into the vagina, the surface epithelium would disappear and any slight injury to the surface mucosa would cause it to drop down, leaving a cavity as large as a lemon. These cervical myomata had frequently been found; they usually began in the substance of the organ and gradually, because of their increasing size, projected down until there was only a growth below with a little uterine tissue on top. The most common degeneration which took place in these tumors was hyaline, and this was probably due to their lack of blood supply; there was no coagulation necrosis. It was very interesting to follow the changes that occurred in hyaline degeneration; first, there was a hyaline appearance over large areas which melted away and only enough tissue was left to carry blood vessels. In the past it had been claimed that sarcoma of the uterus was an independent process and had nothing to do with fibroids, but Dr. Cullen had traced a direct transference of myomata into sarcoma; in one instance there were several myomata; at another point in the uterus there was sarcoma; there seemed to be a direct transference of myoma into sarcoma, sarcomatous areas being in the center of the myomatous growth. Interesting sections were shown of areas of myomata undergoing hyaline degeneration, and in the center were cells undergoing the early changes of transformation into sarcoma. In these cases the histological picture was not so distinct as in cancer. Until 1896 no attention had been called to cases of adenomyomata. They were not malignant, and consisted largely of a diffuse thickening of the uterine walls with a myomatous tendency. The thickening took place only in the mucosa. Sometimes the menstrual blood was dammed back and there was formed a large cyst with its cavity filled with a chocolate-colored fluid. Photographs of sections were shown with the uterine glands running one-half way through the walls. Before operating for uterine fibroids, the surgeon should be informed as to the condition of the uterine mocosa; in every case of myomectomy the operator should know whether or not the uterine mucosa was normal. In nearly every case where there were normal tubes and ovaries there was found a normal uterine mucosa. The degeneration which took place in the mucosa was entirely mechanical, and Dr. Cullen did not agree with the statement that it was due to any changes in the blood vessels. Whatever bleeding occurred was due to mechanical effects. Large veins were found in the endometrium with very thin walls, and at the menstrual epoch much blood naturally escaped; when these veins were placed on the stretch, naturally one would get a leakage, but only when the growth projected into the uterine cavity would there be much hemorrhage. He said that Dr. Noble had been much interested in the coexistence of myoma and carcinoma in the uterus, and he had drawn attention to the association of the two. Carcinoma of the body of the uterus was most prevalent in those who had never borne children; also myomata were more prevalent among those who never had children, and he thought possibly the same factors might be present to bring about these conditions. Nevertheless there seemed to be some relationship between myoma and adenocarcinoma of the uterus. Among the 1,200 or 1,300 cases that he had seen he had observed the coexistence of the two, myoma and adenocarcinoma of the uterine body, in several instances. He showed a picture of a perfectly normal uterine mucosa, and in the center of the organ was an early cancer, no doubt the earliest on record and which he had discovered accidentally. He related an instance of two malignant processes, papillary growths and carcinoma, both with metastases, occurring in association with a fibroid of the uterus. He also showed photographs of myoma associated with lipoma, a simple mixture, merely a coincidence, and which was interesting because so few cases had been recorded. Uterine polypi were mechanical in origin and existed with a perfectly normal mucosa; in these cases the mucosa was forced off and extruded through the cervix. In such cases an examination of the tubes and ovaries would show all kinds of conditions, but the most frequent were adhesions; sometimes there was produced as a result of these adhesions a hydrosalpinx, and, in some cases, a pyosalpinx. Sometimes associated was tuberculosis, and occasionally a tubal pregnancy.

Fibroids and Pregnancy.—Dr. S. Marx said that the association of pregnancy with fibroids was one of danger, and one which might make an otherwise perfectly normal labor one fraught with the gravest dangers. No matter how small the tumor might be, one would not know how large it might become at the time of labor. Patients might be lost from sloughing of the tumor. It was fortunate that many of these patients were incapable of conception; but when they did become pregnant then one was dealing with an uncertain and unknown complication. When Dr. Marx found a fibroid of the uterus in any woman who presented herself to him because of symptoms referable to it, he advised operation. The treatment of this condition during the child-bearing period was one of radicalism. Patients with uterine fibroids situated at the fundus and who became pregnant, presented many difficulties and should be watched very carefully and expectantly. During labor sometimes these tumors might be pushed above the presenting part, but such efforts should not be persisted in too long. When cases were met with at term one might extirpate them by vaginal section, but he thought it better to perform cesarean section. To extirpate during actual labor was practically impossible, and manifold complications might arise. Fibroids at the fundus were, as a rule, harmless; but those that were immovably fixed and blocked the pelvis required operation to free the passages. Many cases required deep and careful thought on the part of the attending physician, and experience had taught that the trouble during the third stage of labor was from hemorrhage and sloughing. Fibroids during and after labor should be handled with gloves. If much difficulty was experienced in enucleating the placenta, it would be better to introduce some gauze and adopt waiting tactics and not invite sepsis by attempting forcibly to tear or dislodge it. The treatment of any hemorrhage was by packing the uterus with gauze. It was Dr. Marx's experience that fibroids were, as a rule, harmless until after some one had used the curette for the removal of supposed fetal secundines. He sounded a note of warning, that the use of the curette in a fibroid uterus recently pregnant was fraught with the gravest danger, and it was not indicated. So soon as the puerperal woman showed a rise of temperature many physicians thought at once of the curette. The curette had no place in either a fibroid uterus or a pregnant one. If one was sure that the rise of temperature was due to sapræmia from retained secundines, the products must be removed, *not* with the curette but with an aseptic finger. The intermuscular and submucous fibroids gave the best prognoses and were most readily extirpated; the subperitoneal fibroids were most difficult to attack, and a total hysterectomy was probably, in many cases, the operation of choice. Dr. Marx wished to emphasize the following points: (1) Prophylaxis. Every fibroid should be attacked by a surgeon. (2) During pregnancy every fibroid should be carefully watched and, if complication threatened should be attacked. (3) During labor these tumors needed watching, and might give rise to much hemorrhage. If the tumors blocked the passage, either vaginal enucleation or cesarean section, followed by hysterectomy, might have to be resorted to. (4) Sloughing of the mass should not be mistaken for retained secundines. The curette should not be employed. (5) Sloughing and necrotic fibroids should be attacked surgically by enucleation or by hysterectomy.

Operative Technique for Uterine Fibroids, Abdominal and Vaginal.—Dr. J. Riddle Goffe presented this part of the symposium and referred to the earlier teachings that uterine fibroids were benign in character, and that after the menopause they would become smaller and finally disappear. The result of this firm belief was that these tumors were seldom operated upon until they had obtained large

dimensions. The man who first planned hysterectomy was Kimball, of Lowell, Mass., in 1855, and he had one success and two failures, one from hemorrhage and the other probably from sepsis. In May, 1888, Dr. Dudley and himself devised an operation, and operated upon four patients with success. Here Dr. Goffe gave a description of the operation, illustrating it by diagrams and showing how adhesions were avoided at the bottom of the pelvis. As a result of discoveries in reference to degeneration, etc., of fibroids, he said he had formulated for himself the rule that every developing fibroid which was small but gave symptoms, or which was discovered during the course of other pelvic operation, should be removed. He had also formulated for himself the rule that every uterine fibroid discovered in a woman during the child-bearing period should be removed at once. The technique of operations, of course, varied to meet the varying indications and conditions. When small, such tumors could be removed per vaginam, either through the anterior or posterior fornix, or both incisions could be made. A description of vaginal myomectomy was given, and in doing this operation there were certain points of danger. First, in making the primary incision it might be found that, if dealing with a large fibroid, it might carry the bladder wall upon the base of the tumor, and this incision might injure it; therefore, he made the rule that in cases of large fibroids the incision should be made near the umbilicus. Again, in dissecting the bladder from the anterior surface of the tumor, care should be taken not to tear into the bladder. A third element of danger was injury to the ureter in ligating the uterine artery. If the tumor was very large, one might bisect the tumor after its delivery through the abdominal incision and then enucleate it; the elastic uterine structure would so contract as to give nearly normal relations. Originally he ligated the artery with silk, but at present time he used chromicized catgut or kangaroo tendon. Sometimes the angiotribe was used, which was of great aid in dealing with possible hemorrhages. Illustrative drawings were shown of the angiotribe in position in working by either the vaginal or abdominal route.

Dr. Henry C. Coe opened the discussion and said that he had seen women made miserable because they were told they had tumors, when an examination revealed tumors at the fundus about the size of a pea and which was of no more importance than a foreign body would be. He asked if it would not have been better to wait and keep the patients under observation. He had had fibroid tumors under observation for ten, fifteen, or twenty years, with the patients remaining in perfect health. Dr. Coe was not willing to subscribe to the opinion that fibroids were necessarily malignant. With regard to certain changes taking place in these tumors, one should bear in mind that no two cases were exactly alike, and because a patient had a small fibroid, operation was not always indicated; he believed they should not always operate, but keep such patients under observation. Each case should be studied separately, and not only the size and character of the tumor noted but also the location. The operative technique at present was practically crystallized, and the mortality now was not over five per cent. Cardiac changes might arise only with large tumors of long standing. Pelvic thrombosis should receive more attention in such a discussion, for quite a number of deaths had been reported due to thrombosis of the pelvic veins, death occurring on the fourth, fifth, or sixth day. But sometimes these thrombi existed prior to operation. While Dr. Coe believed in conservative myomectomy, he said he would not select a case of multiple myomata and remove ten, twelve, or fifteen of them. Pregnancy did sometimes follow myomectomy; but it was sadly disappointing sometimes to tell a woman that, after this operation, she might marry and give birth to children when she did not. He said he favored the abdominal route in operating; he liked to separate adhesions with the aid of the eye, and also to remove appendices when he saw them. He protested against claiming that because a uterus contained a fibroid, it should be removed.

Dr. A. Palmer Dudley thought that Dr. Sturmdorf's paper was a timely one, and when the general practitioner came in contact with such cases he should have the advice and guidance of an expert in this work. He believed that every fibroid tumor that produced pressure would produce systemic changes. These cases could be combated for years by the general practitioner, but so soon as pressure symptoms occurred, one should remove the growth by myomectomy or hysterectomy. He reported a case of myomectomy, the tumor being as large as a child's head, with brilliant results. Regarding the complete or partial removal of the uterus in such cases, he said that depended upon the opinion of the individual operator, and no operator should pledge himself to save certain organs; if a cervix was found to be diseased and it was left, it probably would remain diseased. Hysterectomy by way of the vagina might be all right, but Dr. Dudley did not like this route, and chose the abdominal. Sometimes one discovered gall-bladder or appendicular trouble, or adhesions might have to be broken up; then the abdominal was the operation of election.

Dr. Sturmdorf said that he referred to those cases which presented symptoms, not pressure symptoms alone, but such symptoms as would bring a woman for consultation regarding them. He asked how one could tell when changes would take place in fibroids? He believed it to be impossible. In cases of fibroids, women might be destroyed, not from the pressure symptoms or from displaced organs, but as the result of a toxæmia of which we knew nothing. Ten per cent. of the women with uterine fibroids died; but not from pressure effects. A mortality of four per cent. in cases of operation, as against a mortality of 11 per cent. without operation, spoke for operation. He reiterated his belief that if a woman came to him with symptoms the result of fibroids of the uterus, he considered the condition a source of danger and believed in at once attacking the condition radically.

Dr. Cullen said we should be more conservative in doing myomectomy than we had been in the past, and yet be more radical by doing hysterectomies. There were several instances recorded of very large myomata with extensive myomectomies performed, several large incisions having been made, and from twenty-four to forty-eight hours after the operation the patients died with symptoms of toxæmia, yet bacteriologically there had been no infection. These patients had a temperature of 104° just prior to death. Why death occurred in these cases was not known. Dr. Cullen, therefore, believed that myomectomy should be reserved for those cases in which no large cavities would be left and not much damage done, and little danger of absorption. He believed the secret of success in these operations was the covering of the entire operative area with peritoneum. In bisecting large tumors, as advised in certain cases by Dr. Goffe, he said we should be careful that no carcinoma or sarcoma coexisted, for such cutting might be a fruitful source of malignant metastasis.

Optometry Bill.—Dr. Matthias Lanckton Foster offered a resolution to the effect that because the Optometry Bill was again about to come up for consideration, and because it was claimed that 75 per cent. of the general practitioners of New York favored the measure, and because those who favored the bill were those who would use this bill as a cloak under which to practise medicine, the members of the Medical Society of the County of New York protested against its enactment, and urged that a protest be mailed to every Senator and Assemblyman in the County of New York, and also that a committee of three be appointed by the president to fight against this and similar measures. The resolution was unanimously carried.

Dr. Frank Van Fleet moved that the committee of three to be appointed by the president should be reimbursed for necessary expenditures from the society after these expenditures had been passed upon by the Comitia Minora. This was unanimously carried.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

190th Regular Meeting, November 4, 1904.

THE PRESIDENT, DR. CHARLES STEDMAN BULL, IN THE CHAIR.

Problems in Dietetics.—Dr. W. GILMAN THOMPSON read a paper with this title (see page 921).

Dr. GEORGE L. PEABODY said he was particularly interested in that part of Dr. Thompson's paper relating to the early feeding of solid food to typhoid fever patients. For many years, the speaker said, he had followed this plan, and he had seen no cause to regret it. His rule in this respect was even more liberal than that of Dr. Thompson, as he did not wait for the temperature to drop to normal before allowing the patients to have solid food. If their general condition was good and they were hungry, he took it for granted that their stomachs were ready for work. Dr. Peabody said he was somewhat doubtful as to whether soft-boiled or raw eggs were as easy of digestion as very hard-boiled eggs. As with milk, a soft-boiled or raw egg had to be coagulated before it could be attacked by the gastric juice, and if the coagulation could be produced artificially by boiling, the stomach was saved just that much labor. By a hard-boiled egg he meant one that was boiled for at least twenty or even thirty minutes, by which time the yolk was reduced almost to a powder and was not pulpy or difficult of attack by the gastric juice. The speaker recalled an instance in which a little girl, who was recovering from typhoid fever in Bellevue Hospital, got hold of a bag of grapes that were intended for another patient. She ate them, skins and all, and in spite of the fact that her temperature was still high and she was very much emaciated, no bad symptoms followed, not even a diarrhœa. It was forty-eight hours before the skins were passed. Dr. Cayley, of England, in a very instructive paper which he read some years ago upon the hydrotherapy of typhoid fever, recited an instance in which a woman became dissatisfied with her boy's treatment at the hospital, so she took him home and fed him on beefsteak, and no accident followed. Every typhoid fever case, Dr. Peabody said, must be regarded as individual, and no hard and fast rules could be formulated that could be applied to all. He did not believe that the early administration of solid food had any influence in causing relapses.

In cases of mitral stenosis and regurgitation, with anasarca, the speaker said he favored small, frequently repeated meals of solid food, and the restriction of fluids. These patients often were able to bear solid food well, and it was a great mistake to keep them on a milk diet, and thus add to their embarrassment by increasing the volume of their blood.

Dr. BEVERLEY ROBINSON said he was very much in accord with the statements made by Dr. Peabody. He recalled a case of typhoid fever where the patient had had a normal temperature for four or five days, and was then allowed milk toast in addition to her usual diet of peptonized milk and broths. This was followed in twenty-four hours by a marked rise of temperature, and an examination of the blood showed a moderate leucocytosis of about 15,000. The temperature and leucocytosis persisted for about three days, and disappeared when the patient was put back on a liquid diet. No inflammatory cause for the leucocytosis could be found, and Dr. Robinson said he had been inclined to attribute it to the digestive process in one who had not had solid food for a certain period of time. In another case which he saw very recently there had been a severe intestinal hemorrhage on the twelfth day of the disease. Her physician had been giving her milk without the addition of a digestive. Dr. Robinson suggested modifying the milk by adding pancreatin and bicarbonate of sodium, and thought that in some of these cases the hemorrhage was the result of the presence of masses of casein in the intestinal tract. For this reason, he always favored modifying the milk by adding pancreatin and bicarbonate of sodium, which would aid in its digestion. He also favored the occasional use of a cathartic, in order to clean out the bowels from above. In the treatment of typhoid fever, as in other diseases, each case should be judged by itself, and he still believed in the idea promulgated by the elder Flint long ago that it was often a good idea in many diseases to allow the patients to indulge in the diet that their experience had proved was suitable to them. The personal equation must never be lost sight of.

Dr. ROBERT ABBE said that while the surgical aspect of dietetics was not as interesting as the medical, he had made certain observations regarding it that were perhaps somewhat peculiar to the surgical field. For example, if a normal and uneventful convalescence was suddenly interrupted by a rise of temperature of perhaps one degree, it frequently indicated that the patient had resumed a meat diet. The first chop or red meat generally produced a slight and transient rise of temperature. In certain cases where a restricted diet had been continued for some time, and had become inadequate to sustaining the patient's convalescence, an incidental delirium sometimes ensued, which could be controlled by stomach tube feeding of concentrated nutriment composed of eggs, beef peptones, etc. In those cases the delirium was evidently the result of starvation. In cases of loss of appetite and progressive weakness following operation, it was sometimes desirable to indulge the patients in their peculiar whims regarding particular articles of diet. He recalled one instance where a college girl who had been operated on was losing ground during her convalescence without apparent cause. One day she asked for a big green, soft pickle, which she said the girls "treated" themselves to at a store near the college. The pickle was brought and eaten with evident relish, and this seemed to be the turning-point in her convalescence. In another case a young girl whose stomach had refused food and who seemed to be in a desperate condition, asked for some pickalilli or chow-chow—a mixture composed of bits of cauliflower, tiny onions, peppers, etc., in mustard—and she consumed a good part of a bottle of this relish. From that time on her appetite returned, and she made an excellent recovery. In both of these cases the gastric function was probably stimulated by these highly seasoned articles of diet which appealed to the palate. In changing from a fluid to a solid diet, Dr. Abbe said he usually began with milk toast, which always proved very gratifying and palatable to the patient.

Dr. EDWARD G. JANEWAY recalled a number of instances in which departure from the usual rules regarding diet produced results other than might have been expected. In one case of gout in which a seizure was occurring every two weeks, the patient had been on an absolute milk diet for nine months. Prior to that the seizures had occurred about once every month or six weeks. A change of diet was instituted, and it was a year before the patient had another seizure. He recalled another case of gout in which a characteristic seizure came on while the patient was under treatment for duodenal hemorrhage. He had never drank alcoholic liquor or smoked in his life, was on a very restricted diet, and had never before suffered from gout. Dr. Janeway also recalled a case of pernicious anæmia in a vegetarian who had not eaten meat for years. He was given laxatives, and instructed to eat red meat. When he returned in the course of a few months, greatly improved, he stated that he had disregarded the instructions regarding meat and had continued to live on a vegetable diet. The speaker said he knew of some cases of pernicious anæmia that had been markedly benefited by arsenic and red bone-marrow, while in others those remedies had failed absolutely. In regard to giving solid food comparatively early in the course of typhoid fever, Dr. Janeway mentioned two patients, a mother and son, who were making an uneventful convalescence and were first allowed solid food on the seventeenth day after a normal evening temperature had become established. Within two days a relapse occurred in each case. This might not have been due to the solid food, although the family attributed it to that, and it pointed in that direction. In regard to diet, no general rules could

be laid down. Each case had to be studied on its own merits. Milk did not agree with some persons, no matter in what manner it was modified; in some instances it invariably produced a diarrhœa, while in others it acted almost like a poison. Some persons had a disgust for milk, sometimes sin and pancreatin to aid digestion.

Dr. Peabody spoke of a porter in the laboratory of the New York Hospital who had an attack of typhoid fever. This was some years ago, when a rigid milk diet was strictly adhered to and no solid food allowed until many days after freedom from fever had set in. The danger of taking solid food had been explained to this patient, but he became ravenously hungry, and he induced one of the maids in the hospital kitchen to bring him surreptitiously a large piece of mince pie every day. This relieved his hunger and apparently gave rise to no disagreeable symptoms, as he made an uneventful recovery. Dr. Peabody said he was inclined to believe that many of the relapses that followed the administration of solid food in typhoid fever would have happened anyway, and that the solid food had put the patient in better condition to cope with the relapse.

Dr. Virgil P. Gibney said the dietetics in the treatment of arthritis deformans and chronic rheumatism had often proved a puzzling problem to him. Many of these patients came to him badly crippled, and gave a history of having been kept on a restricted diet for months and even years, until they had reached a stage of nervous exhaustion and helplessness that was almost appalling. His usual advice to those patients was to eat anything nourishing they liked, and avoid depressing drugs. Under this method of treatment he had seen some rather remarkable instances of comparative recovery. His favorite drugs in these cases were iron and arsenic, with hydrochloric acid, and perhaps pepsin and pancreatin to aid digestion.

Dr. M. Allen Starr said that in the treatment of the lithæmic condition that was not infrequently met with in cases of neurasthenia he thought it was wise to put the patients on a fruit and vegetable diet. This treatment was in line with the "grape cures" that were effected in certain parts of Europe. A fruit and vegetable diet, kept up for ten days or two weeks, could do no harm and was usually very beneficial in these cases. In organic nervous disease, however, restriction of the diet was apt to prove harmful. A patient with locomotor ataxia who began to lose weight usually developed many disagreeable symptoms and was always worse. He suffered more pain and the ataxia was more pronounced. An ataxic patient who was getting fat, was getting better. Various forms of sclerosis of the nervous system were distinctly aggravated by a restricted diet. It was very important, in all forms of organic nervous disease, to increase the nutrition as rapidly as possible, and sometimes even the use of alcoholic stimulants was positively beneficial to these patients.

Dr. Janeway, in reply to a question, said that in a patient with a high tension pulse and a weak, hypertrophied heart, when that organ was laboring, it was sometimes advisable to restrict the amount of fluids. This gave the heart less work. The same was true in some cases of Bright's disease.

Dr. Thompson, in closing, said that some years ago he made some laboratory experiments with various digestives in order to ascertain the relative digestibility of hard and soft-boiled eggs, and he found that while the former were more friable, they were not as digestible as the latter. A more flocculent coagulation resulted from acid digestion of albumin than from heat. Raw eggs, the speaker said, were partially absorbed without digestion, as could be shown by rectal injection. A moderate leucocytosis of twelve or fifteen thousand, such as that mentioned by Dr. Robinson, was quite within the limits of normal digestion; if it had been twenty or thirty thousand, some other explanation would have to be looked for. The most common error in dietetics was to keep the patient for too long a time on any particular kind of diet. This also applied to a continuous vegetable diet, which sometimes resulted in serious types of anæmia. The quantity of fluids taken should always be inquired into. In many cases of arteriosclerosis, the condition of the heart was a very important factor, and together with the arterial tension should govern the quantity of fluid ingested. Dr. Thompson said that any gouty patient would be apt to become anæmic if he was kept for any length of time on a milk diet, and by its long-continued use a large quantity of lactic acid was absorbed into the system. A milk diet was mainly useful in gout because it enabled the patient meanwhile to get rid of an excess of toxic products. Gout was not the uniform result of any particular kind of diet.

Philadelphia County Medical Society.

At a stated meeting held November 23, Dr. Randolph Faries read a paper entitled "Typhoid Fever in Philadelphia." He contended that typhoid fever is not so prevalent in Philadelphia as the reports would lead one to believe. In the first place, cases are reported as such that subsequently appear to be other diseases. In the next place, a not inconsiderable number of cases are imported, having originated elsewhere, as for example, at the seashore. Finally, a number of cases are reported twice, once perhaps by the attending physician and a second time by the resident physician of a hospital to which the patient is later admitted. Dr. Faries expressed the belief that if these three sources of error were eliminated the number of cases of typhoid fever would be reduced one-half, if not more. He held out the hope that with clean streets, good drainage, abolition of cesspools, proper construction and ventilation of dwellings, thorough disinfection of possible carriers of typhoid fever, vigilance with reference to impure milk, food adulteration, and impure water, and instruction of the public as to the foods through which the disease may be transmitted, a time would come when few if any cases of typhoid fever would exist in the city of Philadelphia.

Drs. W. S. Newcomet and J. T. Krall presented "A Case of Trachoma Successfully Treated with the *X*-ray." The patient was a girl, 18 years old, who had suffered from granular conjunctivitis since the age of three. The corneæ were cloudy and vision greatly reduced. Treatment of most varied kind had been employed, but without success; *x*-ray treatment was begun with one eye, for a time suspended in despair, and again resumed, the other eye being treated by other means. It was not, however, until a burn of the eye resulted that improvement in the cornea was observed. This continued until the cornea became quite clear and vision greatly improved, while the opposite eye remained much as it had been.

Dr. L. J. Hammond read a paper entitled "The Value of the *X*-ray in the Diagnosis of Obscure Pains in the Wrist-joint, with Skiagraph of an Old Ununited Fracture of the Scaphoid Bone." The patient was a medical student, who had fallen on the outstretched hand and complained of pains about the wrist-joint whose source remained for a long time obscure. *X*-ray examination disclosed a fracture of the scaphoid bone that had failed to unite, but satisfactory union was effected by means of wire, with relief of the previous symptoms.

Drs. Wm. E. Hughes and R. N. Willson, Jr., presented a communication entitled "Pulmonary Syphilis Simulating Tuberculosis." They reported the case of a strong, vigorous ironworker, who presented cough and hæmoptysis, with physical signs of consolidation of the lower lobe of one lung and an absence of tubercle bacilli from the sputum, and without a history or other evidence of syphilis. Improvement failed to take place until potassium iodide and mercurials were administered. The case was considered as one of syphilis of the lung on account of the exclusion of other causes for the condition and of the effects of treatment.

Chicago Medical Society.

At a meeting, held November 23, 1904, there was a symposium on "Criminal Abortion." Dr. C. S. Bacon read a paper on "The Duty of the Medical Profession in Relation to Criminal Abortion," in which he said it was estimated that from 6,000 to 10,000 abortions were induced in Chicago every year, a majority of which were in married women. Four reasons were given for repressing the practice of abortion: (1) It was an injury to the embryo or fœtus destroyed, for the fœtus was a living human independent being, and had the right to existence which belonged to all human beings, and it should be protected in this right. (2) It was an injury to the mother, for it was an unjustifiable risk to her health and life. (3) It was an injury to the relatives of the unborn child and to the father. (4) It was an injury to the State. To illustrate some of these points, a case of successful prosecution of a midwife for manslaughter was reported. It showed the necessity for obtaining unimpeachable evidence of the existence of pregnancy, and the importance of the dying declaration. The author pointed out the need of maternity asylums for the unmarried. Rev. Peter J. O'Callaghan said the Catholic Church had declared that no man had a right to destroy by any direct act the life of an innocent human being. In the face of a sentiment which had persuaded a large proportion of the medical profession that direct abortion was sometimes justifiable and commendable, that church had unflinchingly declared that the direct taking of an innocent human life was always murder, no matter what be the stage of its existence. He cited the decisions of authorities of the Catholic Church in regard to abortion. John E. Traeger, Coroner of Cook County, stated that the first year of his term he investigated forty-two cases of criminal practice, the second year the number fell to twenty-seven; last year it was reduced to eighteen; but this year it reached thirty-five. He had been instrumental in holding six midwives and one physician for the grand jury this year, and had convicted two. Dr. Charles B. Reed discussed "Therapeutic and Criminal Abortion." He said that in certain cases of beginning and advanced pulmonary tuberculosis, cardiac disease, insanity, severe nephritis, or serious and irreducible uterine displacements with dense adhesions, the operation was justly performed. In cases of absolutely contracted pelvis, when the patient refused cesarean section, abortion was sometimes desirable, although the relative dangers of the two operations did not greatly differ in skilful hands. The results of therapeutic abortion, when executed in a careful, scientific way, were generally good, and the indications for its performance were found both in and out of marriage. Let the legal and moral enactments be what they will, a broad humanity demanded the protection of the mother and the illegitimate unborn babe. He urged the establishment and maintenance of maternities. Dr. Rudolph W. Holmes discussed criminal abortion in its relation to newspaper advertising, and reported a medicolegal case of interest. He said the Society should take an active part in aiding the prosecution of notorious abortionists. Mr. J. M. Sheean, attorney for the medicolegal committee, spoke of the common and statute law of Illinois. He said the law itself was as far advanced as was the public conscience. It was further advanced apparently than the public demand for its enforcement would require, and if anything was to be accomplished, it was not by making appeals to the Legislature for a modification of the laws at this time, but public conscience should be so stimulated as to demand that the law as it stood to-day should be strictly enforced. Dr. Harold N. Moyer discussed the subject, "Shall Communications of Physicians be Privileged?" The communication of a patient to a physician was absolutely unrestricted in Illinois and open to the inquiry of the court; this absolved a physician from all legal responsibility in case he went into court with communications of this kind. He argued against privileged communications in Illinois as applied to the medical profession, saying that the courts would amply protect physicians. Mr. Fletcher Dobyns, Assistant State's Attorney, said the court instructed the jury that every material allegation in the indictment must be proved beyond reasonable doubt. It must be proved that a woman was pregnant, and that an operation was performed to induce abortion. It must be proved that such an abortion was not necessary to save the life of the mother, and that she died as a result of it. It was absolutely essential for a physician to make his examination carefully and preserve his data, so that he could refresh his mind, and be able to take the stand and say with absolute accuracy and certainty that the woman was pregnant. This would help the State's Attorney in proving to the jury beyond a reasonable doubt that pregnancy did exist. The next point to prove to the jury was that it was not necessary to perform an operation to save the life of the mother; and the physician must be able to tell the conditions he found, describe the treatment of the patient, and give reasons clearly to the jury to show why it was not necessary to induce an abortion to save the life of the mother. Furthermore, it was necessary to show that death resulted from the operation by which the abortion was produced. The symposium was further discussed by Dr. M. O. Heckard, Mr. H. H. Hart, Mr. Chas. Allen, Dr. Lucy Waite, and Dr. Rosalie M. Ladova.

Books Received.

Practical Dietetics, With Reference to Diet in Disease. By Alida Frances Pattee. Second Edition. 12mo, 312 pages, cloth. Published by the author, 52 West Thirty-ninth St., New York.

The Medical Epitome Series. Toxicology. By Edwin Welles Dwight, M.D. Series edted by Victor Cox Pedersen, A.M., M.D., 12mo, 298 pages, muslin. Lea Brothers & Co., Philadelphia.

Blood-Pressure as Affecting Heart, Brain, Kidneys, and General Circulation. By Louis Faugères Bishop, A.M., M.D., 12mo, 112 pages, muslin. E. B. Treat & Company, New York. Price, $1.00.

Twenty-Third Annual Report of the State Department of Health of New York, for the Year Ending December 31, 1902. 8vo, 925 pages, illustrated, muslin.

Maps—State Department of Health. Parts 1 and 2. Plates I.—LIX. Sewer System and Sewage Disposal Works. For the year 1902.

Therapeutic Hints.

Lumbago.—The local treatment should not be neglected. A good liniment is as follows:

℞ Salicylate of methyl..... ℥ ij
Tincture of belladonna..... ℥ ij
Laudanum .....℥ ij
Spirit of camphor..... ℥ iv

—*Medical Press.*

Earache.—Drop into the ear a few drops of cocaine, 2 per cent. solution; this will stop the pain at once; should the pain return after an hour or two, repeat the application. —*The Medical Summary.*

Syphilis.—Delker says that the following prescriptions for use in syphilis never cause salivation or diarrhœa, if carefully used:

℞ Hydrarg. proto-iodidi..... 1-4 gr.
Pulv. opii..... 1-6 gr.
Resin. guaiaci..... 1-2 gr.
Quin. sulph..... 1-2 gr.
Ext. taraxaci..... 1-2 gr.
" belladonnæ ..... 1-24 gr.
" trifol. pratens ..... 1-2 gr.
" stillingiæ ..... 1-2 gr.
" xanthoxyli ..... 1-8 gr.
" lappæ ..... 1-2 gr.
" phytolaccæ rad..... 1-2 gr.
Iridis ..... 1-4 gr.
M. ft. pil. No. 1.

℞ Ext. fld. sarsaparillæ.....℥ ss
" " lappæ ..... ℥ ss
" " stillingiæ ..... ♏ xv
" " xanthoxyli ..... ♏ xv
" " phytolaccæ rad..... ♏ i
Pot. iodidi..... gr. xv
Glycerin ..... ℥i
Aquae dest..... ℥ ss
Syr. simplicis q.s. ad. ℥ ss

This prescription may also be used combined with 1-12 of a grain of the biniodide of mercury in cases in which there is a prejudice or inability to take pills. Great care must be exercised by the pharmacist in its preparation, as a precipitate is liable to form.—*The Therapeutic Review.*

Vomiting of Pregnancy.—

℞ Sod. bicarb. ..... ℥ ii
Tr. nucis vomic..... ♏ xlv
Syr. cinnam. ..... ℥ i
Aq. distillat..... ℥ v
M. et. sig.: A tablespoonful every two to three hours.

OEHLSCHLÄGER.

Rectal Alimentation.—Drueck describes Leube's nutrient enema as follows: One part of fresh pancreas and three parts of beef are finely minced and rubbed together into a paste with the addition of a little water. All the fat must be carefully removed. A large-nozzled syringe is needed to inject the mass. The principle underlying this treatment, according to Leube, is that digestion begun outside is continued within the rectum, and only rarely are the products absorbed irritating, and they may be retained ten or twelve hours. Mayet suggests practically the same formula, but with the addition of the yolk of one egg, and adds, "mix and let stand two hours before administering." It is occasionally recommended to add HCl to beef solution and also to milk, but the acid is too irritating and all such artificial digestion must be carried on outside the body. To make the enema recommended by Ewald, beat the whites of two eggs with a tablespoonful of cold water, add one or two teaspoonfuls of boiled starch in one-half teacupful of twenty per cent. glucose solution, a wineglassful of claret, and a teaspoonful of peptone solution. Mix at a temperature below the coagulating point of the albumin. The author has had good results with injections consisting of milk, one-half pint, and two whole eggs, alternating with an enema of pancreatized meat solution.—*The Medical Standard.*

Pain in Gastric Cancer.—

℞ Lactose 1.0
Calcined magnesia..... 1.5
Prepared chalk..... 0.7
Codeine 0.01
Sodium bicarbonate..... 1.0
M. for one dose. —A. ROBIN.

Neurasthenia.—

℞ Sodii glycerophosphatis..... ℥ ss
Calcii glycerophosphatis..... ℥ ii
Acidi phosphorici dil..... ℥ vi
Aq. cinnamoni g. s..... ℥ iv
M. et S. ℥ i.—t. i. d. after meals.

—THOMPSON.

New Instruments.

A METHOD OF GASTROINTESTINAL ANASTOMOSIS.*

BY
J. ALLEN GILBERT, PH.D., M.D.,
PORTLAND, ORE.

WITHOUT discussing the relative merits and demerits of various methods of gastroenterostomy and enteroenterostomy, the present method will merely be stated as briefly and concisely as possible, giving some of the advantages in its favor.

The Anastomosis Forceps used (fig. 1) is merely a Péan's straight elastic forceps in which I had a groove cut in each jaw so that when the forceps blades are closed there results a groove a little less than one-eighth of an inch wide extending through the center of and to the full length of the jaws, as represented in *a* and *c*. The jaws of the forceps are so constructed that the outer ends meet first (*b*), and then as the handles are closed the jaws close to

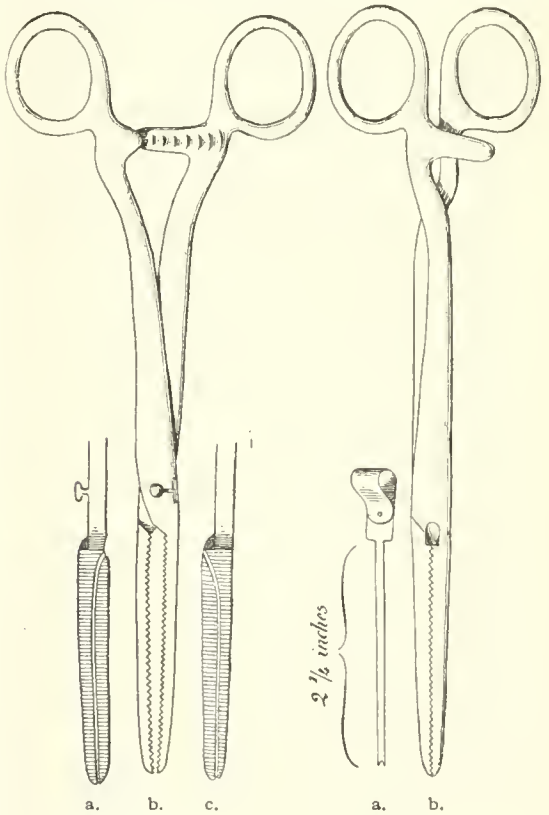

Fig. 1.

Fig. 2.

their entire length under high pressure throughout (fig. 2*b*). An elastic knife made of spring steel (fig. 2*a*) is made to fit the groove when the forceps is closed and is prevented from being pushed in farther than just to the end of the jaws of the forceps by a shoulder on the knife, which also serves as the handle. Thus, with the forceps closed tightly, the knife when introduced into the groove (fig. 3) will cut any tissue in the grasp of the jaws of the forceps.

*During the interval between submission of the present article for publication and receipt of the proof for the same, my attention was called to an article in the *Journal of the American Medical Association*, September 27, 1902, by E. M. Lundholm, of Milwaukee, presents practically the same idea. In explanation of my own position, I can do no better than quote the words of Dr. Lundholm in the article cited: "When I first had my instrument made I was satisfied that it was something entirely new, until a friend of mine directed my attention to an instrument constructed on the same principle by Dr. Ferguson of Chicago. He again claims that his instrument is a modification of a similar one devised by Dr. Grant of Louisville, Ky." Repeated reproduction of the same idea, though precluding claims to priority, is at least some endorsement of its value.

The cutting edge of the knife is in the fork at the end and not on the sides.

Steps in the Operation.—(1) Open the abdomen and bring out the stomach and loop of intestine with which anastomosis is desired.

(2) With a narrow, sharp-pointed knife or with scissors cut a small opening in the intestine just large enough to admit one jaw of the forceps.

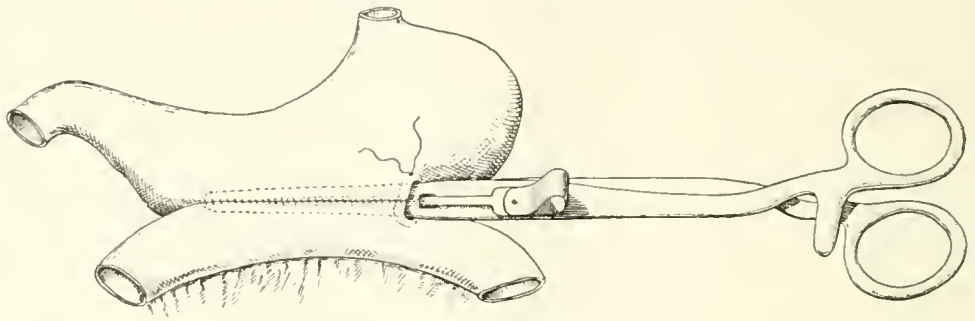

Fig. 3.

(3) Introduce one jaw of the forceps into this opening. (It is best not to take the two blades of the forceps apart.)

(4) Cut a similar small hole in the posterior wall of the stomach where the anastomosis is desired.

(5) Introduce the second jaw into this opening.

(6) Slip the two jaws of the forceps into the intestine and stomach respectively to a depth corresponding to the length of the opening desired in the anastomosis (fig. 3).

(7) Clamp the forceps till the inclosed layers of stomach and intestine are thoroughly crushed.

(8) Introduce a purse-string suture about the openings made in the stomach and intestine and tie the purse-string about the forceps as a whole (fig. 3). (This prevents the contents of the stomach and intestine from exuding, as well as preventing the hole in the viscera from tearing larger during subsequent steps in the operation.)

(9) Commencing at the openings into the viscera and on the side of the forceps opposite the side in which the opening to the groove is found introduce a continuous suture, sewing together the coapted stomach and intestine as far as the end of the forceps. After reaching the end, turn the forceps, together with the stomach and intestine, upside down (fig. 6) and extend the same continuous suture around the end and back to where the forceps entered the viscera.

(10) Push the knife into the groove, thus cutting the tissues grasped by the jaws, viz., the walls of the stomach and intestine (fig. 3).

(11) After withdrawing the knife, unclamp and withdraw the forceps. While withdrawing the forceps push the jaws successively into the cavity of the stomach and intestine. This insures the severance of all the tissues. After releasing the tissues from the grasp of the jaws the forceps may be again closed sufficiently merely to bring the ends of the jaws together and then withdrawn, thus insuring absolute severance of all tissues. These two precautions are really unnecessary, for the knife of my instrument has never failed to cut completely the tissues in the grasp of the forceps.

(12) Cut and pull out the temporary purse-string suture which was introduced to hold the stomach and intestine around the forceps (see fig. 3).

(13) Continue the continuous suture till the hole is closed from which the forceps was withdrawn (fig. 4). Here, in order to turn in the edges, use the Lembert suture, only two or three stitches of which, however, will be needed.

(14) Carry the sewing beyond the knot tied in starting the suture (see fig. 4) and then tie the suture in the usual way, thus leaving only one knot exposed (fig. 5).

(15) Return the viscera to the abdomen and close the incision.

Instruments Needed in the Operation.—Besides those necessary for the laparotomy only the following are needed:

(1) Sharp-pointed narrow knife or a pair of scissors.

(2) Anastomosis forceps.

(3) Straight cambric needle and silk thread.

Advantages of the Method.—(1) Ease and rapidity of making the anastomosis.

(2) Avoidance of contamination by escape of the contents of stomach or intestine.

(3) *Any* sized opening can be obtained. My forceps makes a two-inch opening, but should larger be desired longer jawed forceps can be used.

(4) Minimum handling of the parts. They can be held by the forceps entirely after being clamped.

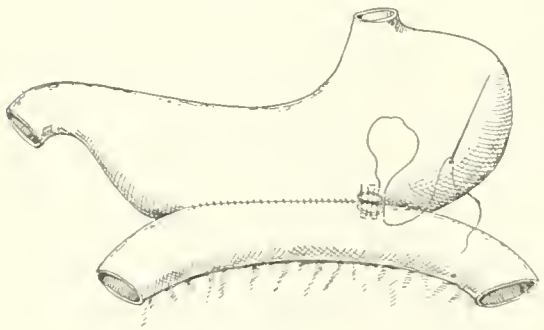

Fig. 4.

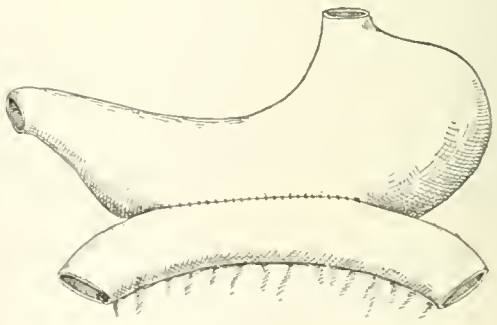

Fig. 5.

(5) Cutting is done within the forceps and therefore within the lumen.

(6) Edges of the opening are smooth and straight and are also crushed everywhere except at the opening for the forceps, where the Lembert stitch is used. This crushing not only helps to prevent hemorrhage and subsequent adhesion of the cut edges, but also

gives more intimate coaptation of the two layers of peritoneum, and thus promotes healing.

(7) Adaptability to viscera of different size, shape or thickness.

Fig. 6.

Suggestions.—(1) Use straight ordinary round sewing needle. It needs no needle-holder and is easily manipulated.

(2) A thimble is a desirable aid to those accustomed to the use of it.

(3) Let the thread and needle be as small as possible.

(4) Be sure to have the needle pierce all the coats of the viscera, for danger of hemorrhage is the principal objection to the method.

(5) Do not make the anastomosis too near the mesentery.

(6) Be sure to get the jaws of the forceps inside the viscera and not between the coatings.

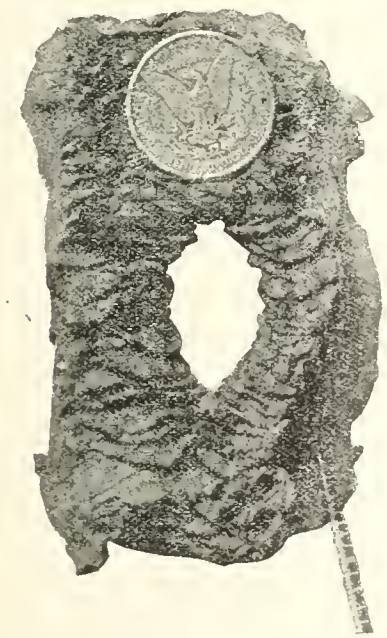

Fig. 7.

(7) Be sure to clamp the forceps to the crushing point before introducing the knife.

(8) The method can be used in enterenterostomy as well as gastroenterostomy.

(9) The method could be used for resection of the intestines by closing the cut ends with a purse-string and then applying the above method for anastomosis. However, there are other methods for this which I consider superior.

Figures 6 and 7 represent two views of intestine and illustrate the stitch and the size of the resulting opening made. The coin, introduced for comparison, is a silver dollar. The process of cicatrization would probably reduce the opening as represented in this specimen, which was obtained from a cadaver and introduced for illustration, and is therefore not the result of an operation on a living subject.*

Surgical Suggestions.

Furuncles.—Hunter describes the following nonoperative plan of treatment of boils: The objects to be borne in mind are: (1) soothing and protecting the inflamed area; (2) the exclusion of air; and (3) antisepsis. To accomplish these take a thick layer of absorbent cotton considerably larger than the inflamed area; on the center of the cotton spread with a spatula an appropriate quantity of the following ointment (Bulkley); this to be laid over the inflamed surface and held in place by strips of adhesive plaster across the ends, but in no case passing over the boil:

Carbolic acid	gr. v-x
Fluid extract ergot	ʒ i-ii
Powdered starch	ʒ ii
Zinc oxide	ʒ ii
Rose-water ointment	ʒ i

The relief which this dressing affords is oftentimes surprising. The ointment soothes and protects the irritated and inflamed area, and the absorbent cotton prevents external friction. If the patient is comfortable the dressing may be allowed to remain intact for twelve to twenty-four hours, and when removed another spread with fresh ointment should be immediately applied. If discharge of pus has occurred, the surface should be gently cleansed with absorbent cotton, but squeezing for purpose of evacuation must not be permitted. In many instances under this treatment the boil is aborted and subsides apparently without suppuration; in others it ruptures spontaneously in a comparatively short time.—*The Medical Age.*

Penile Pain.—Sir Wm. Bennett says that pain in the glans penis may be caused by the following conditions independently of any vesicle disease: (1) Stone impacted low down in the ureter; (2) phimosis with a single small adhesion; (3) anal fissure; (4) rectal polypus; (5) sarcoma of the inguinal region; (6) tuberculous testis. When occurring in conjunction with the latter condition the affection is probably localized in the body of the organ, and the epididymis is not invaded. No other disease of the testicle causes pain in this situation.—*Clinical Journal.*

Epididymitis.—The prophylaxis of this complication consists in the use of a well fitting suspensory bandage during urethral disease, together with attention to keeping the urine unirritating, and the avoidance of all sexual excitement. When late in gonorrhœa, or during the treatment of stricture, complaint is made of a dragging, uneasy sensation in the groin or testicle, the patient should be immediately placed upon his back, with the testicle elevated, and painted with guaiacol and thus the threatened attack may often be averted.—Keyes.

Green Soap for Sterilizing Instruments.—According to Gerson the blades of cutting instruments may be sterilized by rubbing them well with pledgets of absorbent cotton saturated with tincture of green soap. Even infected bougies and larger gynecological instruments may be rendered aseptic by continuing the rubbing for three minutes. If the instruments after being sterilized in this way are firmly wrapped up in the absorbent cotton moist with the soap solution, they may be preserved indefinitely in an aseptic condition. As the solution dries, the fibers of the cotton are closely glued together, forming an air-tight covering, while the surface of the instrument is coated with a thin film of soap left behind by the evaporation of the alcohol.—*Deutsche med. Wochenschrift.*

Beware of small sponging pads in big operations. The larger the sponge the more quickly you can remove blood and discharges, and the less chance there is of leaving one behind in a cavity.—*The Woman's Medical Journal.*

Cystoscopy.—The following points are essential in order to perform a successful cytoscopic examination: First that the urethra will allow the passage of the cystoscope; second, that the passage is clean so that the lens of the cystoscope is not smeared with blood, pus, mucus, etc.; third, that the fluid of the bladder is clear; fourth, that the bladder is distended; fifth, that there is sufficient light; sixth, that the mucous membrane be not touched with the lamp after the current is turned on.—*Medical Standard.*

Induced Radioactivity and Aluminum.—M. Metzenbaum gives the following summary of his investigations: Many aluminum articles were placed on bare photographic plates, and in every instance they produced their own image in from forty-eight to ninety-six hours. The same aluminum articles, when placed on photographic plates, covered with black paper, did not produce an effect on the plate in ten days. The same aluminum articles, when placed on the reverse side of the photographic plate, or when separated from the film by a plate of glass, did not affect the film in ten days. The summary of the experiments of placing aluminum salts, of which there are many, on bare photographic plates is that in no instance was the plate at all affected after ten days. The inferences to be drawn are that when metallic aluminum is placed on the bare photographic plate in the dark, it will produce its own image. Also aluminum will not affect the photographic plate when separated from the film of the plate by black paper or glass, or when placed on the reverse side of the plates. Therefore, aluminum is not radioactive. The action of metallic aluminum on photographic plates is probably either a chemical action or an electrical action between the metal and the albuminate of silver of the plate. This observation, that metallic aluminum, when placed on a bare photographic plate, produces its own image, has heretofore not been pointed out. Tubes of radium were placed in various powders, as bismuth subnitrate, for several days; then these powders were placed directly on the film of the plate, and in no instance, even after ten days, did they show the slightest effect on the plate. The writer believes that these conclusions give positive proof that by suspending tubes of radium of varying strength for long periods in various solutions and various powders, neither the solutions nor the powders are rendered capable of affecting photographic plates. It was not possible to show the supposed induced radioactivity by means of an electroscope.—*Scientific American.*

Pathology of Malignant Growths of the Upper Air Passages.—In a recent discussion on this subject, D. Braden Kyle observes that these growths belong to sarcomatous tissue, and those of connective tissue by the carcinomata or the epithelial type. There has been a great deal of confusion in regard to malignant growths from the fact that we have certain benign tumors that become the seat of malignant growths. That is easily explained. For instance, we may have a benign tumor of the connective tissue type or of the epithelial type. For example, papilloma is of low-grade tissue. It has its type in adult tissue. Papilloma has its type in the epithelial structure, and adult connective tissue tumors, as, for instance, fibroma, has its type in the adult connective tissue. Take adenoma, and it gives us a reproduction of the gland structure. It falls short in one thing, and that is physiological function. That tissue is of lower grade than true tissue, and under irritation predisposes to a malignant condition, whether it be carcinoma or sarcoma. Papilloma occurs at the junction of the skin and mucous membrane, or it occurs at the junction of a fold of mucous membrane. It may occur freely on the surface from such points. It may not always be at the junction, but usually is. There is nearly always a location where it is subject to irritation. The irritation will tend to produce carcinomatous or sarcomatous tissue. One will frequently see, even in this day, articles in journals in which a benign tumor is said to have become malignant. It never became malignant, because a benign tumor is never turned into a malignant one any more than measles turns into smallpox or typhoid fever turns into pneumonia. One predisposes to another. A benign tumor at the point where it is subjected to irritation, a tumor which is not quite up to the standard of type or tissue, will more likely be the seat of malignant growth than if there was no tumor there.—*The Laryngoscope.*

Prof. Röntgen's Modesty.—One of the least self-advertised of scientific authorities is Prof. Röntgen. He has never been interviewed, has never been banqueted, and is even said to have refused immense sums of money offered him by American publishers for a book on what he himself modestly styled "a new kind of ray." Like many other investigators of his race, he carries his years gallantly, and, though sixty, looks more like a man who has led a healthy outdoor life than one who has spent the whole of his manhood in investigating strange physical problems.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 2, 1904.

SMALLPOX—UNITED STATES.

ALCOHOL IN THE TROPICS.

BY MAJOR CHAS. E. WOODRUFF,
SURGEON, U. S. ARMY.

PRIOR to the Spanish war the medical profession in the United States was profoundly ignorant of tropical diseases and conditions, and ignored them in the literature and in the college curricula. This negative fault would not have been so harmful were it not for the absurd opinions they posesssed in matters upon which they were not entitled to have any opinion at all. It was an article of faith in physiology, for instance, that wherever we go in the world we should imitate the native in food, clothing, houses, and methods of work. Upon acquaintance with the native we found him poverty-stricken, weak, undersized, underfed, even half-starved, badly housed, filthy, diseased, and of such lack of vitality as to average less than fifteen years of life. To imitate him as our physiologies taught was merely to die twenty or twenty-five years before we should, and we have been compelled to ignore our alleged authorities.

The false notions are now gradually disappearing in the light of new facts. Take for instance the matter of meat in the tropics. A great blot on the record of the Medical Department of the Army was our stupidity in blindly accepting the orthodox theory that we must cut down these foods below the limit found necessary at home, because, forsooth, the native, dying of nitrogen starvation, did not, could not, get as much as he should. An essay advocating this vicious doctrine was actually awarded a prize, and an Army Surgeon was on the Board of Award. We tried the theory with disastrous results, and nowadays every army officer knows that to avoid the awful exhaustions caused by tropical climates, and the consequent infections, such as tuberculosis, we must have as much animal food as we do at home, or even more.

The stupidity which has brought upon us the most contempt of laymen is that of our former advice as to alcohol. We have long known that a man who takes too much alcohol is poisoned thereby, and that he may die of the acute poisoning or of diseases contracted while intoxicated, for excessive indulgence reduces his resistance to invasion, or he may die of the changes brought about in his tissues by continued over-indulgence, whether he is ever intoxicated or not. We jumped to the conclusion that all alcohol is harmful and useless—a conclusion as silly as it would be to advise a man to take no exercise whatever because many men have died of overexertion.

When we found out that a little alcohol, daily, was oxidized harmlessly and produced energy like the other carbon compounds, we all concluded that in such small doses it was a harmless, though unnecessary, food—barring, of course, Prof. W. S. Hall, of the Northwestern Medical School of Chicago, who claims that nothing is a food unless it can become a part of the material substance of cells, and according to whom some of the foods we eat are not foods. (See *Journal of the American Medical Association*, July 14, 1900.)

Prof. Atwater, in commenting on his own experiments, which prove that alcohol burns in the organism and supplies energy, but does not build up tissue, says it would be called a food according to one's way of looking at it—that is, according to the definition of the word food.

The dean of the Medical Faculty of Paris prepared a paper on the damage done by the excessive indulgence in alcohol, and asserted that alcohol has no use and is always harmful in all amounts, big or little. This was approved by the Academy of Medicine, February 17, 1903, and adopted by the Council of Public Assistance. It excited much wrath among the physicians, and Dr. Léon Meunier, of Paris, published in *Cosmos* (July 4, 1903) a denial of so much of these assertions as relates to small amounts (a quart of light wine in twenty-four hours as a maximum), and asserts that the experience of centuries is to the effect that such an amount is not only harmless, but is a beneficial food, which can take the place of an equal energy in butter and similar fuels, irrespective of the state of rest, work, or any circumstance relating to the consumer. He calls attention to the fact that alcoholism (acute poisoning or chronic disease) never results unless there is immoderate use of alcohol.

The great majority of the medical profession have concluded that alcohol is like every other chemical, whether it be a poison like strychnine or a food like protein—that is, there is an amount below which it is not a poison and above which it is poisonous. Too much table salt is a poison; a little is not. Then we had to change our tactics, and though we advised every healthy man to abstain from all alcohol, we were compelled to confess that a little every day did no appreciable harm. A respectable number of physicians went a step further, and taught that for elderly men, those of feeble health, diseased, exhausted, or in enervating environments, a little alcohol was necessary, as the digestive powers were not capable of digesting enough fuel, and therefore some absorbable fuel ready for burning was necessary, and the alcohol filled the requirements and also assisted the digestion of other foods.

That is where we stand to-day, but there is now another drop in the barometer, a change of wind and other evidence of another storm, which may carry away some of our sails and masts and lay us in the trough of the sea of laymen's ridicule, a butt for their jokes, until we can rig up new masts and sails and head up into the wind again. We need not abandon ship and rebuild, we have merely to reconstruct and repair our theories.

Biologists are pretty well agreed now that animal cells and vegetable cells are not essentially different, except in their methods of obtaining food. The protoplasm is the same in each kind of cells, the functions are alike, and food is used in similar ways. Plant physiologists are coming to the opinion that

a plant cell cannot utilize the hydrocarbons derived from the leaf activities until it has changed them into alcohol, by means of an enzyme, an action identically the same as that of the yeast plant in which an enzyme does the work of fermentation (see *Science,* December 12, 1902). Animal physiologists are now startling us out of our wits by a similar disquieting series of facts, pointing out the same as to animal cells. In the higher animals, the pancreas cells have been specialized to produce this enzyme, which attacks the digested carbohydrates received into the blood, and changes them into alcohol. The body cells, like the plant cells, are wholly incapable of utilizing as a fuel any carbohydrate except alcohol, and if the pancreas is so diseased as to be unable to produce its enzyme, or if it is extirpated, all these sugars drain off through the kidney, producing one form of diabetes. The organism, though bathed in good fuel, is unable to use it, and it dies of lack of energy, unless the diet is so arranged as to present to the cells protein fuel, which they can use. (Dr. Carl Ramus in the *Journal of the American Medical Association*, Feb. 6, 1904.) In other words, we get nearly all our energy from alcohol manufactured in the body in tiny, non-poisonous doses.

In view of these facts what a curious statement for the editor of the *Journal of the American Medical Association* (December 6, 1902) to make when he says: "Alcohol is an irritant of tissue;" whereas, alcohol is probably the chief fuel food that tissue has had for millions of years. Indeed, alcohol may be and probably is the basis of all fat making.

"It is now known that fat is synthesized in the cell from the alcohol and fatty acid that compose it, but is again split up into these components before it can be further utilized or carried away," and this comes from the same journal of February 28, 1903.

If all these investigations are confirmed, they certainly are going to dismantle our present ideas and make us come around to the sensible view that a little alcohol is a good food in our modern civilization which is an environment for which we are physically unfitted as it is so vastly different from the one in which we were adjusted and in which we lived when nature, by natural selection, gave us our present apparatus. We have to eat salt because we are still marine organisms bathed in salt solution, though out of the salty environment in which we lived when animal cells were evolved. A man who would kill himself with too much salt is as great an ass as he who kills himsef with too much alcohol, and the sooner they both die the better.

We are gradually finding out that alcoholism is not causing so many things as we once thought. Dr. R. C. Cabot of Boston, for instance, finds that in arteriosclerosis there is quite a small percentage of cases in which there is evidence of alcoholism as a cause. We are learning that many conditions are coincidences and not the results of alcohol, that alcoholism itself is generally a result of a diseased nervous system, so that, though we believe it to be a potent cause of disease, it is not as great a cause as we once thought.

Now all this applies to the tropics. We know that men who took too much were apt to die just as at home, and that chronics were just as apt to contract erysipelas, pneumonia, or typhoid fever as at home. We also found out that the old hard drinkers were carried off sooner than at home, and jumped to the unwarrantable conclusion that every drop was harmful, even to those who could or should take it at home. Total abstinence in the tropics was an article of faith derived from our teachers. We preached it, and when the laymen found out the truth, how they jeered at us and made ribald remarks about the fool doctors, and how we blamed our teachers and medical editors in the cool north, who, while sipping a glass of claret, wrote smug articles on the necessity of total abstinence in the tropics.

We found out that nearly all tropical people depend on a little alcohol and have little or no drunkenness, which is a fault of northern countries; we found out that Europeans who have been in the tropics for many years instinctively and almost universally used a little; we found some excessive drinkers in young men, but noticed that they didn't die any sooner therefrom than at home, and we found out that the exhaustions of the tropics are so dreadful that a little alcohol is necessary, though we did not believe the Spanish doctors who first told us so. (See fuller details in an article in the *Philadelphia Medical Journal,* April 2, 1900.) We found that the tendency to drink some kind of mild alcoholic beverage was a normal, natural craving of an exhausted nervous system crying out for help. It is precisely like the craving which every race has for some cerebral stimulant, caffeine, coca, kola, betel nut, etc., and every nation has its stimulant.

Then some of us were bold enough to announce the facts, and what a noise was immediately made by the medical wiseacres at home who had never been near the tropics. One doctor actually wrote me that all alcohol was very bad in the tropics, and that he disagreed with me entirely; but he naively said: "I do think that some claret with meals is necessary." A dear lady in Manila said it was nonsense to claim that alcohol was necessary in the tropics, as she found that the only thing she needed and depended upon to keep her up was some Scotch and soda at lunch and dinner.

In spite of the fact that in the above paper it was distinctly stated that the Spanish physicians in the Philippines told us that they had found out that a little wine was necessary, the editor of the *Boston Medical and Surgical Journal* coolly remarked (June 21, 1900) that it was my individual opinion; but, then, had he read the paper he set himself to criticize he would have seen it was not. He evidently belongs to the class of men who cannot enter into the alcohol discussion with an open mind. He also stated that I made little effort to sustain "my views by the opinion of others." Of course I made no such effort. If many of them had the same view the paper would not have been written. It was because we all were wrong and the Spanish surgeons correct that the matter was published. He also stated it was an audacious attempt "to brush aside the results gained by bitter experience during the past centuries." There he was incorrect again in his assertion, for it was an attempt to bring to light and to benefit by the bitter experience gained during past centuries. If he had backed up his opinion by quoting others, he would have been highly successful, for he could get hundreds of testimonials from physicians who had had tropical experience that abstinence is necessary in the tropics, and I do not mean the opinions of physicians who have never lived in the tropics, for their views are, of course, worthless.

We could quote learned ancient astronomers who proved that the sun revolved around the earth, but by reason of new data the orthodox view for some centuries has been the opposite.

Since the old orthodox views on alcohol in the tropics were formulated, new facts have been discovered, and up-to-date tropical experts are taking opposite views to those held fifty or even twenty-five years

ago. Not all of them, of course—that would be impossible. Men over forty accept revolutionary ideas as rarely now as they did in Jenner's time, when it was a notorious fact that in spite of the proofs no physician over forty ever accepted the "fool theory" about vaccination. Under the influence of this ridiculous medical idea the War Department actually issued a warning to the army in 1898 to the effect that experience showed the necessity for total abstinence in the tropics. Nothing has reflected so adversely upon the doctors as that unfortunate lay opinion—a matter which has come back to worry us now that we want and need some alcohol in the canteens in the tropics to keep the soldiers from the awful vino, and the official warning is being quoted by those opposed to the canteen.

But let us see if there are any men who believe that alcohol is needed in the tropics. I cannot quote the numerous physicians who have informed me privately that they accepted my views, nor can I quote the laymen who have told me personally that they have found a little alcohol necessary, for their unprofessional views are worthless as expert evidence. Let us seek further.

Dr. Frederick Semeleder, of Cordoba, Vera Cruz, who was surgeon-in-chief to Maximilian in Mexico, and who was a vice-president of the International Medical Congress in Philadelphia in 1876, and who has had vast experience in the tropics, says (MEDICAL RECORD, October 28, 1899) that alcohol in moderation is a necessity for whites in the tropics.

Henry M. Stanley, in one of his works, the exact page unfortunately cannot be given, states that he found that wine was positively necessary with his meals in Africa, though quite harmful in the day time.

In a discussion on alcohol at the Edinburgh Medico-Chirurgical Society (*Scottish Medical Journal*, 1901) it was said that well-fed Europeans in India generally escape or recover from plague in spite of universal use of alcohol to greater or less extent, while the total abstaining Hindu succumbs to the disease promptly. It is not an argument to use alcohol to prevent plague, but an argument for generous feeding, nutrition being assisted by alcohol to a greater degree than the feeble digestive powers could accomplish unaided.

Sawyer (a layman) in his book, "The Inhabitants of the Philippine Islands" (page 184), mentions the exhaustions of immoderate drinkers, quick onset of delirium tremens, and its frequent fatality, the dangers of drinking in the day, and adds, "Whatever *spirits* you drink, let it be after sunset. I am a believer in drinking *wine* at meals. Having lived for more than twenty-five years in the tropics and having kept my health remarkably well, I feel warranted in giving my opinion."

Science (1891, p. 3) states that alcohol in moderation is said to be beneficial in the tropics, and "Dr. Clark even asserts that light wine is an indispensable part of a hygienic diet." (*Journal Royal Statistical Society*, XIX, p. 75.)

Dr. C. L. G. Anderson (*American Medicine*, March 22, 1902), as a result of his personal experience, concludes: "To those who feel the need of it, I believe a reasonable allowance of alcohol is beneficial in the tropics."

The British *Quarterly Review* (quoted in the MEDICAL RECORD, 1899) states that "alcohol is not more deadly in the tropics than in any other climate," and calls attention to the almost universal opinion that none at all can be safely taken. (See also MEDICAL RECORD, December 22, 1900, for similar statement.)

Drs. Burot and Legrand, of the French Navy, state, in their work on the "Hygiene of the Soldier in the Tropics" (English translation published by Hudson-Kimberly Publishing Company) that wine is an excellent and hygienic drink which forms a part of the ration of the colonial soldier (half-litre), though it is not issued at home except in war. "We are of the opinion that it has its marked place in the ration of the colonial soldier," and that on days of march or fatigue "there is no harm in doubling the wine ration at one of the meals." They are much opposed to rum or brandy, which should be reserved for the sick or those suffering from cold or wet, and even then given mixed with tea or coffee. They consider that in the French Army in the tropics there is an increase of illness from the drinking of undiluted spirits. In the absence of wine they advise that spirits be added to the coffee or tea.

Dr. H. G. Byer, U. S. Navy (*Boston Medical and Surgical Journal*, August 22, 1901), does not believe that alcohol should be given to men exhausted by a tropical climate, but he confesses that he gives it to sailors exhausted by a tour of duty in a hot fire room of a man-of-war. Curious mind has Dr. Byer to reason that what is scientifically correct for sailors is scientifically wrong for soldiers. He had better be sent to Cavite to study tropical exhaustions, as it so happens that in the last twelve months eight officers have been invalided home by reason of it from that most dreadful station. He will learn something of tropical exhaustion there. In the discussion of Dr. Byer's paper (*ibid*) Dr. Edes brought out with approval the fact that it was the unanimous opinion of officers and men in Wolseley's Ashanti campaign that alcohol was harmful on the march, but taken in the evening, when exhausted, it was of some value, and Parkes agreed with these officers that alcohol taken at night might ward off certain diseases occurring with fatigue.

Dr. Byer also mentioned the benefit of keeping alcohol from Malays in Van Heutsz's campaign in Sumatra, and the benefit of giving a very little to the white soldiers, as described by Surgeon M. Filbij (*Archiv für Schiffs- und Tropen-Hygiene*). Yet Byer thinks that in the Philippines, an identical climate, it would not be beneficial.

Now let us get at some new facts. In 1902 I obtained a mass of data as to the physical condition and drinking habits of a regiment of infantry which had been about three years in the Philippines, to which was added two troops of cavalry of about fifteen months' service. Each company commander divided his men into four classes as to health: (1) Those who retained health; (2) those who deteriorated in health; (3) those who were invalided home for disease, and (4) those who died of disease. The drinking habits of each man were also given, as (1) total abstainer, (2) moderate drinker, who was never drunk; (3) excessive drinker, who was occasionally or periodically intoxicated. I know the figures to be as near the truth as it is possible to make them, because officers gave me the data, and their minor personal equations were neutralized; that is, some reported many more men deteriorated than in other companies in identical conditions. The number of total abstainers (1 per cent.) is not as great as in former days, and the percentage who drink excessively is, I believe, about the same as among young men of this age and type in civil life. About 60 per cent. are moderate drinkers.

I must confess to being somewhat disconcerted and disheartened at first by the totals; the excessive drinkers were far healthier than the abstainers, only one-half as many were sent home sick, and only one-

sixth as many of them died. I had hoped to prove the opposite.

	Numbers.			Percentages.		
	Excessive.	Moderate.	Abstain.	Excessive.	Moderate.	Abstain.
Retained health	243	534	56	68	66	46
Deteriorated	86	179	38	24	22	31½
Invalided	22	65	16	6½	8	13½
Died	5	32	11	1½	4	9
	356	810	121	100	100	100

Calculating the percentages of each class according to health gives the following:

	Percentage.			
	Excessive.	Moderate.	Abstainers.	
Retained health	29	64	7	100
Deteriorated	28	59	13	100
Invalided	21	63	16	100
Died	10	67	23	100

We have seen now and then statements from surgeons who have been with volunteer companies in a few days' or few weeks' campaign in Porto Rico or Cuba that the abstainers retained health best of all, the moderate drinkers not so well, and all the heavy drinkers got sick or died. This for a campaign, short enough to be mentioned in hours, rather than days. Here we have prolonged residence, and the figures are the exact opposite; one cavalry officer indeed informed me that in his old volunteer company in the Philippines he was astonished to see all the "soaks" thrive and all the abstainers go under.

If these figures prove anything, they prove that in the terrible depressing, neurasthenic, anæmic conditions brought about by living in a tropical climate, against whose onslaughts we have no protection like the dark-skinned native, a white man who is not assisted by a little alcohol is more harmed by the climate than the man who does get it. Moreover, the damage done to these young men by occasional sprees is not so great as the damage done by the climate to the abstainers. What a lot of mis-statements have we received from our teachers, textbooks, and authorities.

I suppose some medical editors would advise hiding these figures on the ground that they would be an advantage to the whiskey dealers who buy Kansas corn from prohibition farmers. He would no doubt rather see our soldiers die than let them know that a drink of wine at meals might save their lives. Think of the statement that "the claim that the use of alcohol is desirable in the tropics is refuted beyond the possibility of discussion" (*Boston Medical and Surgical Journal*, June 21, 1900), a statement for which there is no basis in fact. There are no figures, statistics, or trustworthy data in existence upon which such a statement could be based.

This attitude in defense of current opinion is dangerously near to the old one, which we hoped had disappeared from New England forever; we can almost hear the echo of that short dark period when its people said: "The claim that there are no witches is refuted beyond the possibility of discussion."

It is a well-known fact that in certain diseased states such as puerperal septicæmia, far more alcohol can be harmlessly and beneficially taken than in health, and the figures seem to show that in the exhaustions of the tropics the same rule holds.

When yellow fever first broke out among the army officers in Havana, it came as a shock to find that the only ones who died were total abstainers, and the drinkers recovered, or escaped entirely. This refers to the first outbreak. I do not know about later statistics.

Only two officers died of cholera in my brigade. One was an ignorant scout officer who allowed his company to drink unboiled water, with frightful loss of life. The other was a careful man and a total abstainer, and was the only officer infected in that neighborhood. There was a notorious little outbreak of cholera among officers near Cavite, in which the abstainers died, the moderate drinker recovered, and the heavy drinker escaped.

But the facts are explained by the experiments of M. Roos, reported to the Paris Academy of Science (*Chemist and Druggist*, April 6, 1901). He experimented with six pairs of guinea pigs, four pairs of which were given wine daily, while the others were provided with the usual food only. He found that in "regard to endurance, weight, strength, number of offspring, and longevity, the tests were altogether in favor of the wine-fed animals." A man, similarly, by reason of a little wine in the tropics is better in endurance, weight, and strength, and is also evidently better able to resist bacterial invasion than the abstainer. Indeed, the symposium on alcohol in the *Boston Medical and Surgical Journal* of March 13, 1902, brings out these facts as proved: (1) Alcohol in moderation aids digestion; (2) first it increases nitrogen waste and then lessens it, and is reflexly a nitrogen food; (3) it burns and gives up energy, and takes the place of the fats and carbohydrates; (4) it is valuable in certain conditions of disease and exhaustion, as after profuse diarrhœa.

The evidence is clear-cut then that by reason of the increased nutrition, alcohol enables men to resist disease in the tropics, and Mircoli even goes a step further, for his experiments with the blood of alcoholics show that it has a greater antitoxic power over tuberculin than the blood of abstainers (*Münchener Medizinische Wochenschrift*, March 4, 1902). Whether the drinkers in the Philippines resisted tuberculosis in greater number than the abstainers, I do not know, but Mircoli's experiments would seem to prove that they would, except those whose tissues had become injured by long continued overindulgence, for Mircoli shows that in such men the blood lost its antitoxic power. Experiments innumerable have been made with other animals, and always with the same result—overdosing with alcohol invariably increases the animal's susceptibility to infections. But these figures show that the slight overdosing of soldiers is not as harmful to the tissues as is the climate of the Philippines to the abstainer.

Dr. W. J. Simpson (*Journal Tropical Medicine*, April 15, 1903) states that alcohol is harmful for newcomers at any time of the day, but worst of all, before exposure to the sun, but is often necessary after some years' residence and must be taken with the meals, preferably with an evening dinner. It is quite likely that during the first few months' residence, while newcomers are in that curious condition of stimulation, due to the climate, which makes them feel so comfortable and energetic, alcohol is harmful as Simpson says, but as soon as the inevitable re-

action occurs and neurasthenia results it is needed, but experience in the Philippines shows that it is needed sooner than Simpson believes.

Dr. Jas. Cantlie (*ibid*) mentions the peculiar stimulation which newcomers experience in the tropics, increasing all physiological processes and making people feel better than they did at home. After six months the initial stimulus wanes and the opposite maintains, which may even need alcohol. He evidently refers to the dreadful and universal neurasthenia, for he mentions the loss of rest and sleep, impaired digestion, and insufficient nitrogen from the absence of fresh meat. These conditions demand alcohol, and yet he says: "Alcohol is a curse in the tropics as at home, and its effects on economy are even more pronounced in a warm than in a temperate climate. The total abstainer has an enormous advantage in the tropics from the point of view of health, and every one who tastes alcohol in any shape before the sun goes down is certainly injuring his health." These two statements are mutually contradictory, for if it is harmless after sundown, the total abstainer cannot have such an immense advantage, and our statistics show Cantlie's opinion to be unfounded.

Perhaps there is an advantage in the water taken in such large quantities by the drinkers. It is a well known fact that those who drink large quantities of water in hot weather or in the tropics are far less liable to sunstroke than others. There is a constant flushing of the kidneys and great elimination of products of the excessive metabolism going on when exposed to heat and light, and it is evidently a great advantage, no matter what we think is the cause of sunstroke. Consequently numerous writers advise tropical residents to drink largely of water. Walffert and also Rubner (*Archiv für Hygiene*, XXXVIII, p. 154) advocate 4½ quarts a day, including the water of fruits. As total abstainers are not likely to consume as much water as the others, they are thus at a disadvantage as to health; nor can plain water be taken in as large amounts as the mineral waters so popular with drinkers, as it causes indigestion and is not so easily absorbed.

People rarely appreciate how bad the climate of the Philippines really is. A few mountain resorts are cool and comfortable, but there are few soldiers there. They must be kept in the hot lowlands, where they are needed. Newcomers praise the climate, for they are in the preliminary stage of stimulation, when they feel extra well and extra vigorous. The newspaper correspondent, Wm. E. Curtis, is the latest recruit to this list of men who consider that the climate has been maligned. The British claim that there is nothing in India so bad as the Philippines, but indeed the most of India is in the temperate zone, and the hill stations are cooler and better than the mountains of Kentucky, nearly as far north, cooler, higher, and with a longer winter. But in the bad stations, they never retain a regiment longer than twelve months, so it is said, the remaining four years of the India tour being spent in the cool stations. It is necessary in our service to keep troops two years in the Philippines and staff officers three years, so that as they have no cool stations as good as in India to go to, it is necessary to resort to every precaution which is likely to enable them to get through unscathed.

In order to be quite sure of the facts in the case, I collected statistics from two more regiments of soldiers who had been more than two years in the Philippines, twelve companies of infantry, and eight troops of cavalry, a total of 1,347 men, and found that the percentages were practically the same as in the previous lot. In this case I separated a fifth class, of men who had actually improved in health.

	Numbers.			Percentages.		
	Excess.	Mod.	Abs.	Excess.	Mod.	Abs.
Improved	10	60	10	3.2	7.0	6.6
Retained	194	471	70	62.2	54.0	46.0
Deteriorated	71	218	24	22.7	25.0	15.9
Invalided	30	95	29	9.6	10.8	19.0
Died	7	29	19	2.3	3.2	12.6
	312	873	152	100.0	100.0	100.0

Calculating the percentages of each class according to health, gives the following:

	Percentages.			
	Excessive.	Moderate.	Abstain.	
Improved	12.5	75	12.5	100
Retained health	26.4	64.1	9.5	100
Deteriorated	22.5	69.9	7.6	100
Invalided	19.3	61.7	19.0	100
Died	12.8	52.7	34.5	100

The abstainers died or collapsed in higher ratios than the moderates and excessives, and deteriorated or retained health in less ratio, but have an advantage in that nearly double the percentage improved than of the excessives; but this advantage is lost again, in that the moderate drinkers showed a higher per cent. of improved health than abstainers. These figures are still more significant in that they include many deaths from cholera, which was believed to be far more fatal to the drinkers than to the abstainers.

Silly people, who have no facts, but who have positive opinions in lieu thereof, generally bolster up their crude ideas by quoting British army statistics, showing that whereas the deaths from alcoholism present a gradual decrease decade by decade, both in India and at home, yet the Indian figures are always slightly the higher. Of course they are, and that brings us to the fallacy in deduction from them.

It is an axiom that none but healthy men should go to the tropics, for the experience of all observers is unanimous that the enervation and destruction of vitality from climatic causes sooner or later breaks down an ill man, no matter what his complaint is, nor how long he has had it. This applies to healthy elderly men, too, for they age rapidly as a rule after one or two years. It applies with startling frequency to the men whose tissues have become sclerosed or fatty—the conditions of chronic alcoholism. Hence, as a rule, the men who had over-indulged for many years and whom we would call alcoholics, whether they had sworn off or not, broke down or died after a short residence. This applies to men who were apparently healthy and good for many years of life at home—only fair insurance risks in the temperate zone, but bad ones in the tropics. The rule also applies to tropical residents who, through over-indulgence, have developed alcoholic tissues since going to the tropics. It is almost impossible to predict how soon an old alcoholic will break down in the tropics. Such a man demands great care at the best to keep him alive, and even healthy men over 35 show morbidity and mortality increasing with age, so that men over 45 should stay home anyhow. In one sad case, a man of 62, who had been an alcoholic for 30 years or more, we predicted a 12 months' stay, and in 17 months his active career was ended by a cerebral apoplexy, though the

preliminary stage of stimulation had caused him to feel better than he had for years.

But what a perversion of the truth, to say that if over-indulgence to the extent of tissue degeneration is far more deadly than at home, then also must every single drop be harmful, and to doubt whether it be possible to obtain scientific proof that it can be beneficial. According to the old orthodox view, too much meat was the cause of liver abscess in the tropics, and, to be logical, one should advise tropical residents to abstain from all meat. There were no deaths from alcoholism reported to me among these men. From the fact that they were all young soldiers, mostly from twenty to twenty-eight years of age, who had not had time to develop alcoholic tissues, we can repeat the assertions, that while some alcohol is necessary in the tropics, and excessive drinking by young men is not any more deadly than at home, nevertheless men with alcoholic tissues die much sooner than in temperate climates.

The young men in the tropics who drink too much are harmed thereby—of course, they are. No one denies that a man is a fool to get drunk anywhere, but a great fool to get drunk in the tropics. The figures only show that the harm done to them by alcohol is less than the harm done to abstainers by the climate. It is a frightfully bad climate for white people, in which, in less than three years, 38 per cent. of the Americans die, are invalided home, or deteriorate in health. Many companies, by the way, reported no men improved in health, and a few companies reported that no one had retained his usual health, irrespective of drinking habits.

Of course some brilliant statistician will venture an opinion that as the figures show that nearly 99 per cent. of the men took alcohol, more or less, it is evident that if they had taken none at all the health record would have been far better. In anticipation we can answer that the asses, mules, and horses have died in far greater proportion than the men, because they were more exposed to the deadly climate and its diseases and could not get alcohol to help them; and at the opposite extreme, the business men and other civilians who can and did avoid the worst effects of the climate by working in houses or in the shade, while soldiers had to be exposed to the sun's rays, had far less sickness and death than soldiers, even though they consumed much more alcohol than soldiers. It is the climate which kills, and now that the war is over and the soldiers are housed more at mid-day, the death and sick rates are decreasing markedly, while the alcohol consumption, as far as I could determine, was increasing. Soldiers in the field cannot get as much as those in garrison.

Formerly, in war times, and probably also at present, there was more drinking in the Philippines than at home, but there has always been less drunkenness. The stories of the increase of drunkenness in the tropics in the daily press are simply inventions. The admissions for acute alcoholism in the United States are 24.63 per 1,000 and only 17.63 in the tropics, and for chronic alcoholism there were 1.21 and .84 respectively. Likewise delirium tremens is less, being .14 at home and .08 in the tropics. There are no records of deaths from chronic alcoholism, as such cases are invariably reported under the name of the terminal infection. All statistics show that drunkenness as a national vice increases from the tropics to the north and is greatest in the north of Europe.

Statistics do not show the relative morbidity of troops at home and abroad; for instance, our reports state that in the last year 12 cases of abscess of the liver occurred in the United States, and 13 in the Philippines, but we are moderately certain that they all arose in the Philippines; nevertheless, the statistics as to acute alcoholism can be relied upon, as the cause is immediately followed by the disability.

A volunteer surgeon is quoted by the *Journal of the American Medical Association* as saying that "the use of liquor in any form in the tropics is unnecessary, except it be the red wine issued by the Spanish Government to their troops," in which the editor makes the comment: "Judging from the condition and efficiency of the Spanish troops this [red wine] would not seem to have helped them much." Let us see! General Shafter's army of regulars was declared by all experts to be the finest and most efficient army ever organized in the history of the world. Nevertheless, about five thousand of these men were successfully fought nearly all day long at El Caney by about five hundred Spanish soldiers, who subsequently withdrew with honor. Later our whole army was brought to a standstill by inferior numbers of these same inefficient Spaniards. Not only was retreat talked of, but General Shafter was compelled to advise allowing these inefficients to withdraw from Santiago, and he held on by reason of orders from the President. (See Col. Wiley's book, "With Shafter in Cuba.") If a little red wine can be even suspected of accomplishing such wonders in these undersized, half-starved, Spanish peasants, why didn't we send a ship-load of it to our men. It would have lessened that awful sickness, which later compelled the return to Montauk. Military experts are unanimous in praising the high efficiency of the Spanish soldiers who inflicted such loss upon our men. But the editor calls them inefficient, and his opinion on such military matters is, of course, far more valuable than that of a mere army officer.

In the tropics a long time ago people were advised not to look upon wine when it is red, and were told that no drunkard could enter the Kingdom of Heaven. But the Apostle Paul, from his experience in the sub-tropics, wrote this to Timothy: "Drink no longer water, but use a little wine, for thy stomach's sake and thine often infirmities." After all these centuries this is the attitude of the men of the present, who have investigated it.

Now let us get down to the practical application of all this. It is reported that the President of Harvard University, in addressing some candidates for positions as teachers in the Philippines, told them that any one who drank alcohol need not apply, as only total abstainers would be accepted. What dreadful and deadly advice! I have been repeatedly called in professionally to see these teachers, and a more horrible condition of health I have never encountered in any people as a class. They were anemic, neurasthenic, and enfeebled. A high percentage have broken down completely, though I haven't the exact data. I only know personally that every woman among them whom I saw was in a wretched state. President Eliot would have had fewer deaths and fewer people in broken health to account for if he had told them that no one would be accepted unless she promised to take a little wine with her meals. His fanaticism has had deadly results. It is dreadful to send women to the tropics to work anyhow. Ripley, the anthropologist, says it is next to murder; but to send them over without the wherewithal to combat the dreadful exhaustions is a felony. Almost all the women come home in a dreadful condition, even though they have had the greatest care. A man who publicly reported that we could safely stay five years has lost his wife and

had a daughter go insane from a fever. I have heard people praise the climate who were themselves in a marked condition of anæmia and exhaustion.

The most important practical point is in relation to restoring beer and light wines to the Army canteen. A few years ago there was an attack upon the canteen system, in which such violent and false assertions were made that the W. C. T. U. combined forces with the whiskey interests and had the wine and beer excluded by law. Then there sprung up around every army post the old liquor shacks, which had been driven out of business by the canteen some years earlier. In these low dives drinks of the vilest kind are kept, and drunkenness is encouraged, so that the soldier has been very seriously injured. Instead of lessening drunkenness, the W. C. T. U. have actually been so misled as to join with the whiskey sellers to increase it. Some of these women have been imposed upon no doubt by the violent assertions made in the heat of that campaign. One dear old lady was so wrought up by the reports that she went to the War Department to know what they were going to do about it. As she seemed befuddled as to the facts she was asked what she meant by the Army canteen. "Why," she said, "that awful tin thing the soldiers carry on a strap over the shoulder and is kept filled with whiskey by the officers so that the soldiers are always drunk." Its real use was explained to her, but it didn't budge her an inch. "I don't care, we want it abolished anyhow."

This is always the result when petticoats interfere in war—a man's business. The poor soldier gets the worst of it.

The W. C. T. U. has done such grand work in other directions that it is a shame they should blot their own record and increase drunkenness anywhere. At present the results are so bad that there is a demand from all parts of the army for the abolition of the law. One doctor in Pennsylvania (*American Medicine,* 1903) wants the army officers to go outside the reservations and break up the saloons—like Carrie Nation—but we do not want to do anything so illegal.

The great obstacle to restoring beer and wine to the canteens in the Philippines is the false attitude of the medical profession, who, without any facts, are asserting that the soldier in the tropics should not have any alcohol, even though it might be tolerated in the canteens in the United States. This paper is written in great part to prove that it is really needed, and urgently needed, in the tropics, and the sooner it is supplied as a hygienic necessity the better it will be.

The soldier, like all other men in the tropics, wants light wine or beer, but at present he takes to vino, which he doesn't like and doesn't want, because it is the only thing available and is very cheap—5 cents a quart. It is a spirit distilled from anything containing sugar or starch, certain palms, rice, molasses, sugar, cocoanut juices, potato, mouldy flour, etc., and its action is that of the worst kinds of new whiskey at home. Having no age nor artificial purification, its harmful effects are dreadful. "Blind pigs" exist everywhere, and cannot be found, as the liquor can be hidden in the jungle. It is doing so much harm, and the establishment of the canteen for beer and wine is such a hygienic necessity that it is a pity we cannot have the law abolished at once. But nothing can be done until the medical profession ceases its foolish and false assertions, that alcohol in small amounts is harmful in the tropics, and will publicly preach that a little is positively needed.

The effects of vino, by the way, are exactly the same as those of new whiskey made from inferior materials at home. There is a general impression that it creates a peculiar nervous condition, and insanity and all sorts of troubles, but there is no truth in such popular ideas. It is nothing but raw whiskey distilled from a fermented sugar. It causes an intense gastritis, and a debauch is thus followed by a thirst which water will not relieve. The sufferer finds no relief until he takes more vino to anæsthetize the irritated nerves. Thus is the spree prolonged, and alcoholism results—that is, the alcohol habit. There is more alcohol taken than in a spree at home, because it is so cheap, and the nervous effects are purely in proportion to the amount of alcohol, and differ in no respects from the acute cases in cooler climates. Vino contains a little wood alcohol and other products from the destructive distillation of cellulose and starch, but the nervous effects are those of ethyl alcohol.

All sensible people, except the liquor men and the farmers, who sell the grain to the distillers, are anxious to put a stop to drunkenness in the United States. But we must make up our minds that we can do no good if we conceal scientific facts. We should know that every fact will aid us, and that we must have the truth, the whole truth, and nothing but the truth. If we conceal the truth we must expect drunkenness to increase in the Philippines. This paper merely refers to health conditions, but from all over the army the cry goes up from officers that the new canteen law has made it more difficult to control soldiers, and has damaged discipline.

It is quite common to hear that the universal opinion of tropical physicians is that no alcohol should be used in the tropics, whereas on investigation we find that they have merely stated that *spirits* in the daytime are bad, and all alcohol in excess is harmful, but that they said nothing of small doses of wine or beer at or near meal time, or may have actually said they were useful and harmless. Consequently, as this is a very vital question to the welfare of the army, we should warn writers to confine themselves to facts and not give groundless hearsay. These questions should be asked of the hundreds of physicians who have had extended experience in the tropics—not a few hours merely:

1. Is alcohol in moderation useful, harmless, or harmful in the tropics; if not harmless, what is the limit of safety; if useful, what is the limit where it becomes excessive? Do you refer to diluted spirits, or to light wine or beer? Do you refer to it taken between meals, at meals, or at night? Give opinions based on facts, and no others.

2. Is total abstinence in the tropics more or less desirable than moderation? Give opinions based on facts and no others.

3. Is excessive drinking more harmful than at home? Give opinions based on facts, and be sure you know how harmful alcohol really is when taken in excess in northern latitudes.

4. Are men with alcoholic tissues destroyed sooner in the tropics than at home, whether they continued drinking or not? Give opinions based on facts and no others.

There are two other views of the alcohol question—the ethical and sociological, both of which are so wholly dependent upon scientific investigation as to be jeopardized unless we publish the whole truth. Every sensible physician is aware of the awful destruction of life, health, happiness, and prosperity by over-indulgence, and he also knows that though he cannot truthfully say that moderate drinking is harmful, he can say that it often, perhaps generally, leads to occasional, or frequent, or even habitual over-indulgence, which may be fatal to a man's pros-

perity, happiness, health, or even his life itself. Hence, good ethics demands that we should preach total abstinence, and give our hearty support to all societies which have this ideal in view—universal abstinence, except for those for whom physicians advise it—the aged, sick, or those in exhaustive surroundings. It is utopian, of course, but not a whit more so than our frantic efforts to prevent all diseases and exterminate every plant or animal which is inimical to man. We cannot accomplish the ideal for a very long time, and it is merely a matter for one's own conscience to determine, whether he shall strive for the unpractical ideal at once, or join the ranks of those who desire the same eventual end but who strive in the present to limit the evil by less drastic means. In the army we are forced, whether we like it or not, into the latter column of workers. We know by sad experience that we cannot bring about total abstinence among soldiers, but we do know by happy experience that we did limit excessive drinking to a very marked degree until we were checked by the extreme wing of the temperance agitators. The army has been agitating for temperance since long before the W. C. T. U. was organized, and it is a shameful falsehood to state that we encourage drunkenness. We have the same end in view, but we know we can accomplish only a restriction at present by driving out of existence the low dives which the W. C. T. U. have caused to spring up.

The temperance reform we are fighting for in the army is on the identical lines found so successful in the great temperance movement in England—the Public House Movement, so carefully fostered by the clergy of the Established Church. It is ably defended by Bishop Henry C. Potter, of New York, who very sanely remarks that as the saloon cannot be abolished, and as it is a very great evil, we must find a substitute for it. He says that "nothing which has occurred during this century has done more to restore to the Church of England the sympathy of the common people and the friendship and respect of the multitudes who are not of her fold than the organization and work of the Church of England Temperance Society." The Bishop advocates in New York City exactly what we advocate in the army as a substitute for the wretched conditions and drunkenness fostered by the vile saloons around army reservations.

In Raleigh, N. C., churches have organized "dispensaries" on the same plan as our old army canteen, and for the same purpose. The people share the profits, the low saloon is driven out of existence, and drunkenness has been decreased nearly 50 per cent. Bapists, Methodists, and other Christians are handed together in this work. Now why cannot the Christian workers of the United States at large join in and help us to reduce in like manner the drunkenness brought about by the W. C. T. U. interference with the identical plan in the canteen.

The conditions of modern society will probably settle the question for us in its own way, in its own time. The sociological view then is all important. A century or two ago a drunkard injured only himself and his family. Society did not bother about it. But in the modern coöperation of society we are wholly dependent upon each other. We are finding out gradually that the moderate drinker is apt to take a drop too much at a critical time, and that the fine adjustment of mental faculties is so disturbed that he is liable to blunder and ruin or kill others. Scarcely a day passes that we do not place our lives in the keeping of a ferry-boat pilot, a locomotive engineer, or a motorman, who might, by a slight defect of judgment, due to alcohol, kill us and scores, hundreds, or thousands of others. As a matter of property interests, railroad owners have long found it necessary to insist upon total abstinence in engineers. Such high wages are offered that they can afford summarily to dismiss the drinker. The result is that railroad engineers are probably the finest body of laboring men in the world. We can trust ourselves to their care and sleep peacefully while whirling along at sixty miles an hour. Business men also are finding out that their interests are better served by abstainers and that they make more money by employing abstainers, even if they pay more wages. Hence, in many walks of life abstinence means higher wages and permanent employment. There are now scores of employments which could not possibly be filled if men drank as they did one hundred and fifty years ago, or even seventy-five years ago. But this is all business. The real sociological point follows.

We are now so congested in cities that even a drunken teamster may kill pedestrians, an elevator man, chauffeur, motorman, electrician, or, indeed, any one of the thousands of men serving the public, may kill us. We see the handwriting on the wall already, and the time is nor so far off when we shall, in self-defense, be compelled to insist that any one who has the power to injure or kill the public by reason of defect of judgment from alcoholic excess shall be an abstainer like a locomotive engineer. If he drinks, he will violate law and be imprisoned like an habitual criminal. So we see that the whole drift of civilization is towards compulsory abstinence in public servants, and by public servant is meant any one who serves the public, even though hired by private parties. If he becomes so feeble from disease or age as to need alcohol, he shall then be pensioned as of no further use to society, and shall pass the remnant of his years in comfort.

Whether society will ever dare to go further and make it criminal for any one to drink, on the ground that a moderate drinker is a menace to society should he accidentally over-indulge, is extremely doubtful, though possible. Stranger things than this have happened. Our forefathers of a century ago would have laughed a man to scorn if he had told them of a coming time when such public servants as locomotive engineers would have to be abstainers.

Many observers think that drunkenness will cease soonest if we only let those with the tendency have all they want and thus destroy themselves, and the race be temperate by natural selection. But this is doubtful, because drunkenness is merely a symptom of a serious nervous condition—practically a disease which is produced newly and constantly in the high pressure of modern society. The symptom is not hereditary in any sense of the word, but the underlying nervous condition is, and there may be some other symptom than drunkenness.

But it is more likely that when society becomes so complex that all of us fall into the category of locomotive engineers, unable to find employment if we drink, then drinkers will eliminate themselves, for they are the least fit for survival. It will be a natural selection due to a new environment.

It is perfectly safe to teach our school-children that, though we cannot prove that alcohol in small amounts is of the slightest harm to the body, the time is not far off when any man who drinks is liable to lose his employment and be ruined. It will be far safer than to tell them the awful things now published in some of their text-books, and which cause them to have so much contempt for temperance agitation.

Now all this applies to the army. A drunken officer is so dangerous that society long ago willed that if he was drunk on duty he should be discharged, no matter whether Lincoln approved of some drinking or not. Lincoln had a different problem—he wanted generals to replace the worthless ones he had, and when he got one he held to him in spite of his drinking, for he accomplished things that the more sober ones were too stupid to do. Drowning men never care whether or not their savers are abstainers. It is now rumored that the early Russian losses in Manchuria were due to the lack of judgment of a drunken officer. So the time is not so far off when the law will go a step further, and society shall say to its soldiers what the railroad corporations said to its engineers: "You must not drink at all; we will pay well to get the proper men, but we must have them." This will come about when society is willing to pay its soldiers the same amount which railroads pay their engineers. But as long as they limit the pay to $13 a month the army will never have that grade of men for its soldiers. If we are too mean to give good pay to our life-savers and guardians, who are constantly risking their lives that we may stay home and make money in safety, then we cannot insist upon total abstinence. Therefore, in army temperance agitation we must do the best we can and limit the drunkenness and fight the W. C. T. U., which has increased it. The American Public Health Association recommended the repeal of the iniquitous canteen law, and this opinion is of greater value than that of a few fanatical women.

But we can do no good whatever if we lie about tropical conditions, tell soldiers they should not drink a drop, and then let them find out we are not telling them the truth. As a little alcohol is needed in those terribly exhausting conditions, we are murderers to keep it from them, no matter what we desire at home, and cowards not to come out openly and advocate it. Let us advocate abstinence for the great majority of people, who, we know, can get along with the internal alcohol manufactured from corn and rye by their own pancreas.

There is still some uncertainty as to the attitude of life insurance companies to drinkers, for the first reports seemed to favor moderate drinkers as better risks than the abstainers, but the statistics have been so violently assailed that one gathers the impression that healthy abstainers are longer lived. But the discussion will not subside, and it is evident that more data are needed, and a separation of different classes. The young and healthy do not need it, and by abstinence are saved from occasional harmful excesses, while there may be an actual prolongation of life by its judicious use by the feeble, in the unnatural environment of civilization. The London *Lancet* apparently advocates the use of light red wine, to counteract the growing tendency to revert to spirits, brought about by modern life.

The editor of the *Journal of the American Medical Association* actually warned his readers against saying a good word for alcohol, and more deplorable advice cannot be imagined. This paper has shown that there is not the slightest inconsistency in advocating total abstinence in the young, and showing its future necessity, and yet advocating the use of alcohol where it is needed. One need never be afraid of facts.

Some years ago we stated that we were not prepared to recommend the addition of alcohol to the ration in the tropics, but from a study of the facts presented in this paper there seems to be no doubt that it would be a wise measure to add about a half pint or a pint of red wine to the ration, and in addition supply the company commander with money to purchase foods locally, in situations where it is impossible to supply the men regularly from the base with fresh meat, and that in every case they should have 2c. or 3c. per man daily for extra purchases to keep their nutrition up to the highest point.

This paper has been given for criticism to two officers, Major Edwin F. Glenn and Chaplain G. H. Jones, of the Fifth Infantry, neither of whom uses alcohol or tobacco. The former has seen men fail in health in the tropics until they used wine at meals under a physician's advice, and he was formerly opposed to the beer feature of the canteen, but from the results of the present system he cordially supports the attitude of this paper. Chaplain Jones, before entering the Army was naturally much opposed to the old canteen, but from his experience in the army in his efforts to save the soldier and protect his morals, he has come to the view that the beer feature of the canteen, though an evil, is infinitely to be preferred to the present conditions, and he now advocates its restoration. I am quite sure that all clergymen who will look into the matter will support him. This paragraph is added with the consent of these two officers.

Among the periodicals which advocate the present system with the low dives which take so much of the soldier's money, is a prohibition organ. The copy before me asserts as its purpose, "to keep calling attention to personal ideals in political life," but its ideals must be very low, for it contains numerous swindling advertisements of quack medicines for the cure of incurable diseases. Of all the swindlers, those who swindle dying men by promises of cure, certainly are the lowest. We must expect such a paper to advocate what is harmful to the soldier, but why it should have any weight with law makers, and why its opinions are considered better than those of army officers who have the soldier's welfare at heart is a mystery.

TWENTY YEARS' EXPERIENCE WITH MANUAL DILATATION OF THE OS AND CERVIX UTERI TO EFFECT IMMEDIATE DELIVERY IN THE LATTER MONTHS OF PREGNANCY.*

WITH PRESENTATION OF A NEW OBSTETRICAL UTERINE DILATOR.

By PHILANDER A. HARRIS, M.D.,
PATERSON, N. J.

More than twenty years ago, while endeavoring to dilate the cervix uteri for the purpose of immediate delivery in a case of placenta prævia, I discovered that with the hand within the vagina, I could with the thumb and the first finger exert a very great dilating force upon the cervical ring. After the uterus, which had first barely admitted my first finger, had thus been dilated sufficiently to allow two fingers to be introduced, I found that, by resting the extended first finger (which was in the uterus) upon the thumb and flexing the second finger (which was also within the uterus), a still greater dilating force could be exerted on the cervical ring.

The power thus obtained is owing to the fact that traction upon the cervical ring is effected by the strong flexor muscles of one or more fingers, while the point of counter traction is upon the dorsum of the first finger, which finger is sustained in a position of incomplete extension by resting upon the ball of the partially extended thumb. In this

*Read at the American Gynecological Society, 1904.

maneuver the flexor muscles of the thumb are the chief factors in the counter traction. So considerable is the dilating force which may be thus applied by anyone who understands this method, that the os and cervix of any uterus of seven or more months gestation may be enlarged, and the child and placenta delivered in an average time of one hour or less, provided the cervix uteri fully admits the first finger at the beginning of operation.

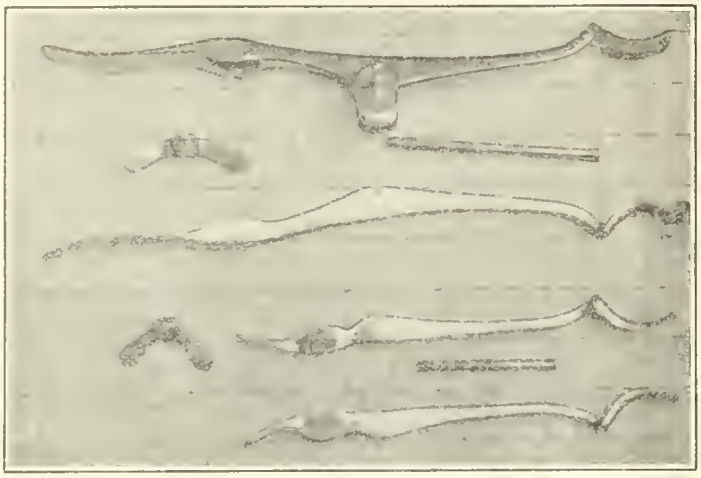

Fig. 1.—The various parts of the dilator. The lines breaking the field into squares are one inch apart, by which the dimensions of the various parts of the instruments can be readily determined.

So far as I know, or have been able to learn, the first written description of this method of dilating the cervix uteri, formed a part of a paper written by me, and read at the Pan-American Medical Congress at Washington, in 1893. I then reported a series of nine cases of placenta prævia, all more or less aided and consequently delivered by this method and without maternal mortality.

After the reading of my paper in Washington, I occasionally met with a physician who told me he had long used the method described in my paper. I always insisted that any such show me the method. Not one, however, has been able to demonstrate it. I am particular to mention this fact to prove that the profession has had many misconceptions regarding this method of dilating the cervix. For such misconceptions I perhaps am more to blame than anyone in that I did not in my original paper succeed in writing a very clear description of the method. A few evidently succeeded in understanding my description, and they have since learned from experience that they can place almost any patient seven or more months advanced in gestation, upon the operating table, manually dilate the cervix, and safely deliver the woman in the average time for all cases of less than one hour.

Having brought out and practiced this particular method of dilatation for more than twenty years, I now wish to make record of some of the more important impressions which much experience has left upon my note-book and memory.

Manual dilatation of the cervix and immediate delivery have been performed mainly for placenta prævia and eclampsia.

In more than one-half of the cases of eclampsia and placenta prævia, I have found the os and cervix uteri at least slightly and often one-third or one-half dilated. In less than one-half, of all the cases in which immediate delivery was advised and practised, there had been an entire absence of both labor pains and appreciable dilatation of the os uteri.* Of the sixty or more cases wherein I employed manual dilatation, not more than twenty-five can be placed in a class wherein neither labor pains nor appreciable dilatation of the os and cervix uteri preceded operation and delivery.

Nine years ago, I collected for presentation (in discussion) at the Philadelphia Obstetrical Society my first ten cases of this class. Six were immediately delivered on account of placenta prævia, and four of them because of eclampsia. General ether anæsthesia was employed in every instance, the anæsthetic being withdrawn at the moment the cervix uteri was sufficiently dilated to encircle the expanded fist. The membranes were then ruptured, and a foot was brought down. Uterine contractions usually rapidly ensued, and the delivery of the child and placenta was accomplished in a very short time. The time employed to dilate the cervix uteri in the cases of placenta prævia varied from sixteen to twenty-two minutes, the average for the six cases being nineteen and one-half minutes. The average time required to dilate the os and cervix in the four cases of eclampsia was twenty-eight and one-half minutes. Of the ten cases, it may be said that the average time required to dilate the os and cervix uteri, from the time the index finger could be introduced, until the cervical ring was made to encircle the expanded fist, was exactly twenty-three minutes.

The average duration of the second and third stages of the six cases of placenta prævia was twenty-three and one-half minutes, while the average duration of the second and third stages of the eclamptics was twenty-seven and three-quarter minutes.

The average time for the three stages of labor in the placenta prævia class was forty-two and three-quarter minutes, while the average time for the four eclamptics was fifty-six and one-fourth minutes for the whole operation.

The average time for dilating the cervix in all ten of these cases was twenty-three minutes, with an additional twenty-five and two-tenth minutes as the average time for the second and third stages of the delivery.

Thus it will be seen that the average time of all cases for the manual dilatation of the cervix, together with the delivery of the child and placenta, was forty-eight and two-tenth minutes. The most speedily delivered case was operated upon in forty minutes, while the longest one required seventy-five minutes. All of the women in this class of ten lived, excepting one, a case of eclampsia. As you will

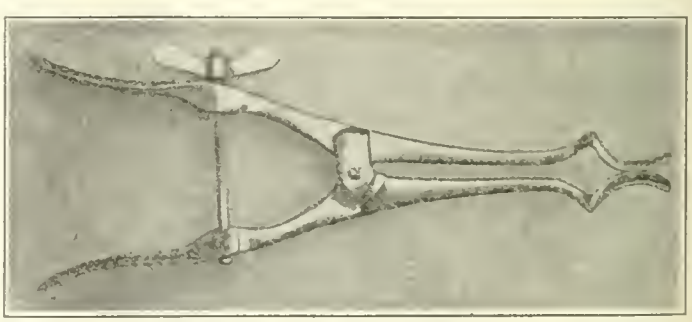

Fig. 2.—The two long or working levers with terminals closed.

* Most of these patients, especially in the past ten years, have been referred to me by their regular attendants.

notice by the appended table, she had been comatose for sixteen hours prior to the delivery.

Although some bleeding occurred from cervical lacerations, in one case only did the loss of blood especially annoy me, or cause apprehension of any particular danger. The case speedily recovered. Of this series of ten cases, only four of the children ultimately lived. The infant mortality is readily accounted for, when we appreciate that the average duration of gestation for these ten cases was less than thirty-four weeks.

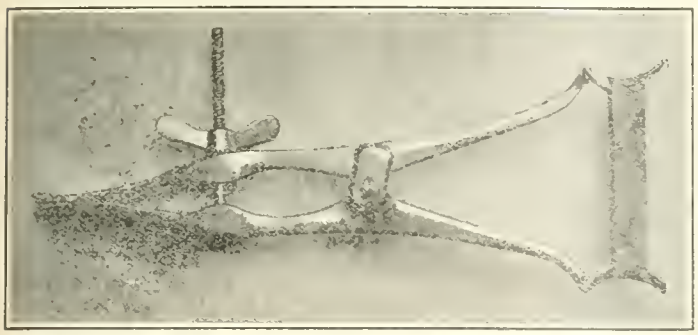

Fig. 3.—The terminals of the long levers opened to the limit of their movements. The rubber band upon the terminals indicates the relation of the cervical ring to the instrument.

Since the ten cases just referred to were reported to the Philadelphia Obstetrical Society, I have performed fifteen other purely elective deliveries. By purely elective delivery is meant, delivery by operation where neither labor pains nor any appreciable dilatation of the cervix uteri had occurred.

The method of manual dilatation, which I have employed, presupposes the possibility of introducing the whole hand within the vagina, and the index finger into the cervix to the metacarpophalangeal knuckle.

I have met with three women, all primiparæ, whose vagina did not admit my hand without laceration of the perineum, and to some extent the vagina. (My hand measures about seven and three quarters of an inch glove measurement.)

For want of a proper lubricant and a Goodell or other cervical dilator, I once failed in the attempt fully to introduce my first finger into the cervix uteri. The anæsthetic was withdrawn, the patient sent to the hospital, and successfully delivered as an elective operation one week later.

I prefer sterile soapsuds or sterilized and diluted tincture of soap as a lubricant for the hand. The perineum and vagina are less likely to be lacerated if the hand is slippery.

The fingers of the dilating hand should exert so far as is possible tonic strain upon the cervical ring. Spasmodic jerks or momentary out-thrusts of digital strength should never be practised. When the first hand grows tired, withdraw it, and introduce the other. When this becomes fatigued, change to the first hand, thus maintaining, as far as possible, a tonic strain upon the ring.

While the tonic strain upon the cervical ring is being properly exerted, the fist of the working hand itself occupies a perfectly passive position in the pelvis. On one occasion, having exhausted much of the strength of both my hands, I asked a most intimate friend and colleague, who chanced to be present, to relieve me. He and I both supposed that he was familiar with the particular method which I employ, but from the continual alternating, inward and outward movement of his arm at the vulva, and a more particular examination of his capabilities, I found that he did not at all understand the method.

There is danger of lacerating the cervix uteri by this method. I have myself, in a few instances of the sixty or seventy women thus operated upon, caused appreciable laceration of the cervix. Inattention to certain cautions which I am now trying to emphasize might surely result in embarrassing if not dangerous lacerations.

There is probably little risk of lacerating the cervix until after it has been sufficiently dilated to admit three or four fingers. When the cervical ring is enlarged to that degree, the amount of force which was hitherto necessary and safely employed begins to become dangerous if continued. So that, from the time three fingers and the thumb are admitted to the uterine cavity (when the circumference of the cervical ring will be found to measure from six to seven or eight inches), the cervical ring will not only be found to dilate with less force, but it is desirable that less force be applied in order that tearing or undue lacerations may be avoided. I am convinced that in my earlier operations I generally used too much force in effecting the dilatations. Some uteri can doubtless be safely dilated from the size of one's first finger to a circumference of eleven or twelve inches in twenty-three minutes, which was the average time for my first ten cases of purely elective delivery. Other cases, especially such as have not advanced much beyond the sixth and one-half, or seventh month, yield so slowly that one hour or one hour and a half may be required to effect full and harmless dilatation. I should say that fifty minutes might be taken as an average time for safely fully dilating the cervical ring in purely elective delivery, and twenty or twenty-five minutes more for the completion of the second and third stages of labor.

My experience with placenta prævia embraces twenty cases, with but one maternal death. In a small proportion of the cases only was very much blood lost while dilating the ring. If in any case of placenta prævia alarming hemorrhage should occur while effecting dilatation, I should at once withdraw the anæsthetic, rupture the membranes, bring down one foot, and allow the uterine contractions to effect the delivery. In no instance have I thought it necessary to resort to this encroachment upon the application of the Braxton-Hicks method.

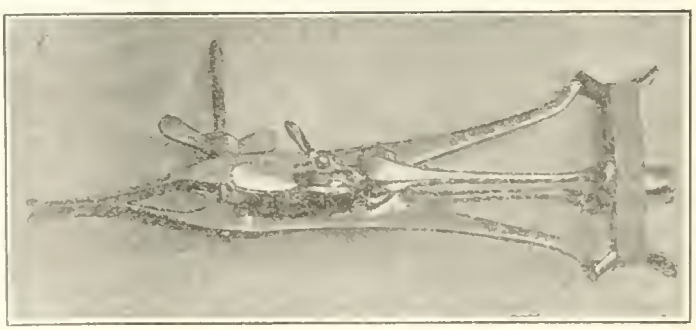

Fig. 4.—The short levers set in place on their fulcrums.

My tendency in more recent years to employ a longer time for the dilatation is but the result of experience, which has taught me that the risk of lacerating the cervix is greatly diminished by less speedy work.

It is the continual or tonic strain upon the cervical ring which dilates it. If the fingers and hand tire,

so that they cannot exert a moderately equable and continuous pressure, the work of dilatation lags. He whose hand can only exert a pressure for one minute, and must then be rested for three minutes, resumes the strain for one minute more, and rests again for three minutes, and so along until the uterus

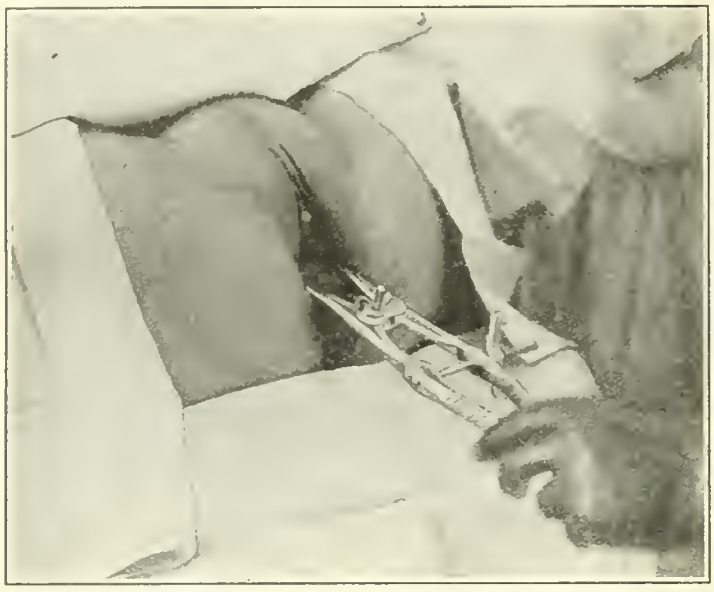

Fig. 5.—The proper position of the long levers while in action. About one-half of the dilatation possible with them has already been effected. (Taken in the preparation for delivery on account of placenta prævia.

is fully dilated, should take about three times as long to safely dilate the cervix as the operator whose hand can exert the necessary unremitting pressure for three, five, or seven minutes, and can find that hand rested after the other hand performs a similar task. Probably some hands are weak, or tire so rapidly, that they are illy suited to the performance of manual dilatation of the uterus.

If at any stage in the task of dilatation the operator finds the cervical ring suddenly yielding, he is entitled to the presumption that he has unintentionally lacerated the cervix uteri.

It has been my custom in all cases so fully to dilate the cervix that it is not likely to offer any obstruction to the passage of the larger portion of the child.

I prefer, and have usually employed, general anæsthesia, produced by sulphuric ether, and have always entirely withdrawn the anæsthetic at or before completion of the dilatation. It is doubtless an advantage to allow the patient to recover somewhat from the anæsthetic before rupturing the membranes. I seek to bring down one foot, and turn the child while the waters are escaping. Version, however, is often uncalled for, and might be dispensed with. The chief object in having the patient partly out of the anæsthesia before rupturing the membranes is that nature may exert more of its force, to aid not only the expulsion of the contents of the uterus, but that the physiological contractions of the uterus may be more pronounced and the dangers of intrauterine hemorrhage thereby lessened.

Any condition of the patient calling for an immediate or elective delivery is from the very nature of things in itself serious, consequently any art which must be resorted to for the purpose of lessening the danger to the life or lives in interest should be skilfully and cautiously practised.

I believe that general anæsthesia in labor predisposes to intrauterine post-partum hemorrhage. My preference for ether to chloroform is based upon a belief that the latter is more injurious to uterine muscular tonicity than is the former. Whether previous post-partum hemorrhage follows a physiological or manual delivery, it has been my custom to at once widely open the vagina with a speculum or retractors, drag down the always patulous cervix uteri and ascertain the source of bleeding. If the blood pours from a laceration of the cervix, I insert with a curved needle the catgut ligature at bleeding points. If needles and suture material are not at hand, and the demand for action appears very urgent, I grasp the bleeding point or points with one or more vaginal hysterectomy clamps. The forceps are removed on the day following. The amount of blood already lost, as in placenta prævia, or the rapidity and weakness of the pulse at the wrist, may require that we not only avoid any further waste of blood, but that we also support the circulation by throwing a quantity of normal salt solution in a vein.

In no instance can I remember of having accidentally ruptured the membranes while accomplishing manual dilatation of the cervix. One inexperienced in this work would suppose that the membranes would frequently be unintentionally ruptured while effecting the manual dilatation.

In total manual dilatation one must change from one hand to the other from five to ten or more times, according to the rapidity with which the hand fatigues.

For many years I have not reintroduced a hand without rewashing and resterilizing it. If gloves

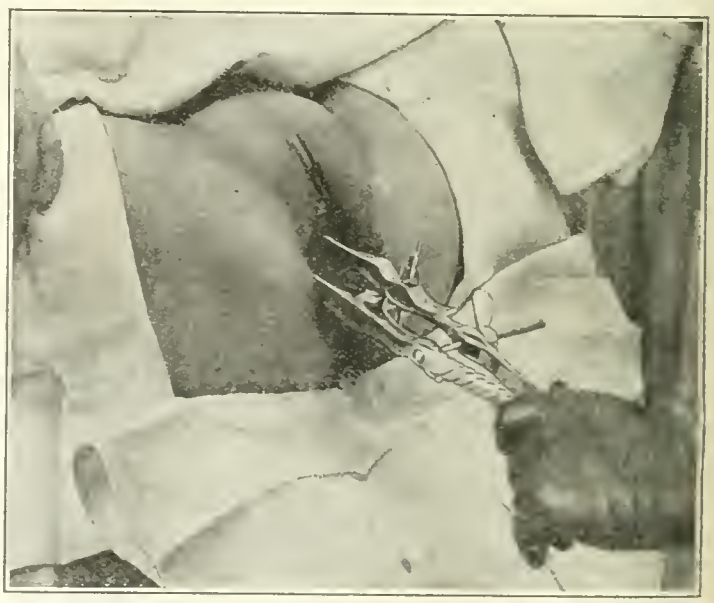

Fig. 6.—Full expansion of long levers with the short levers placed in position and ready for the transference of the partly dilated cervical ring from the long levers to them.

were worn, a freshly boiled glove was put on for each succeeding introduction of the hand, while the vulva was frequently irrigated with physiological salt solution, and occasionally with a solution of bichloride of mercury. The especial reason for irrigating the vulva with salt solution was that any escape

from the rectum might be carried downward and away from the vagina. The stretching of a towel to cover the anus is of little value in protecting the ingoing arm from any discharge from the rectum, unless it is of several folds, and its upper border held by the fingers of the assistants in such manner as to

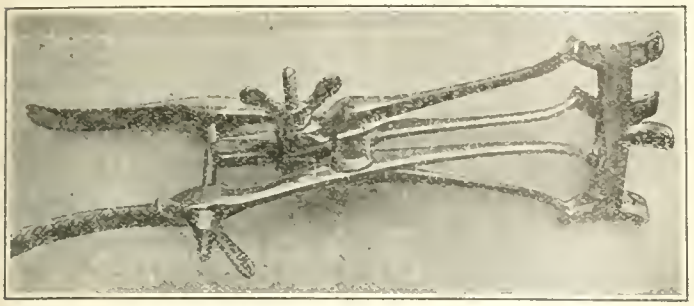

Fig. 7.—Transference of the partly dilated cervix from long to short levers.

effectually form a dam across the perineum between the introitus vagina and anus. No attempt should be made to cover the rectum, but the energy of the assistants should be directed to thus draping a few folds of sterilized linen and holding it by firm pressure against the perineum. Notwithstanding all this care, however, the nearness of the rectum to the ingoing hand and arm would seem to expose the patient in a degree at least to the dangers of septic infection. I regard the necessarily repeated introduction and withdrawal of the hand as the most objectionable feature of manual dilatation.

With this brief review of my own work, which has been and may be so easily imitated by others, and which has the one and very great characteristic advantage of being non-instrumental, I wish to direct your attention to another method of effecting dilatation, but which possesses one very serious disadvantage, and that is that, unlike the hand, we may not always have it with us when required for use.

The instrument which I present was recently devised by me, and with it I have since effected two purely elective deliveries. One for a case of small and contracted pelvis, where in the interest of the child the birth was precipitated at the thirty-seventh week. The other, a case of placenta prævia between the sixth and seventh month of uterogestation.

The instrument consists of two levers about twelve inches long, with a fulcrum near the center of each. One of these long levers has a pin through its center, either end of which serves as a fulcrum for the two short levers, which move in transverse plane to that of the long levers. Each pair of levers is provided with a bolt and thumb-nut, with which to hold all advancement gained. The spring or resiliency of the levers effects the tonic strain upon the cervix ring.

The limit of expansion upon the two long levers is about four inches, which, of course, effects a dilatation of the cervix, amounting to about eight and three-quarter inches circumferential measurement.

In the middle months of gestation the cervix may be dilated sufficiently by this pair of levers to permit the escape of the uterine contents; but for purely obstetrical purposes, from the thirtieth week of gestation onward, the cervical ring should be dilated from eleven to twelve inches in circumference. When the limit of expansion possible with the long levers is attained the two short levers are introduced.

By the combination of the two pairs of levers the cervical ring can be dilated to twelve inches. The levers are introduced one after another in the following manner: While the vagina is being held open with a speculum or retractors, grasp the cervix with a hook or traction forceps. If the cervix will not admit both the long levers, it must first be sufficiently dilated with a Goodell or other cervical dilator.* So soon as the cervix will allow introduction of the two long levers, lock them at the fulcrum, set the bolt in the handles, approximate the hand-parts, and hold them in place with the thumb-nut.

About every two minutes by the watch reapproximate the hand-parts of the levers, turning the thumb-nut by the merest touch of one finger until it is again arrested upon the lever. The spring or resiliency of the levers bears such relation to the naturally yielding character of the cervix that renewed pressure upon the proximals of the hand-parts, after each succeeding interval of two minutes or less, will permit the thumb-nut to be turned for about one-quarter of a revolution.

My dilator as at present made is without a pelvic curve, so that from the moment it is applied until the dilatation is completed the operator or his assistant should maintain a slight but constant pressure downward upon the perineum; but he should also at the same time steadily but slightly continue to press the instrument upward in the pelvis and against the cervix, in order that the cervical ring may not slip off the terminals.

All my experience in manual and the slight experience in instrumental dilatation of the cervix in the latter months of pregnancy convinces me that at the beginning of dilatation far greater force is required than at later stages of the task.

From a series of tests of the strength of my own hand as applied in manual dilatation, and also from a study of the force exerted upon the levers of my

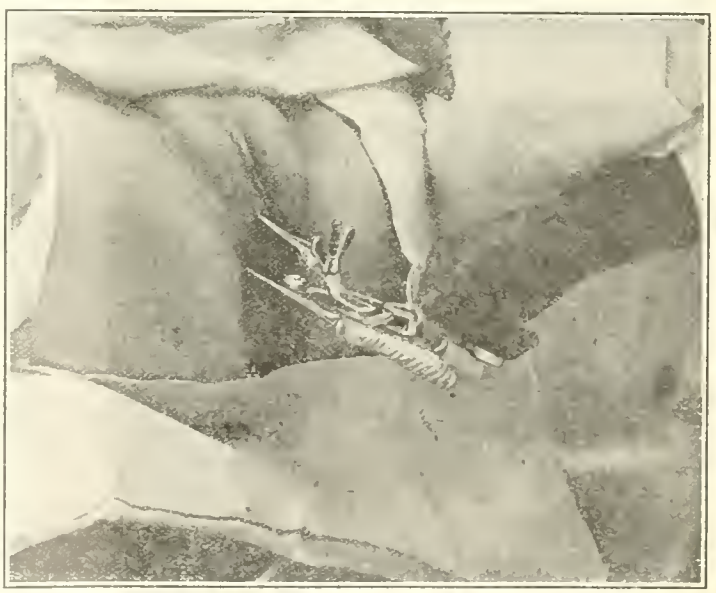

Fig. 8.—The position of the short levers after transference to them of the strain from the long levers. The hand-parts of the long levers appear widely separated and are ready for their reapproximation required for a continuance of the dilatation.

dilator, I judge that in the beginning of dilatation of the cervix uteri from fifteen to twenty pounds of

* The writer has already devised extension tips for this instrument, which may be momentarily attached to it, and used to dilate the cervix sufficiently to first admit the long levers, thus dispensing with the need for a Goodell or other dilator to begin the dilatation.

counter traction are probably not only bearable, but requisite, for the proper advancement of dilatation. As the cervix grows larger less force is required.

So that when the cervical ring has been dilated to a circumference of six or seven inches I judge that a counter traction force of from ten to fifteen pounds is not only sufficient to carry along the work of dilatation, but that this compression may be reapplied after shorter intervals than was possible in the earlier stages of the task. A gradually diminishing force is not only advised in the finishing stages of the dilatation, but this lessened force will be found to increase the dilatation more rapidly than the greater force which was applied at either the beginning of dilatation or in the middle stages thereof.

I am particular to direct attention to my assumptions in this relation, for by so doing I may prevent the inexperienced from applying undue force in the latter stages of dilatation, whereby unnecessary lacerations of the cervical ring might be effected. This caution is directed even more to the manual than the instrumental operator, for the reason that the strain exerted by the fingers upon the cervical ring cannot thereby be so definitely gauged as by that exerted by one finger and a thumb upon the proximals of such an instrument as I have devised.

When the limit of dilatation possible with the two long levers is reached, the two short levers are introduced, and the bolt set and tightened with the thumb-nut. The next step is to gradually release the strain upon the long levers, and to just as rapidly take up with the short levers every particle of slack in the cervical ring. In this manner continue the transference from the long to the short levers, until the proximals or thumb-parts of the short levers are together. We thus, without much risk of dislodging the cervical ring from the instrument, practically transfer the strain and distention of the cervix from the long to the short levers.

Fig. 9.—Position of fall levers when the cervical ring has been fully dilated by opening for the second time the terminals of the long levers.

This accomplished, renew the intermittent approximation of the hand-parts of the long levers, holding every succeeding gain with the gentlest turn of the thumb-nut, to which must never be applied more force than is possible with the touch of a single finger. Almost before the full limit of the four levers is atained the unruptured membranes will present themselves to view at the vulva.

Thus the work of dilatation, if slowly effected, is accomplished easily and safely, and the uterus afterward so rapidly emptied that I feel as though I should never again employ manual dilatation, if this dilator is at hand.

By the use of two simple levers, with the fulcrum near their centers, the dilating strain upon the cervical ring nearly equals the pressure exerted by the hand upon the tips of the hand-parts. The instrument thus constructed when used at once becomes an educator of the senses required for its proper employment. Obstetrical dilators, in which the strains are effected with a screw, are undoubtedly open to the very serious objection raised by Dr. J. Whitridge Williams, and possibly others, that one has no idea of the amount of force or strain thereby exerted upon the cervical ring.

Conclusions.—If the condition of any patient is such that elective delivery is desired and advised for her, the delivery can be effected by first fully dilating the os and cervix uteri, either with the hand or by a simple multi-lever dilator.

The strain upon the cervical ring should not be too strong, and as nearly equable and constant as possible. Some uteri may safely yield to the mechanical strain exerted by the operator, and dilate as much in thirty minutes as will others in ninety minutes.

The greatest strain, possibly fifteen to twenty pounds, is needful in acquiring the first four or five inches of dilatation. As the cervical ring enlarges beyond this point the strain should be gradually diminished.

Any strong hand employing the particular method practised by the writer is doubtless capable of lacerating the cervix after its ring has been one-third dilated.

Fifty minutes may be taken as the average time required to dilate safely the os and cervix uteri from the size of one's finger to a circumference of twelve inches. Twenty-five minutes should be the average time for rupture of the membranes and delivery of the child and placenta.

The hand can never be made to exert the continuous and equable strain upon cervical ring which may be imparted by a properly constructed simple lever dilator.

The instrument which effects a moderate but steady and unremitting strain, and in which the operator balances the strain on the proximals of the levers, is probably the ideal method of effecting rapid dilatation.

In the latter months of gestation the cervical ring should be so enlarged that it is not likely to offer any obstruction to the birth of the child. The occurrence of alarming hemorrhage in placenta prævia may demand more rapid enlargement of the cervical ring than is generally advised for other purposes, while version and bringing down one foot before very much dilatation is effected may be the measure requisite to avoid further loss of blood and save the mother.

This instrument will be provided with movable tips, so constructed that they can be momentarily attached to the terminals of the two long blades, and so shaped that they will serve to dilate any cervix which is not large enough to admit the broader terminals of the two long levers, as you now see them. Furthermore, the instrument will also be provided with a dial to register the number of pounds of strain upon the cervical ring, and this weighing device will be so adjusted that the amount of tension will be shown at any stage of the dilatation.

Although I have assumed that a given number of pounds of strain are requisite for the accomplishment of dilatation of the cervical ring, I wish to emphasize the assertion that such estimations may be open to considerable modification by me, or by others who may hereafter work with my improved dilator, whereby the exact number of pounds of strain may be noted as frequently as the operator desires from the very beginning to the completion of dilatation.

ADVANTAGES AND DISADVANTAGES OF MANUAL AND INSTRUMENTAL DILATATION OF THE OS AND CERVIX UTERI IN THE LATTER MONTHS OF PREGNANCY.

The Hand Method.	*The Instrumental Method.*
The hand is always with the operator.	It is an instrument for which the general practitioner would have but little and infrequent legitimate use.

Most but not all hands are strong enough to apply the force required for dilatation. Because of the fatigue, the counter traction strain is more or less irregular.	Always ample in force. Maintains a continuous and equable strain upon the cervical ring without fatigue to the operator. Constantly indicates the strain in pounds as shown on the dial.
Can not be sterilized by boiling, although the rubber gloves, if at hand, can be thus sterilized and worn.	May be sterilized by boiling.
Hands must be rested, thus requiring, in some cases, twelve or fifteen introductions of the hand within the vagina, loss of time, and some risk of infecting the patient.	Unless the cervix is so small as to require the tips to begin the dilatations, the instrument is introduced but once, and is not removed until dilatation is completed. With vaginal retractors and a hook the instrument can be introduced without passing the fingers into the vagina.
Some vaginæ are too small to admit the hand without laceration.	Every vagina should admit the instrument, and tolerate its expansion, so far as its use for dilatation may be necessary, without injury.
The operator forms indefinite ideas of the amount of force exerted on the cervical ring.	The operator may read at any moment the amount of force exerted on the cervical ring.

AN INTERESTING CASE OF TUBERCULOSIS OF THE LARYNX.

By E. HARRISON GRIFFIN, M.D.,
NEW YORK.

LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE NEW YORK UNIVERSITY AND BELLEVUE MEDICAL COLLEGE.

Tuberculosis of the lung may run a course of years, resulting either in the recovery or the death of the patient. Tuberculosis of the larynx generally runs a short, quick course of a few months, or a couple of years, ending usually one way. This is especially true when the disease has not been early diagnosed and proper treatment advised. I had one clinic case of laryngeal phthisis, when the ulceration was held in abeyance for three years. The tuberculous sore in the larynx never completely healing during this period. It would partly heal, then reulcerate, and then partly heal again, this see-saw condition lasting for three years.

Patient A., male, aged 23, was brought to my office some five years ago, complaining of a severe cough, loss in weight, night sweats, and an inability to swallow on account of the intense pain produced in his throat, when he attempted either to drink or eat. The patient was very much emaciated, and had to be supported to my chair for a laryngeal examination. His face and feet were swollen, indicating the last stage of the tragedy. His voice was so low that it amounted to only a whisper. He had his hat on while his friends were helping him to my chair, and it had sunk low down on his neck, so that the hat extended from the frontal bone in the front to the lower part of the occipital bone in the rear, a mark generally of old age or of extreme emaciation. His eyes were dull, and seemed to be covered with a film, showing that dissolution was fast approaching.

An examination of his throat showed the pharynx, the soft palate, and the larynx involved in tuberculous ulceration. There was no prognosis. He had been brought to my office by his friends, to see if it was advisable for him to be sent to the mountains to obtain a cure. I opposed this suggestion, and told them to retain their brother at home, as the end was only a matter of a few days. The patient was admitted to the St. Joseph's Home for Consumptives, where he died four days afterwards. This patient had had his cough for one year, pain in his throat (one of the first attending symptoms of laryngeal phthisis) for three months. Thus the tuberculosis of his larynx had a rather rapid course. Treatment in his case had been neglected until the last moment, when medication was fruitless.

Laryngeal phthisis can be divided into three stages: first, the œdematous, or primary stage; second, the deposit of the tubercle, or stage of infiltration; third, the breaking down of the tubercle, or stage of ulceration.

Five days after this visit, Mr. A.'s brother applied at my office to have his throat examined, as he also had been complaining of a cough for the past two months, had had night sweats, had lost over ten pounds in weight, and had had pain in swallowing.

He was rather a small man in stature, very slight of figure, weighing not more than one hundred pounds. An examination of his chest showed marked dulness on percussion, and slight cracked-pot sound at the apex of the right lung. In both sides of the chest, anteriorly, there were numerous coarse râles. The respiration was exaggerated, and the expiration prolonged. The patient had a fever ranging from 101° in the morning to 103° in the evening, and was taking little nourishment, as he experienced such pain in degultition.

An inspection of his sputum showed innumerable tubercle bacilli. An examination of his larynx disclosed a thickening of the mucous membrane, and some œdema of the arytenoid bodies, with a deep ulcer on the right arytenoid cartilage. His epiglottis showed an extension of the tuberculous process, with an ulceration at its lip. The mucous membrane was bathed in a profuse purulent secretion. His voice was reduced to a low whisper. The general condition of this patient was far from favorable. I treated his larynx at my office, and directed him to give up his business, which was in Brooklyn, and to move permanently to Colorado. He followed my instructions to the letter. He took up his residence in Denver, and stayed there eight months, when he came East to sell out his business.

An examination of his larynx at this period showed a thoroughly normal membrane, and free from an œdema or inflammation. The ulceration had entirely subsided.

He felt so well, upon his return, that he postponed selling his business from month to month, and rarely came to my office, as his health was so robust.

A year and a half after his return, he had an attack of influenza, and was confined to his bed for some days. His recovery left him with a hacking, harassing cough, and the pain returned to his throat.

He again paid me a visit. An examination of his larynx now showed a return of the œdema of the arytenoids and epiglottis, with a ragged ulcer secreting a tenacious mucus situated on his left arytenoid. The ulceration of two years previous had been on his right arytenoid. This patient now had a return of his night sweats, and his cough. I advised an immediate trip to the Adirondack mountains, his general condition being so grave that I did not think a trip to the West justifiable. He remained in the mountains for four months, when he came back and called for an examination. I was surprised to see the ulceration healed and the larynx again normal.

The subcrepitant râles were still present in his right chest at the apex.

He was again advised to move to the West, and to make it his permanent home. He now paid short visits to the mountains, and stayed there three months at a time; very little medicine was given, but strict attention was paid to hygiene. My patient had a cold bath every morning upon rising, slept with the windows open, winter and summer, and ate as many eggs and took as much beef as possible. By these means he was able to attend to his business and kept his weight to the normal.

Five years from the time of his first visit to my office, he developed typhoid fever. Upon his recovery, he came to see if I could do something for his throat. His voice was reduced to a whisper, and he was able to swallow milk and blood pressed from beef only with the greatest difficulty. The epiglottis and the arytenoids were œdematous, and an extensive deep ulcer involved the left arytenoid and extended high up on the epiglottis. He had a most distressing cough, which sent a pain to his left ear every time he coughed.

The patient was very weak, and appreciated his serious condition. I advised him to leave the city in a week's time, and to make his home permanetly in the West. In five days he was on his way to Denver, but was so weak that he was compelled to rest at several points on the road.

It is now over a year since he left New York. I have heard from him, he is still alive; his throat has again healed, and he has gained in weight and is able to attend to business.

The interesting points in this case are the three attacks of laryngeal phthisis, every attack running into the third stage, namely, the stage of ulceration; and the rapid recovery upon his leaving the city. The internal treatment in this case consisted of a creosote preparation, and small doses of morphine in tablet form, namely, one-twentieth of a grain, repeated every one to five hours as required to keep the cough in abeyance.

The local treatment was the same as I have used for the last fifteen years in clinic and private practice, namely, to treat the throat as little as possible. Any violent or rough spraying into the larynx tends to inflame and spread the ulceration. I have looked upon this ulceration very much the same as a surgeon looks upon a fracture of a bone. Keep it quiet until it has healed. Morphine I have found less objectionable than any other drug; it is given in small doses, often repeated, and an occasional large dose to quiet a paroxysm of coughing. The tablet, allowed to dissolve in the mouth, has a most quieting effect, both on the cough and the throat. Cocaine is an excellent anæsthetis, but it is prone to disturb the digestive system much earlier than morphine. The patient also becomes tolerant to its effects, and the dose has to be increased again and again to produce local results. Thus, to-day I use very little cocaine in the treatment of laryngeal phthisis, unless as a last resort for the period, when hope is out of the question.

Hygiene, that great exponent of nature, plays the principal rôle in these cases who recover. Open windows day and night, proper clothing, not too warm, the cold bath every morning, and sponging with alcohol or cold water when the patient has his thirst (another name for the fever), eggs, beef juice, blood, anything that will support the impoverished system and help nature to do her part in the great drama, unshackled and unconfined.

I have seen more of these cases recover, lately, under this treatment, than when we looked at laryngeal phthisis as a local trouble and ignored the fact that the platform upon which this disease rests is an impoverished constitution, and a general depreciation of the patient's health.

Give Nature plenty of ammunition in the shape of fresh air, the daily cold bath, eggs, beef, and the best hygiene possible, and she then has the best means of waging war upon that most painful and distressing disease, laryngeal phthisis.

112 West Forty-fifth Street.

THE TRANSMISSION OF SYPHILIS BY BARBERS.

By Wm. T. BELFIELD, M.D.,
CHICAGO.
ASSOCIATE PROFESSOR OF SURGERY, RUSH MEDICAL COLLEGE.

In 1893 a man, 47 years old, sought treatment for a skin eruption. Examination revealed the typical lesions of recent syphilitic infection in throat, tongue, skin, and lymph-glands, and a small ulcer with indurated border and base below the angle of the jaw, left side. The genitals were free from disease. He stated that about two months earlier a barber had cut the skin at the site of the present ulcer, and had checked the bleeding with a styptic pencil; about two weeks later the cut, which had never entirely healed, began to develop the features of the present ulcer. There was marked enlargement of the cervical glands on that side.

In 1903 a man, 39 years old, had an indurated ulcer on the chin. Two weeks earlier his barber had removed an ingrowing hair with a forceps, and had checked the ensuing bleeding with a styptic pencil. The wound thus created had enlarged, its edges had hardened. Glands on each side of the neck were much enlarged. Under the local and internal use of mercury the ulcer promptly healed. About nine weeks after the inoculation, during which period the patient had continuous fever and lost about 20 pounds in weight, constitutional syphilis became manifest in the throat, on the tongue and skin, and in the accessible lymph-glands; the genitals showed no lesion.

Our text-books give no definite information as to the manner or the frequency of the transmission of syphilis by barbers, most of them merely stating that a few instances are known in which chancres have developed at the site of razor-cuts. Bulkley's elaborate study—Syphilis in the Innocent—published ten years ago, contains only one fairly definite instance of such transmission.

In 1898 Robbins[1] reported an initial lesion of the chin just below the border of the lip, with constitutional syphilis, the infection having apparently been acquired in a barber-shop through a razor-cut. He compiled also the following seven cases reported in the literature: A chancre of the scalp at the site of a wound made by a barber's clipper, and a chancre of the eyebrow infected from a papular syphilide of a barber's hand—both cases observed by Judkins[2]; a chancre developing at the site of a barber's razor-cut, reported by Fleischer, and a similar case by Chudnooski; infection through a cut on the chin by a razor borrowed from a syphilitic subject, observed by Catrin[3]; a chancre of the lip of a young lady, who ascribed it to a rouge-stick used by a hair-dresser whom she had patronized. This stick—a firm, red ointment—was regularly moistened (sometimes in the mouth of the hair-dresser) and drawn along the lip of successive patrons as a final touch to the toilet; the case was reported to the California Academy of Medicine, September 18, 1897, by Montgomery; a chancre of the lip of an actress who applied to her lip the same rouge used by a companion suffering from syphilis, reported by Griffin.

In order to secure further information on this subject, a request for his personal observation was addressed to each of twenty-five well-known syphilographers of this country; and to most of these gentlemen I am indebted for the courtesy of a reply.

A chancre at the site of a wound made by a barber whose razor cut off a protuberant mole, and who made various styptic applications to the bleeding surface, was observed by E. Fuller, New York, and another such by W. L. Baum, Chicago; one following the use of the forceps in extracting an ingrowing hair, by Baum; one of the scalp, probably though not certainly inoculated by a barber, by Fuller.

Chancres developed at the site of razor cuts, most of which were treated with styptics and failed to heal, have been rather numerous: one each is reported by Horwitz, Philadelphia; Fanoni, New York; Keber, St. Louis; Baum, Chicago; Post, Boston; Gilchrist, Baltimore; Schmidt, Chicago (a linear chancre, 3 to 4 cm. long); "at least half a dozen" by Morrow, New York—in one the initial lesion, as large as a silver dollar, had been treated as ringworm; "certainly over a dozen instances of chancre of the bearded face—presumably through shaving," but exact method of transmission uncertain—by Bulkley, New York; "probably eight to twelve," by White, Philadelphia.

Drs. Keyes, Sturgis, Otis, and Hayden, New York; White, Boston; Hardaway and Burnett, St. Louis; Chismore, San Francisco; Hyde, Zeisler, and Anthony, Chicago, state that they do not recall an instance of the undoubted transmission of syphilis through the manipulations of barbers, though several of these gentlemen suggest the possibility that some of the numerous chancres of the lip may be acquired in this way rather than by the usually assumed kiss of an infected person.

These returns would seem to indicate that the transmission of syphilis by barbers must be a rare incident. Yet when it is remembered that the victims of such inoculation, because they have no suspicion of the nature of their sores, naturally consult not specialists but family physicians, it seems probable that most of these cases are prescribed for by general practitioners. The prevalence of syphilis among barbers and their patrons, and the general neglect to sterilize their tools, warrant a doubt of the extreme rarity of such transmission.

Of all the barbers' tools the razor seems, for obvious reasons, the least likely to convey the infection, while the alum-stick, forceps and clipper are the most frequently culpable.

The object of this note is, not to inaugurate a crusade for the education of barbers and the protection of their patrons, but to call attention once more to certain facts that are familiar to all in theory, but are forgotten by some in practice.

1. Sore throat and fever are not infrequently, especially in women, the first discovered symptoms of syphilis. I have known recent syphilis of the throat in each of two married women whose respective husbands were under my care for syphilis, treated as diphtheria—in one the antitoxin had been injected. In another case sore throat with fever was called tonsilitis, until a pink eruption on the chest was noticed, whereupon the diagnosis was changed to scarlet fever and the house was quarantined. A girl just recovering from alleged quinsy and canker-sores—really syphilis of the throat and mouth—inoculated her lover's lip with a chancre. Examination confirmed her assertion of virginity, but revealed a scaly, indurated papule on her left nipple, to which she admitted having applied, on several occasions, the sickly, fretful infant of her married sister with whom she lived. This child had mucous patches and snuffles; its father was syphilitic. It behooves us, then, not merely to divorce our conception of the chancre from sexual immorality and from the genitals—which most of us do—but also to eliminate the chancre from our conception of the essential clinical features of syphilis—which some of us do not; and to regard a sore throat with fever, especially in adults, as a possible manifestation of acute syphilis, as well as of tonsilitis, diphtheria and scarlet fever.

2. Syphilis could be minimized, if not virtually eradicated, far more quickly, surely, and easily than can tuberculosis; not by licensing prostitutes nor by educating youth to chastity, but by making the acquisition of syphilis practically impossible through the general practice of circumcision. That the notorious infrequency of syphilis among the Jews is not due to their superior continence is shown by their acquisition of their full share of gonorrhœa. That it is due to the toughening of the penile covering resulting from early circumcision is obvious, and is illustrated by the rarity of syphilis among all other circumcised races. The Egyptian practice of circumcision just before puberty is one of several facts suggesting that the general adoption of this measure by the early Semitic races was for protection against syphilis.

3. The later evils of syphilis can be restricted by impressing upon the subjects of the disease two injunctions: to take antisyphilitic remedies for two months in every year after the termination of active treatment; and (especially) to inform any physician consulted for relief from an obscure, chronic ailment, of the earlier syphilitic infection.

REPORT OF A CASE OF TETANUS FOLLOWING LABOR.

By A. STRACHSTEIN, M.D.,
NEW YORK.

Mrs. E. M., 34 years of age, admitted to the Beth Israel Hospital, August 27, with the following history: Three weeks prior to admission, patient was delivered of a mature child by a midwife; labor was normal, without complications. The puerperium was apparently normal, the lochia were not foul, and the woman left her bed at the end of eight days. Two weeks after the delivery, the patient began to complain of severe, continuous pains in the sacral region. The same day she began to experience rigidity in the lumbar region, which soon became more marked and extended upwards along the spinal column, and by the following day the posterior neck muscles were involved. Some trismus set in, with difficulty in speech and increasing trouble in swallowing. These symptoms grew progressively worse, and there were frequent paroxysmal pains. There was no fever or chilliness, and the mental condition was bright, but later both upper and lower extremities became rigid, and the woman complained of occasional left-sided hemicrania. She had no convulsions, but any disturbance, as change of position or examination, caused a clonic spasm, which after a few seconds terminated in a tonic spasm; the patient was in constant agony.

On admission, the patient had a profuse bromide rash over the entire body, and all the above signs were well marked; she could not separate the jaws

more than one-quarter of an inch. The temperature was ranging between 99° and 101°. Vaginal examination showed a moderate, thin, greenish-yellow discharge, not foul. The cervix was closed, the uterus somewhat enlarged. Microscopical examination of the discharge showed a number of streptococci, numerous micrococci, and many rod-shaped bacilli, also a few pus cells.

We at once procured tetanic antitoxin, and began giving subcutaneous injections in quantities exceeding that recommended by the Board of Health. The woman received an initial dose of 40 c.c. in the arm, and seven subsequent injections of 20 c.c. per dose every three hours into different parts. As some improvement was shown, the injections were now given every four hours, then every six hours, until marked improvement was seen; we then continued to give her 20 c.c. per day for fourteen days, so that when complete disappearance of symptoms was obtained, we had used 720 c.c. of the serum.

Other therapeutic measures were vaginal douches of bichloride 1-5000 three times a day, followed by saline solution, while internally the patient received occasional doses of chloral and morphine. Towards the end, her temperature has gradually risen to 104° F., but this was due to a gluteal abscess, and the temperature subsided when this was incised. There appeared on the skin, at various periods, blotches of erythema, which in places were ecchymotic. This was probably due to the effects of the serum; the kidneys at no time showed signs of irritation.

Orthostatic Albuminuria.—According to M. A. Courcoux, authorities have ranged, under the name of orthostatic albuminuria, a variety of cases, certain ones of which ought to be eliminated. It is not sufficient for a case to be called orthostatic, that the albuminuria be influenced by the upright position. It is necessary that only the change from the horizontal to the vertical position provoke it. Albuminuria consecutive to muscular fatigue, to strong emotion, or that which is due to certain digestive troubles, does not belong to the class of orthostatic albuminuria in case of which affection it is sufficient that the patient merely arise, whatever be the hour of the day, in order that the albumin may appear in the urine. By no method is it possible to discover the least renal lesion. Little influenced by the diverse intercurrent infectious maladies, true orthostatic abuminuria never ends in nephritis. It disappears without leaving any traces, at the end of a longer or shorter period. Pure orthostatic albuminuria should be diagnosed from the albuminuria of fatigue, from cyclic, digestive, intermittent, and functional albuminuria, in which there exist, nearly always, gastric, hepatic, or renal troubles, and in which the albuminuria is subject to daily variations which are not at all like the conditions of orthostatic albuminuria: and from the orthostatic albuminuria of floating kidney that may be perhaps recognized by separating the urine of the two kidneys. As to treatment, it is admitted that in pure orthostatic albuminuria, rest in bed and the milk régime are not only useless, but often harmful. The patient should live at a moderate altitude, and avoid intellectual fatigue. Muscular exercise, practised with moderation, is to be highly recommended. The digestive functions should be carefully looked after. When the orthostatic albuminuria is associated with a renal lesion, the treatment should be along the customary lines.—*Gazette des Hôpitaux Civils et Militaires.*

Physical Condition of American Hebrews.—In an address delivered before the annual convention of the American Federation of Zionists, Dr. Maurice Fishberg spoke of the physical condition of the Jews in the United States. The average circumference of the chest of the Jews in Eastern Europe, he said, is about 32 to 34 inches, and is less than half their body height, but the girth of the chest in a healthy man exceeds half his stature. In Russia, however, the military authorities have learned by experience that the narrow, flat chest of the Jew does not incapacitate him (other things being equal) and does not predispose him to consumption. In fact, the proportion of men affected with this dread disease is much lower among the Jewish soldiers in the Russian Army than among the Gentiles. It is remarkable that while the stature of the Jews born in the United States is much superior to that of the foreign Jews, this is not true of the girth of the chest. While investigating the physical conditions of the younger generation of Jews in New York City he was struck by the fact that Jews of the first generation are, on the average, taller than their parents, but their girth shows little, if any, improvement. Their chest is almost flat, the ribs are just as oblique, and the general contour of the chest is just as bad as those of their foreign parents. In order to assure a muscular Judaism, Dr. Fishberg told his hearers they must encourage physical culture among the younger generation of American Jews; they "must preach to them the gospel of the utility of a healthy body, which will shelter their intellect to a better advantage to themselves and to the community in which they live."

Burning Foot, or Erythromelalgia.—P. N. Gebhard defines this disease as one of the plantar nervous or arterial supply occurring in Eastern natives accustomed to working barefooted on roads and plantations. It commences with a "pins and needles" sensation affecting the soles of the feet, and progressing to an acute burning sensation, which becomes so severe as to prevent walking and necessitates the administration of narcotics to produce sleep. In the histories of the six cases upon which his paper is based he notes that although a previous history of malaria could usually be obtained, there was no such history occurring during the progress of the erythromelalgia. This suggested the possibility of the disease being a neuritis of malarial origin. The blood supply to the nerves may have been cut off by a deposit of malarial pigment. The duration of the disease at the time of presentation was from three days to three months, from which a chronic course may be argued. It also seems that the affection is not any form of acute local disease occurring in a given place after a fixed incubation period. Length of residence in this particular country seems to have no influence on the production of the disease. In two out of the six cases sugar was found in the urine. Usually there is a variable amount of swelling and occasionally slight sclerodactylia. The author is inclined to the view that the disease does not exist so much in the congestive as in the cellulitic form, although it may commence with the congestive form. Aside from a possible malarial origin, it may be due to arteriole fatigue. Paralysis of the sympathetic, excitation of the vaso-motor nerve fibres and general toxic vaso-motor derangements do not seem to be factors in the disease. A varied treatment was employed. Narcotics and sedatives give only temporary relief; various lubricants and ointments, general tonics, with or without strychnine, failed to give any relief. In two cases relief was experienced by immersing the feet in hot salt water.—*Dublin Journal of Medical Science.*

Operative Opening of the Mastoid Bone in Otitis Media Purulenta with Extension of the Disease Beneath the Mastoid Process.—F. Leimer analyzes a series of 17 cases observed in a series of 97 cases of acute middle-ear suppuration extending over a period of 9 years, which required operative opening of the mastoid. Of these 17, 13 were discharged cured, 3 died and 1 discontinued treatment. The mortality of acute middle-ear suppuration with burrowing of pus in the neck is, therefore, if we include the missing case, 18.7 per cent., whereas the operated cases of mastoiditis that did not present this complication showed a mortality of 8.8 per cent. If there be the further exclusion of one case, which ended fatally, independently of the aural condition, on account of myo-degeneration of the heart and pulmonary œdema, there still remains a mortality of 13.3 per cent. for Bezold's mastoiditis against 8.8 per cent. for simple mastoiditis.—*Archives of Otology.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 17, 1904.

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE annual report of the Surgeon-General of the Navy has been recently issued. It is a well-compiled and instructive document and contains several recommendations which, if acted upon, cannot fail greatly to increase the efficiency of the service. The health of the Navy during the year was good, although the ratio of admissions to the sick list per 1,000 of strength was slightly higher than for the previous year. The average strength of the active list during the year 1903 was 37,248, a small increase over that of 1902.

The total number of admissions for all causes was 28,569, the ratio per 1,000 of strength being 782.24. as compared with a ratio of 767.63 for the previous year, and 797.10 for the eight preceding years. There were 24,545 admissions for disease and 4,024 for injury, giving ratios of 671.82 and 110.4, respectively. The admissions for injuries were less and for disease greater, during the present year than for 1902.

The daily average of patients was 1,289.03, and the ratio per 1,000 of strength 35.23, both being greater than the previous year. The total number of sick days was 470,496, or an average of 12.88 sick days for every man in the Navy and Marine Corps, and the average duration of treatment for each case was 16.49. These figures differ but slightly from those for 1902.

The number of persons invalided from the service during the year for disease and injury was 1,541, giving a ratio of 41.37 per 1,000 of strength. This ratio is much higher than that of the previous year or than the average ratio for the eight preceding years. This result is due to the large number of recruits admitted into the service during the year. The discharges for disability include 1,348 for disease and 193 for injury, with ratios per 1,000 of strength of 36.19 and 5.18, respectively. The corresponding figures for 1902 were 1,001 and 143, with ratios of 33.09 and 4.72 respectively. The deaths during the year numbered 224, giving a ratio of 6.01 per 1,000, considerably less than that of the previous year. One hundred and sixty-four deaths occurred from disease, with a ratio of 4.40, and 60 from injury, with a ratio of 1.60.

There was a general increase in admissions for diseases of the digestive apparatus, while malarial diseases, diarrheal affections, dengue, dysentery, and alcoholism showed a marked decrease, and smallpox a relative decrease.

A feature of the report is the statement that venereal diseases continue greatly to impair the fighting strength of the Navy. With the exception of the class of "general infectious diseases," venereal diseases during 1903 gave a greater number of sick days than any other class, namely, 114,571, equal to the entire loss of the service of 314 men for the year. As the report remarks, this has the same effect upon the fighting strength of the Navy as the loss of a second-class vessel yearly. Gonorrhœa had 1,052 and syphilis 816 admissions, as compared with 771 and 606, respectively, in 1902. The total admissions for venereal diseases during the year were 1,207 in excess of 1902, a fact not to be accounted for by the increase in strength.

Epidemics of cerebrospinal fever, diphtheria, epidemic catarrh, mumps, and pneumonia occurred during the year, and account for the increase in admissions for these diseases. Pulmonary tuberculosis showed a marked increase, and typhoid fever was slightly in excess of 1902. It is satisfactory to note that while the admissions to the sick list per 1,000 of strength were greater than in 1902, the mortality was not only less than that of 1902, but lower than the average for the past eight years.

The two preceding annual reports have called attention to the inadequate capacity of the naval hospitals for the needs of the rapidly growing navy. Nearly every one of the present hospitals requires to be remodelled and renovated and brought up to date. The naval hospitals, with the single exception of the New York hospital, compare unfavorably in all respects with the best civil hospitals. The report recommends, therefore, that radical changes—even to practical reconstruction in several instances—be initiated in order to modernize the hospitals and make them satisfactory and creditable institutions.

The question of properly housing recruits is one of pressing importance. Suitable, ample and sanitary barracks are urgently needed. The report dwells upon the point that sanitary barracks, with every modern convenience, can promptly be made insanitary by overcrowding. Consequently, the number of men housed in any barrack should not exceed a fixed maximum based on well-established laws of hygiene.

The report lays special emphasis upon the desirability of having trained women nurses as a part of the medical department of the United States Navy. It is pointed out that, in addition to supplying better and more efficient nursing to the sick, valuable assistance could be rendered by the woman trained nurse in teaching the men of the Hospital Corps of the Navy their special duties, and in the event of war the men could be, in large part, released from hospital duty and assigned to vessels of war.

Recommendations made in two preceding reports for the enactment of legislation authorizing the employment, under the control of the Bureau of Medicine and Surgery, of skilled dentists for service in the Navy, is renewed.

The experiment made by the Bureau of Medicine and Surgery of the Navy, of treating consumptives in tents at Pensacola, Fla.,—despite many draw-

backs—has been attended with such conspicuous success that the Bureau strongly advises an extension of this system, and recommends that Congress be asked to make special provision for the acquisition of an appropriate site for a camp for tuberculous sailors.

The necessity for having an adequate number of properly constructed and equipped hospital ships is urged in the report.

The question of obtaining competent surgeons for the Navy is discussed at length. The report insists that the naval medical officer should be treated as generously as his brother of the army, and states the case as follows: "There has always been difficulty in securing qualified medical men for the Navy, recent legislation giving assistant surgeons of the Navy the rank, pay (less 15 per cent. for shore duty), and allowances of assistant surgeons of the army, has more nearly equalized the advantages offered by the two branches of the military service. There is sound reason for a comparison of the status and pay of these two grades, inasmuch as they perform the same kind of service for the Government, are drawn from the same civilian source, have practically identical qualifications, and it would seem best for the public service that there be equalization of their emoluments in every detail. The highest interest of the entire naval personnel, official and enlisted, is too seriously involved in the success of the effort now being made to secure and maintain the highest state of professional efficiency in the medical corps for it to be wise to place it at a disadvantage, in comparison with the medical staff of the army, by offering inferior inducements to civilian medical men who might be inclined to enter the naval service." The foregoing is very true, and there would seem to be no valid reason why the naval medical service should not be on exactly the same footing as that of the army.

THE TRAINING OF THE SURGEON.

This was the subject of an address delivered by Dr. William S. Halsted, at the Yale Medical School, last June (*Bulletin of the Johns Hopkins University*, September, 1904). In this address, after a brief review of the progress of the art of surgery during the second half of the nineteenth century, the speaker dwelt upon the needs of the present day, that, namely, of an organic connection of the medical school with a university and that of a prolonged hospital training of the surgeon. While it may be that the rise and multiplication of the proprietary medical school was a necessary incident of the development of medical education in a new country, such schools are not able to give the training that can be given in schools affiliated with strong universities and permeated with the university spirit. "Although we now have in the United States," he says, "several (five or six) moderately well-endowed medical schools with a university connection, the problem of the education of our surgeons is still unsolved. Our present methods do not by any means suffice for their training. Nowhere, certainly, can a surgeon in a given period acquire so much and mature so rapidly as in a hospital with an active and well conducted service. The time for training should not be curtailed, but students who wish to become surgeons should begin to specialize as early in life as possible." After describing at some length the German system of training surgeons, Halsted says: "The faults of our system of educating surgeons begin almost at the bottom and continue to the very top."

Every important hospital, he contended, should have on its resident staff at least one surgeon not only able to deal with any emergency and perform any operation, but also able to recognize the gross appearance of all the ordinary pathological tissues and lesions. But the interne leaves the hospital unequipped, to become eventually attending surgeon, when he is expected to teach others what he has not learned and pronounce at the operating table on conditions unfamiliar to or possibly unheard of by him. We need a system which will produce surgeons of the highest type, who will stimulate the best students to devote their energies and lives to raising the standard of surgical science. Reforms, the need of which are apparent to every American teacher of surgery, must come from the side both of the hospital and of the university. It is eminently desirable, if not absolutely essential, that the medical school control a hospital of its own, with such an organization as will provide for the prolonged and thorough training of those preparing for the higher careers in medicine and surgery and permitting close and stimulating relations between chief and assistants.

The author quotes with approbation from Barker: "I should like to see what the result would be if men with these capacities were bred to university careers, were placed in charge of hospitals especially constructed for university purposes, and were sufficiently paid to permit them to give up private practice entirely and to devote their whole time and strength to teaching and investigating in such hospitals." Halsted then discusses the difficulties arising out of such an arrangement, such as that of apportioning the pay for such high-grade professional work among the professors, concluding that the surgeon or physician could not receive a larger salary than the chemist or physicist. He would favor a compromise by which the hospital surgeon and physician might receive compensation from certain of their patients.

The speaker closed by saying that while American surgery has been hampered by the lack of such training as he desires to see it have, still the courage, ingenuity, dexterity, and resourcefulness of our operators have made it renowned throughout the world. In particular in the field of appendicitis, are its achievements conspicuous, the continental surgeons having been for several years unable fully to grasp the teachings of their American co-workers.

Immunity Against Streptococci.

Dr. D. H. Bergey, Assistant Professor of Bacteriology, University of Pennsylvania, has recently been undertaking investigations, published in the University of Pennsylvania *Medical Bulletin*, July-August, 1904, primarily with the view of obtaining information as to the identity of the streptococci found in cows' milk, and their relation to the streptococci encountered in the human organism in health and disease. The results obtained by Dr. Bergey were at variance with the usual inference, held up to a comparatively short time ago, that in different diseases distinct species of streptococci exert their influence.

Dr. Bergey states that the studies upon strepto-

coccus infection and the immunity that can be conferred against such infection indicate that the immunity against streptococcus is of a somewhat more complex nature than that encountered in some other infections. It is probable, thinks Dr. Bergey, that in this respect the infections by staphylococci and the pneumococcus are closely related to that by the streptococcus. The relatively small amount of toxin produced in streptococcus cultures indicates that the formation of antitoxin is of minor importance in the immunity. Again, the absence of any evident bactericidal properties in the serum of an animal treated with streptococci indicates that the immunity is different from that which is seen in typhoid fever, for instance. The investigator therefore is of the opinion that it is most probable that in streptococcus immunity there is a stimulation of phagocytosis, which plays an important rôle in the process, though Dr. Bergey is inclined to believe that this is not the sole factor involved.

The following deductions may be drawn from the investigations: (1) The serum of animals immunized with cultures of streptococcus acquires an agglutinating power for all varieties of streptococci, though the agglutination occurs in somewhat higher dilutions for the homologous culture than for those derived from other animals. (2) The agglutination reaction affords no means of definitely differentiating between cultures of streptococci of human and animal origin. (3) The serum of an animal immunized with cultures of streptococcus shows no definite bactericidal action against such organisms. (4) The serum of an animal immunized with cultures of streptococcus possesses some antitoxic effect against the action of the filtrates of streptococcus culture. (5) The protective and curative properties of antistreptococcus sera, as at present prepared, are of very slight value, as indicated by animal experimentation. (6) No great reliance can be placed on the statements of the efficacy of antistreptococcus sera in the treatment of streptococcus infections, until animal experimentation gives us more definite insight into the mechanism of streptococcus infection, and the manner in which the organism overcomes such infection.

Treatment of Erysipelas of the Face and Scalp.

Erysipelas of the head is always to be regarded as a dangerous disease, owing to its liability to extension to intracranial structures, because of the communications between the external veins and the superior longitudinal and lateral sinuses. In the *Journal of the Royal Army Medical Corps* for October, Major C. H. Hale says that carbolic acid is not resorted to frequently enough in the treatment of such infections as erysipelas and lymphangitis. Though bacteriology has advanced by leaps and bounds, the old treatment of dusting zinc and starch, or starch alone, is still too much in vogue, both in practice and even in the text-books. As in broken-down subjects, a rapid extension to the cerebral membranes, with an early fatal termination, is by no means out of the question, a more active local treatment is indicated than the dusting of innocuous powders. The streptococci must be vigorously combated, and the patient not left to fight them alone, or only with the aid of iron and other drugs. The chief indication, the reduction of pain and swelling, is best met incidentally by antiseptic treatment. The author employs pulvis cretæ aromaticus cum opio of the British pharmacopœia, rubbed with glycerin to the consistence of treacle, with 10 per cent. of liquefied carbolic acid added. This is painted over the surface with a camel's hair brush, and after about ten minutes the surface is covered with a single layer of lint. The result of the application is that pain very soon disappears, the swelling subsides, and a fair amount of water exudes through the application (much as perspiration oozes through theatrical paint), and the part is thoroughly protected from the air. More important, as showing that the streptococci are being successfully attacked, is the ensuing reduction of the fever, which often falls from 105° to normal in twenty-four hours, and is rarely higher than 99° after forty-eight hours. In twelve hours the application should be washed off and the mixture reapplied. The application gives rapid relief, the patient often saying, before the painting is finished, "How beautifully cool and soothing!" The author concludes by describing a case of erysipelas of the greater part of the scalp with several areas of bogginess, a temperature of 105°, and a very rapid pulse, in which the application was followed by a practically normal temperature and the establishment of convalescence the following day.

Pipe Galleries for New York.

The subject of pipe galleries for New York is discussed by James C. Bayles, M.E., Ph.D., in Bulletin No. 2, of the Municipal Art Society of New York, just published. The fact is obvious that the underground engineering of New York is in many respects defective. Especially is this true as regards the piping of the city for gas and water distribution and like purposes. The streets of New York are generally more or less in a state of chaos, largely due to the necessity of frequently opening them to repair gas and water leakages, damaged sewers, electrical communication, etc. The evils of holes in asphalt pavements from a health standpoint were catalogued by the Grand Jury in its presentment of July 28, 1903, as follows: "The sprinkling of the streets, in the summer, causes an accumulation of water and street refuse matter in these cavities, which necessarily resolve themselves into offensive and objectionable conditions to which the public should not be exposed. Prompt and proper sweeping and cleaning of the streets is an important municipal function, at all seasons of the year; but in summer time decomposition of street refuse is a distinct menace to public health, which is augmented by the existence of holes and breaks in the asphalt pavements. Many yards of pavement in good condition can be properly cleaned while a representative of the Street Cleaning Department is consuming time by excavating accumulated matter from the holes which should not exist." All this is self-evident, but so long as the present system of piping is adhered to there can be no remedy.

The pipe gallery has been in use in Great Britain and in Europe for years, and has served its purpose admirably. The almost perfect condition of the Paris streets is largely attributed to the excellent system of pipe galleries in that city. The contention of those opposed to pipe galleries in New York is that they are a menace to life and property. Mr. Bayles considers that this fear is simulated, and is of the opinion that the engineer who cannot conduct gas in a main through a tunnel without a measurable leakage loss, or one which involves any danger even to workmen in such tunnel, should go abroad and study foreign practice. Since then it has been proved that pipe galleries can be constructed without menace to life, and that they are an effective means of preserving the various pipes necessary in the economy of a great city, New York should assuredly have them. The manner in which

the streets of New York are kept is dangerous to health and the cause of serious interruption to traffic.

The Efficiency of Spark Gap Radiations.

The component parts of the emanations produced by the various sources of radiant energy that have so far been investigated seem to increase in complexity as our knowledge of them develops. H. C. Piffard (*Medical News*, December 3, 1904), shows that in the condenser spark we have three forms or types of energy in coincident action, namely, the intense and penetrating luminous ray, the more superficially acting ultraviolet rays, and a furious bombardment by ions. To this combined activity he applies the terms triradial or triergic. The author describes the steps by which it was demonstrated that the Piffard ultraviolet ray lamp gives off in addition to the ultraviolet rays another class of radiations which are not negative electrons, as they are not deflected by the magnetic field, and which perhaps are identical with the so-called *Entladungsstrahlen* observed by Wiedemann. The hypothesis held to be most probable is that they are ions, using the term in its physical and not in its chemical sense, and considering the velocity with which these are projected in consequence of the pressure behind them, and the rapidity with which they are developed, it is not surprising to find that clinical experience justifies the author's prophecy expressed in a previous communication to the effect that the "rays" in question would be found to possess a powerful influence on the skin. Various dermatologists have already expressed gratification at the results obtained by the author's method, and in addition to the high efficiency of these spark radiations, which is so marked as to require caution in their application, they present certain advantages in practical use. The author describes a "spark-ionizer" which may readily be introduced into the cavities of the body through a speculum, and gives details as to the technique of actuating the instrument. The great penetrating power possessed by the radiations is ascribed to their association with a large volume of the longer light waves toward the red end of the spectrum.

Acute Rheumatism.—James M. Beattie sums up his paper as follows: The present position is that an organism with distinctive characters from the ordinary bacteria with which we are familiar has been isolated from typical cases of acute rheumatism and chorea (which is admittedly rheumatic in character) by different observers. This organism has been cultivated outside the body, by injection into rabbits has produced typical acute rheumatism and chorea, and has been recovered from the infected animals. Streptococci, staphylococci, etc., do not produce these effects; and this organism, even when its virulence has been raised, does not, as Poynton and Paine have shown, produce the effects which are obtained by the injections of the ordinary pyogenic organisms. Therefore, the writer believes that he is justified in claiming that if not the only, at least it is one of the causal agents in acute rheumatism. This was the position taken up by Poynton and Paine in 1900. Their position has not been successfully assailed, but has been very much strengthened by further observations, and it seems extremely probable that we shall yet be able to give the Micrococcus rheumaticus the place in relation to rheumatic fever which the pneumococcus to-day holds in relation to pneumonia. The writer thinks it quite unnecessary to deal with a recent objection—that the organism is merely the cause of the terminal phenomena in cases of acute rheumatism.—*The Edinburgh Medical Journal.*

News of the Week.

Medical Appointments on the Isthmus of Panama.—The United States Civil Service Commission announces an examination on January 18, 1905, to be held at the usual places to secure eligibles from which to make certification to fill vacancies in the following-named positions under the Isthmian Canal Commission on the Isthmus of Panama: Surgeon, physician, pharmacist, hospital interne, trained nurse. Each applicant for the Isthmian Canal Service will be required to submit to the examiner, on the day he is examined, a recent photograph, not more than three years old, of himself, which will be filed with his examination papers, as a means of identification in case he receives an appointment. An unmounted photograph is preferred. The date, place, and kind of examination, the examination number, the competitor's name, and the year in which the photograph was taken should be indicated on the photograph.

The age limit for surgeons is 25 to 50 years; salary, $250 per month. The examination will be on anatomy, surgical bacteriology, surgical pathology and diagnosis, surgical practice, surgical gynecology, and practical experience. Special attention will be given to the quality of the applicant's experience, and applicants who have had extensive work in large hospitals will receive special credit. It is the desire of the Commission to appoint in this position only surgeons of thorough training and wide professional experience.

The age limit for physicians is also 25 to 50 years; salaries, $150, $200, and $250 per month. The examination will be on letter-writing, anatomy, therapeutics, physical diagnosis (including questions relating to tropical diseases), general pathology and practice (including questions relating to tropical diseases), bacteriology and hygiene, obstetrics and gynecology, and practical experience. Special attention will be given to the quality of the applicant's experience, and applicants who have had experience in hospitals, particularly in the treatment of tropical diseases, will receive special credit. Only those who have had extensive hospital experience and are familiar with the treatment of tropical diseases, will be selected for appointment to the highest salaried positions. Promotions may be made in the discretion of the Isthmian Canal Commission from the lower to the higher positions in this grade.

The age limit for hospital internes will be 20 to 30 years; salary, $50 per month, with board and quarters, provided that if appointees are retained in the position of interne after one year they will be paid $125 per month. Only graduates of reputable medical schools having a three years' course will be admitted to this examination. It is expected that within the next few months twelve or more vacancies in this position will be filled as a result of competitive examination. The examination will be on letter-writing (the subject-matter on a topic relative to the practice of medicine), anatomy and physiology (general questions on anatomy and physiology, and histological or minute anatomy), chemistry, materia medica, and therapeutics (elementary questions in inorganic and organic chemistry; the physiological action and therapeutic uses and doses of drugs), surgery and surgical pathology (general surgery, surgical diagnosis; the pathology of surgical diseases), general pathology and practice (the symptomatology, etiology, diagnosis, pathology, and treatment of disease), bacteriology and hygiene (bacteriological methods, especially those relating

to diagnosis; the application of hygienic methods and prophylaxis and treatment), and obstetrics and gynecology (the general practice of obstetrics; diseases of women, their pathology, diagnosis, symptoms, and treatment, medical and surgical).

The age limit for pharmacists is 20 to 40 years; salaries, $900, $1,000, and $1,200 per annum, with board and quarters. The examination will be on letter-writing, chemistry, pharmacy, materia medica, and practical experience. Graduates of pharmacy only will be eligible to this examination. Experience will be rated upon the time spent in the general work connected with pharmacy, the preparation and compounding of prescriptions, and the making of official preparations.

The age limit for trained nurses (male or female) will be 20 to 35 years; salary, $50 per month, with board and quarters. Only graduates of schools for trained nurses having at least a two years' course will be admitted to this examination. Applicants having hospital experience in connection with the treatment of tropical diseases will be given special credit for such experience and will be preferred for appointment. The examination will be on anatomy and physiology, hygiene of the sick room, general nursing, surgical nursing, obstetrical nursing, and experience in nursing. Male applicants will not be required to take the subject of obstetrical nursing. The scope of the subjects in this examination is that covered by the customary course of study in recognized training schools for nurses or in the standard text-books prepared for the instruction of students in nursing.

These examinations are open to all citizens of the United States who comply with the requirements. The Isthmian Canal Commission furnishes free transportation to the Isthmus from either New York, New Orleans, or San Francisco, and also free return transportation upon completion of satisfactory service. The employees of the Isthmian Canal Commission are allowed six weeks' leave of absence annually on full pay. This leave of absence is not granted until after eight months of satisfactory service. In visiting the United States on leave, employees and members of their immediate families are granted special rates to the above-named ports. (The prevailing special rates are $25 between New York or New Orleans and Colon, and $70 between San Francisco and Panama.) The special rates also apply when members of the family of an employee accompany him to the Isthmus. All inquiries concerning examinations for competitive positions under the Isthmian Canal Commission should be addressed to the United States Civil Service Commission, Washington, D. C. Further communication relative to service, situation, climate, and conditions on the Isthmus should be addressed to the Isthmian Canal Commission, Washington, D. C.

Election at the Academy of Medicine.—The annual election of the New York Academy of Medicine was held December 15. The following were the nominees: *President,* Charles Loomis Dana; *Vice-President,* T. Mitchell Prudden; *Trustee,* Abraham Jacobi; *Treasurer of Board of Trustees,* Reginald H. Sayre; *Committee on Admissions,* William C. Lusk; *Committee on Library,* L. Emmett Holt; *Delegates to State Medical Society,* David Bovaird, Jr., James Ewing, Charles L. Gibson, Homer W. Gibney, Edward L. Keyes, Jr.

Award of the Nobel Prizes.—The winners of the Nobel prizes were announced in Stockholm on Saturday last. The medical prize was awarded to Prof. Pawlow, of St. Petersburg; that for chemistry to Sir William Ramsay, and for physics to Lord Rayleigh. The literature prize was divided between José Echagaray, of Spain, and Frederic Mistral, of France.

Falsifying Druggists.—It is said that a great number of Chicago apothecaries will be prosecuted for selling adulterated drugs. Chemical tests have been made and evidence procured which prove the presence of alien matter in many prescriptions calling for pure drugs. In nearly 20 per cent. of the samples obtained there was not even a trace of the drug called for in the prescription. The tests, conducted by Dr. John A. Wesener, showed the following: 23 prescriptions, no trace of the drug called for; 66 prescriptions, 80 per cent. impurities. 10 prescriptions, 20 per cent. impurities; 9 prescriptions, 10 per cent. impurities; 31 prescriptions, pure.

Hospitals on the Isthmus.—The following is the clause relating to hospitals in the agreement between this country and Panama recently, signed by Secretary Taft: "The United States will construct, maintain, and conduct a hospital or hospitals either in the canal zone or in the territory of the republic, at its option, for the treatment of persons insane or afflicted with the disease of leprosy and any indigent sick, and the United States will accept for treatment therein such persons of said classes as the republic may request, but this order shall not be operative unless, first, the Republic of Panama shall furnish without cost the requisite lands for said purposes if the United States shall locate such hospital or hospitals in the territory of the republic, and, second, that the republic shall contribute and pay to the United States a reasonable daily per capita charge in respect of each patient entering upon the request of the republic, to be fixed by the Secretary of War of the United States."

The National Association for the Study and Prevention of Tuberculosis.—The first annual meeting of this Association will be held in Washington, D. C., on the third Tuesday of May, 1905. Arrangements will be made for a two days' meeting, in which there will be one or two general sessions, with addresses upon the broad topics of tuberculosis, and special meetings of three sections, viz., Sociological, Pathological and Bacteriological, Clinical and Climatological. So far as possible, these sectional meetings will not conflict one with another. The membership of the Association includes a large proportion of workers in the subject of tuberculosis throughout the country, and it hopes to make its first annual meeting an important one in the crusade in this country against tuberculosis. The President of the Association is Dr. E. L. Trudeau, of Saranac Lake, N. Y., the secretary Dr. Henry Barton Jacobs, 11 Mt. Vernon Place, West Baltimore, Md.

Bellevue Diet.—The cooking system of Bellevue Hospital has been reorganized, and the diet kitchen is now under the direction of Miss Harriette Gorton, a graduate in domestic science of the Drexel Institute of Philadelphia. It is the aim of the new head of the department to establish a more scientific system of diets for the different classes of patients, and so assist the work of the medical staff. The cooking will be done entirely by gas, and the cost of the new plant which has been established will not amount to more than $500. Miss Gorton estimates that the cost of the new diet system will not be more than $50 a month beyond the cost of the existing kitchen, for the reason that the dishes she will supply will mean the sending out of a correspondingly less amount of food from the ordinary kitchen.

Research Fund for Columbia.—The trustees of Columbia University have announced a gift of $50,000

to establish a fund for physical research, from Edward D. Adams, father of Ernest Kempton Adams, who was graduated from the university in 1897. He died last July, and in his memory the gift is called the "Ernest Kempton Adams Fund for Physical Research." The income is to be applied to the stipend of a fellow of the university and to the publication of the results of his investigations. The research fellow may be appointed from among the faculties, teaching staff, alumni or students of Columbia.

Beriberi on a Ship from Java.—The British tramp steamer *Coulsden* came into Quarantine last week with five of the Chinese crew sick with what Health Officer Doty declares is beriberi. Four previous deaths occurring on the way from Java were alleged to be due to cholera by the authorities at Suez. The ship has been disinfected and the crew are under observation at Hofman Island.

Plague in London.—A report from London states that one of the crew of the steamship *Weybridge*, from the River Plate, which arrived in London on November 30, was taken with a suspicious illness, and bacteriological examination proves that he has the plague.

Cincinnati Hospital Site.—Since the matter of the new City Hospital and its site was brought before the Academy of Medicine, some weeks ago, a number of members of the staff and of the Tax Payers' Association have formed a party of opposition to the removal of the institution from its present site to the one purchased on the Hill Tops. A committee of staff officers, composed of Drs. George Fackler, P. S. Conner, J. M. Withrow and William F. Taylor, waited on the Board of Public Service and protested against the proposed removal. A committee from the Tax Payers' Association will carry the same matter before the board at an early date.

Cincinnati Branch Hospital—This institution for the care of consumptives has a capacity of 80 patients, but it is now looking after 113 patients, many of whom must sleep in the aisles of the wards and in store-rooms where the air and light are wholly inadequate. The members of the Board of Public Service made a tour of inspection and ordered that no more patients be accepted.

Physician Arrested for Negligence.—As a result of an investigation conducted by the grand jury in St. Louis, a physician of that city has been arrested on the charge of manslaughter in the fourth degree. The action followed the investigation by the grand jury into the death of a woman whom the accused attended when she gave birth to a child. Witnesses testified that at a time when the patient was in a critical condition the physician absented himself for forty-eight hours, and at another time he left the bedside when she needed attention and went out to look after his horse, being gone some time. The death certificate assigned puerperal fever as the cause of death.

A New Mode of Treatment of Pneumonia.—At a meeting of the Paris Académie de Médecine, held on December 7, Dr. Albert Robin is said to have reported remarkably good results attending the hypodermic injection of colloidal gold, silver, or platinum in pneumonia. By electrolysis these metals may be reduced to a peculiar state of subdivision in which they develop a ferment-like activity. By the use of these metallic ferments Dr. Robin claims to have produced defervescence in six cases out of ten before the seventh day, and that thirteen patients out of fourteen recovered. It is not asserted that the injections form a specific treatment for pneumonia, but simply that they hasten natural defervescence and so aid the other remedies usually employed.

Cincinnati Post-Graduate Medical School.—The Cincinnati Polyclinic and Post-Graduate School of Medicine was opened in a building at 911 Race street, about three weeks ago. The faculty is composed of Drs. H. A. Ingalls, Travis Carroll, H. D. Hinckley, F. L. Ratterman, W. E. Kiely, William Gillespie, M. H. Axline, William H. Wenning, Louis J. Krouse, D. I. Wolfstein, O. W. Spark, Th. R. Christen, William C. Harris, A. F. Morgenstern, T. V. Fitzpatrick, C. F. Winton, C. T. Pearce, E. Harlan.

Nurses' Home Destroyed.—The Nurses' Home, adjoining the Baptist Sanatorium in St. Louis, was burned to the ground early in the morning of December 3, the inmates narrowly escaping with their lives. There were forty nurses in the building, some of whom were saved by jumping from the upper windows. The Baptist Sanatorium was set on fire by sparks, but the fire was quickly put out.

Homœopathic Coalition.—What will probably be the largest homœopathic educational institution extant is to be formed in Chicago under the presidency of Dr. George F. Shears, by combining the Hahnemann Medical College and the Chicago Homœopathic College under the name of the Hahnemann Medical College of Chicago.

Professor Koch to Return to Africa.—Professor Robert Koch will start from Berlin for South Africa on December 17, in order to resume his interrupted study of rinderpest and other allied diseases.

Hospitals for Brooklyn.—The Bethesda Deaconess' Hospital of the East German Conference of the Methodist Episcopal Church was incorporated with the Secretary of State at Albany, on December 6, for the purpose of maintaining hospitals in Brooklyn.

Dr. J. A. Schmitt was elected president of the German Medical Society of the city of New York at the annual general meeting of this society, held December 5.

Fined for Using Disinfectant in Milk.—A dairyman of St. Louis, and the driver for a condensed milk company, of the same city, were fined recently for selling impure milk. One was fined $25 each on two charges of using formaldehyde as a preservative for cream, and $25 each on two charges of diluting unskimmed milk with 20 per cent. of water. The other was fined $25 on one charge of using formaldehyde as a preservative of cream.

Philadelphia Hospital.—The eighteenth annual banquet of the Association of Ex-President and Resident Physicians of the Philadelphia Hospital (Blockley) was held on the evening of December 6, with nearly eighty participants. Toasts were responded to by Drs. Horatio C. Wood, D. J. McCarthy, E. M. Wetty, George W. Guthrie and H. P. Calhoun.

College of Physicians of Philadelphia.—The Mütter lecture on Surgical Pathology was delivered on December 2 by Dr. George H. Monks, of Boston, the subject being "Studies in the Surgical Anatomy of the Small Intestine and Its Mesentery." At a stated meeting held December 7, Dr. J. W. Holland read "A Memoir of the late Dr. Roberts Bartholow," and Dr. Herman B. Allyn read a paper entitled "The Diagnosis of Tuberculous Cavities in the Lung."

Rock Island System Surgical Association.—This association held its second meeting December 7 and 8, in Chicago, with an attendance of nearly 150.

Twenty-two papers were read and discussed. Most of the papers dealt with subjects of special interest to railway surgeons. A surgical clinic was given in honor of the association by Dr. Weller Van Hook at the Wesley Hospital. Several interesting surgical cases upon which Dr. Van Hook had previously operated were exhibited, and he also operated on four cases.

Sudden Deaths in Chicago.—The report of Coroner John E. Traeger, of Cook County (Illinois), shows that the total number of deaths investigated during the year was 5,960, and 3,821 inquests were held. There were 426 suicides, and 382 met death in railroad accidents. Of the suicides, 103 were between 40 and 50 years of age.

Pathological Society of Philadelphia.—At a stated meeting held December 8, Dr. Victor C. Vaughan, of the University of Michigan, delivered an address entitled, "The Relation of Food-preservatives to the Public Health, and the subject was further discussed by Professors C. B. Cochran, of West Chester, and Charles Harrington, of Boston.

Fourth Pan-American Medical Congress.—The secretaries of the Sections of the Congress for the United States are: C. W. P. Brock, of Richmond, Va., Railway Surgery; Henry P. Newman, of Chicago, Gynecology and Abdominal Surgery; A. H. Doty, of New York, Hygiene and Quarantine; Judson Daland, of Philadelphia, Medicine; R. Matas, of New Orleans, General Surgery; Bert Ellis, of Los Angeles, Diseases of the Eye; Hudson Makuen, of Philadelphia, Diseases of the Throat; Frederick Jack, of Boston, Diseases of the Ear; C. H. Hughes, of St. Louis, Nervous Diseases; George Goodfellow, of San Francisco, Military Surgery; John Ridlon, of Chicago, Orthopedic Surgery; D. W. Montgomery, of San Francisco, Dermatology; C. G. Kerley, of New York, Pediatrics; Noble P. Barnes, of Washington, Therapeutics; Walter Chase, of Boston, Pathology; Howard Morrow, of San Francisco, Cal., Dermatology. Communications from physicians in the United States interested in these branches can be sent directly to these different secretaries.

Obituary Notes.—Dr. Hugo W. Kohler died at his home in St. Louis, on December 5. He was born in St. Louis January 27, 1864, and graduated from the grammar school when but 12 years of age and immediately entered the classical department of St. Louis University. In 1883 he graduated from the St. Louis College of Pharmacy and entered the drug business. In 1900 he retired from the drug business and entered the Marion-Sims Medical College (now Medical Department St. Louis University), from which he was graduated in 1902.

Dr. S. S. Purmer, of Washington, D. C., said to be the oldest contract surgeon in the regular army, died on a Northern Pacific train, west of Fargo, N. D., yesterday. Dr. Purmer was seventy years of age and had been an army contract surgeon since 1861.

Dr. John Fidelle Fisher died at Philadelphia on December 9 of apoplexy at the age of sixty years. He was graduated from Jefferson Medical College in the class of 1872.

Dr. Wm. H. Bigler, a lecturer on pediatrics in the Hahnemann Medical College, died suddenly at Philadelphia on December 10, at the age of sixty-four years. He was graduated from Hahnemann Medical College in 1871. He was president of the Homœopathic County Medical Society, and at one time president of the Homœopathic Medical Society of Pennsylvania.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL COUNCIL—PRESIDENT RETIRES—DISPLACEMENT OF EPIPHYSIS OF FEMUR—CHRONIC OSTEITIS—MULTIPLE SYPHILITIC JOINT DISEASE—HOSPITAL SUNDAY FUND—ACTOR ON DOCTORS—FADDISTS' HOSPITALS—ITEMS—DEATH OF DR. POORE.

London, November 25, 1904.

The eightieth session of the General Medical Council was opened on Tuesday, when Sir W. Turner presided, and delivered an address in which he summarized, as usual, what had passed since the last meeting, and the programme of the present one. There was, however, a departure from his previous addresses. Referring to the common seal of the Council, he said the design selected bore in the center the figure of Hygeia, robed and holding the serpent and cup, and on the one side was the device of a roll of parchment, on the other a mace. The roll might represent the literature of the Council, but up to the present the mace was nothing more than a device on paper, and he wished to give that emblem an objective form. He therefore offered to the Council the specimen lying on the table as a parting present, and concluded by intimating that at the close of the session he must resign the chair he had occupied for six years, in consequence of the heavy call on his time as the Principal of the University of Edinburgh. The best thanks of the Council were thereupon voted to the president for his conduct in the chair and his magnificent gift of the mace. His successor will be appointed before the close of the meeting, and there is talk of the members entertaining Sir William at a dinner. He has been an efficient president, with an intimate knowledge of the duties of such an office. I hope his successor will be equally efficient. I should hope, too, he will discontinue the useless practice of epitomizing the programme in an opening speech at each session. The Council spends so much time—and time in these meetings is an expensive item—in talking that the profession has long been dissatisfied with its "talking-machine," and as I have more than once remarked, the members are quite able to understand a printed programme.

Mr. E. Muirhead Little showed at the last clinical evening of the Medical Society a case of traumatic displacement backward of the lower epiphysis of the femur. The patient, a youth of 17, was admitted to the hospital on May 11, last, complaining of his right knee, which he had struck violently on the ground in a bicycle accident some six weeks previously. Skiagrams showed the displacement, and an operation was performed. The femur was fractured at the junction of the middle with the lower third; the leg was then straightened, and only half an inch of shortening resulted. Backward displacement of this epiphysis being much less common than forward, the case was worth reporting. A good recovery had ensued, but though the result was satisfactory, Mr. Little thought in future he would prefer to perform osteotomy of the lower end of the shaft rather than produce a fracture higher up. The president, Mr. Langton, thought the fracture was commonest under the age of 20. In all the cases he had seen the epiphysis was also displaced backwards, as in Mr. Little's case; one had been complicated with gangrene from pressure on the vessels.

Among other exhibits at the same meeting were two cases of chronic osteitis of the tibia, both in girls, aged 16 and 18 years, respectively, otherwise healthy. Some bone removed from one gave a cultivation of staphylococcus albus, to which Mr. Wallis attributed the affection. He had had five cases, all in girls, all mild, but he thought they belonged to the same category as the more serious cases of infective osteomyelitis. Mr. Langton mentioned a similar case occurring in a woman whose femur was affected. The disease was very intractable, and of long standing. Dr. Buckley had seen a case in which the fibula was affected. Mr. Waring referred to a case which resembled these, but turned out later to be tuberculous.

Another case was one of multiple syphilitic disease of joints in a girl of 15 years. The condition was one of very chronic, but painless, synovitis, having lasted seven years. There were various indications of hereditary syphilis, or the case might have been taken for osteitis deformans.

The Lord Mayor presided at a meeting of the Hospital Sunday Fund on Tuesday. The report was made up for the year ending October 31, and showed subscriptions, £63,064 19s. 10d.; collections in places of worship, £47,012 5s. 4d. Mr. George Herring's munificence in adding one-fourth to the collections was referred to. His check this year was for £12,000. The country clergy in the home counties have not taken up the fund with the zeal one would look for, considering that quite 25 per cent. of the patients in the metropolitan hospitals come from their districts.

Sir S. Bancroft distributed the prizes at Charing Cross

Hospital on Wednesday, and said he considered it a favor to be allowed in any way to pay a fragment of the debt, always owing and increasing, due by members of his precarious profession to the physicians and surgeons throughout the land. Actors were not ungrateful. They remembered with gratitude the help they received, as well as the allusion by the Princess of Wales, at the meeting of King Edward's Fund, to the help of the theatrical profession to the hospitals. Sir S. Bancroft congratulated the students on starting with the best stock in trade—youth and hope. He half believed opportunity knocked once at every one's door. When it came to them let them be ready. He wished them success in the noblest of all careers.

The "Lady Margaret" Hospital, started a few months ago at Bromley, celebrated, on Wednesday, the naming of four cots. There are thirty beds and cots altogether, and a donation of 25 guineas gives the donor the privilege of naming a cot, and 50 guineas a bed. The hospital itself is named after four patronesses bearing the name Lady Margaret. The institution is a vegetarian one—another example of faddists pushing their views by founding hospitals or charities. But the promoters avoid the word vegetarian and call it "fruitarian." The warden quoted a daily paper's correspondent to the effect that the meat-eating American soldiers in Cuba did not get over wounds so well as the almost vegetarian Japanese. As to that, we can wait for more authentic information. Perhaps many people eat more meat than is good for them, but I doubt if this hospital will act as a deterrent. At present the most remarkable feat of the institution is to be out of debt.

A more pernicious faddists' hospital is the antivivisectionists'. Their staff has already achieved some notoriety by the "demonstrations" of one of them before reporters of sensational papers of his cures of ocular defects by manipulation—thus making spectacles useless. A challenge by an optician to produce cases satisfactory to an ophthalmic surgeon was at first accepted, but has gone off by the conditions being refused. Meanwhile spectacle makers continue their labors.

The North Eastern Hospital for Children is in great straits for want of money. Notice has been published that £4,000 must be obtained before Christmas, or else fifty-seven beds will have to be closed. Only a few months ago a large extension was opened. The hospital is in a poor district, and one of the most deserving, but it is obvious the governors were not justified in making the enlargement. It is too common a case. Hospital managers seem always to be ready to run into debt.

The Surrey County Council has decided to erect a new lunatic asylum on a site of 350 acres which it acquired five years ago. The new buildings are expected to cost about £400,000. Poor rate payers! The present asylum accommodates above 1,300 inmates. The new one will hold almost as many.

Mr. A. A. Bowlby, C.M.G., has been appointed surgeon to the King's Household, in succession to the late Mr. Herbert Allingham.

Dr. Vivian Poore died on Wednesday, aged 61 years, at Andover, where he was born. He was a University College student, where he took the Atkinson-Morley scholarship in 1868. He graduated M.B. and M.S. at the London University and became university medical scholar, following with M.D. in 1871. He was surgeon to the *Great Eastern* steamship while she was laying the Atlantic cable. Afterward he became medical attendant to the late Duke of Albany, and then to the Prince of Wales (now the King). He was elected on the staff of the Charing Cross Hospital and served there and taught in the school, rising rapidly to distinction in consulting practice, and in 1877 was elected to the Fellowship of the R. C. Physicians. A vacancy occurring at his old school, he obtained the appointment, and so, in due course, became professor of medicine and clinical medicine at University College and physician to the hospital.

In 1901 he was secretary-general of the Sanitary Congress. Much of his literary work was on sanitary questions, as his "Essays on Rural Hygiene," and many contributions to the journals show. He wrote also "A Text Book of Electricity in Medicine and Surgery," and translated Duchenne's works for the New Sydenham Society. His "Treatise on Medical Jurisprudence" was the outcome of his lectures when he held that chair. He also wrote a volume on "Climate in Its Relation to Health." He received the Dannebrog order for professional services to Princess Thyra, Duchess of Cumberland, and was a member of various societies.

Field Hospitals for Sick and Disabled Horses will be part of the war equipment of the British army in future. Two have been formed in England, and the system is proving satisfactory in India. The Japanese have adopted it in Manchuria, where the loss of animals is only 6 per cent.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CANCER IN THE TROPICS—A GOVERNMENT LIBRARY OF SCIENTIFIC BOOKS—RECRUDESCENCE OF SMALLPOX—RINDERPEST—FATALITIES AMONG ANIMALS.

MANILA, October 28, 1904.

AN examination of the mortality and morbidity statistics of the Insular Board of Health for the past year shows that there were thirteen deaths from cancer. The population of the city of Manila is given at 219,941, which would give approximately a death rate of .0612 per thousand. There were four cases of cancer of the stomach, five of cancer of the female genital organs, two of cancer of the breast, one of cancer of the buccal cavity, and one of cancer of the liver. Figures from other tropical countries are not at hand, and it is, therefore, not known whether this compares favorably with the deaths occurring from cancer in such countries. But these figures do show that cancer is much less prevalent here than in temperate countries, like Great Britain, or the United States. There is much food for thought in these figures, and it becomes quite pertinent to inquire what effect climate has on this disease. All the cases reported occurred among natives, with the exception of one case, viz., of death from cancer of the genitals, which occurred in October. The European and American population of Manila amounts to about 7,000, and only one case was reported in a white person. Is there some influence at work which exempts these from the disease or is it because the great majority of them are in the prime of life, or else that they have not yet reached the age at which this disease may be contracted? With few exceptions, the cases reported among the natives are all in persons beyond fifty years of age. It is also quite possible that the disease is more prevalent among the natives than the reports would indicate.

The figures are based mostly upon the reports of the native practitioners, who have not had an elaborate medical education, and, therefore, could not be expected to make very reliable diagnoses. Still, by allowing a reasonable margin for error, the fact remains that among a white population of 7,000, composed of British, Germans, and Americans, which has as good medical attention as can be obtained anywhere in communities of like size, there was but a single case reported.

In order that the medical and other scientific books which are the property of the various branches of the Insular Government in Manila may be of service to the greatest number of persons, and to prevent needless duplication, and in order that the money which would be used for the latter purpose may be utilized for the purchase of more books, the Secretary of the Interior has directed that all books should be placed in the library at the Government Laboratory, the idea being to have them properly catalogued, after which those which are needed for constant reference by the various bureaus are to be returned to them. By this arrangement it will be possible to have access to any book which the Insular Government has purchased by merely consulting the catalogue and ascertaining at what bureau it is to be found. The plan, of course, provides that the great majority of the books shall be kept at the central library.

After the most unusual freedom which the islands have enjoyed for the past few months from the more grave contagious diseases, smallpox has appeared in a number of places in more or less epidemic form. Surigao, in the island of Mindanao, and the islands of Siquejor and Marinduque, are at present most affected. At Boac and Gasan it has become necessary to close the public schools. The natives have been predicting for some time past that a severe epidemic of smallpox was about due. They state that it appears regularly every ten years. They are sometimes a little uncertain in their estimates, but it is only given for what it is worth. It is indeed unfortunate, but it seems impossible for these islands to remain free for any length of time from serious contagious diseases, either in man or animals.

The contract which the government held with a Shanghai firm for restocking the islands with caraboa has recently been annulled. Hundreds of thousands of dollars were spent in the purchase of these draft animals, with the result that they nearly all died, either en route or after they landed in the Philippines. Hundreds of them were killed by direction of the government, in order to arrest the spread of surra, with which they were afflicted. Others died soon after they were inoculated with antirinderpest serum. Such animals as were not inoculated soon contracted rinderpest and died. So that whichever course was pursued, it seemed doomed to failure. All kinds of animals seem to lead a perilous existence in the Philippines. Recently a fine herd of milch cows was imported from the United States. They seemed to be doing nicely. Excellent

milk was furnished daily to the government hospitals. It was finally decided to inoculate them against rinderpest, which was done, whereupon over half of them died. The calves which were used in the manufacture of vaccine virus are at present afflicted with surra. The orang-outangs which were imported from Singapore by the Harvard Smallpox Commission for experimental work, soon after landing developed a peculiar form of hemorrhagic septicæmia and died.

POST-PARTUM HEMORRHAGE.

To the Editor of the Medical Record:—

Sir: Apropos of the treatment of post-partum hemorrhage, recently discussed in the Medical Record, the writer will mention what has been his practice in treating that form which occurs from a non-contracting uterus only. First, in every case of labor, as soon as the child is born, the left hand grasps the uterus over the abdomen, and so holds it, kneading the uterus, or not, as relaxation or contraction is present, until the womb is as hard as a cocoanut, and about the size. It is so held until there is no longer any tendency to relaxation. If this does not produce uterine contraction, I proceed with the right hand to "turn out the clots," and when this does not suffice, I put no gauze or cotton in the uterus, but push the entire hand into the uterine cavity, and move the closed fist all around the cavity; this will excite contraction and expel the hand. Waiting for hot water, gauze, etc., to be brought by a nurse, when often there is no nurse, is too slow. Besides this, the principle of packing a non-contracting uterus is not correct. You cannot control the bleeding by pressure, as is the idea of gauze packing, but it must be done by exciting uterine contraction, and this is done best by the motion of the hand in the uterine cavity, which, by its irritation excites muscular contraction.

Of course, if the bleeding is from a torn cervix, the condition is different, and pressure is then rational surgery.

T. M. McIntosh, M.D.

Thomasville, Ga., December 4, 1904.

Some of the Less Commonly Recognized Manifestations of Rheumatism in Childhood; with Remarks on the Treatment of This Disease.—James Burnet declares that pharyngitis and tonsillitis deserve to be more often regarded as rheumatic than they are at present. Although tonsillitis is said to be more common in the rheumatism of adolescents and of adults than in that of children, the writer is convinced that pharyngitis in the child should always be looked on with suspicion, the heart carefuly examined, and the child kept in bed till all doubts are set at rest. He also believes that possibly some cases of pneumonia attributed to "chill" are in reality due to the specific virus of rheumatism. Further work must be done on this subject. Psoriasis scarcely ever occurs, save in rheumatic subjects, according to the personal observations of the writer. In not a few cases appendicitis is undoubtedly a rheumatic affection. A condition, called by the writer gastroenteric spasm, in which the child complains of acute gastric pain after a meal and has an urgent call to stool, is often of rheumatic origin. That common condition of childhood, pain in the side, or in the upper part of the chest, is often greatly relieved by the administration of anti-rheumatic remedies. The pain is often referred to the loin or to the infraclavicular region. It may often be detected in choreic subjects. Children of rheumatic heredity do not always show any definite manifestation of the disease. They are often nervous and irritable, thin and spare, sensitive, subject to fits of violent temper, and are generally restless. Chorea often develops. As to the treatment of rheumatism in childhood, the salicylates generally give the best results. These must be given in large doses. Calomel keeps the gastrointestinal canal in good working order, and so is very beneficial. The heart requires special attention. An ice-bag wrapped in flannel may be applied locally. If convalescence is slow, cod-liver oil in small doses should be given, and anti-rheumatic remedies should be continued.—*The British Journal of Children's Diseases.*

Eugenics.—Francis Galton has endowed, in London University, a fellowship for the promotion of the study of "National Eugenics," which is defined as "the study of the agencies under social control that may improve or impair the racial qualities of future generations either physically or mentally."

Progress of Medical Science.

The Boston Medical and Surgical Journal, December 8, 1904.

Four Cases of Laparotomy During Typhoid Fever: with Recovery.—R. R. Fitch reports these cases as being illustrative of the good results of early operation. The first patient, a boy of 9 years, was admitted to the hospital with a history of typhoid fever of two weeks' duration. On the second night after entrance the child complained of slight abdominal pain. It was not relieved by a turpentine stupe. Two hours later the abdomen was extremely tender, somewhat rigid and not distended. There was no diminution in liver dullness, the blood pressure was unchanged, and the white count had fallen to 4,200. The pulse became somewhat more rapid and smaller in volume. Temperature and respiration were practically unchanged. Operation was performed four hours after the onset of the abdominal pain, and gas and intestinal contents were found in the peritoneal cavity. The intestinal wall was perforated a short distance above the ileocæcal valve. This was closed and the peritoneal cavity washed out with normal salt solution, and drained. The patient had an uninterrupted convalescence. The second patient was a man of 20 years. In the fifth week of his illness there developed slight tenderness, dullness and resistance, just inside the crest of the right ilium. These signs increased till the next morning, when there was a distinct mass palpable in this region. The white count was 6,000. At operation the mass was found to be an appendix abscess. The appendix was removed and the wound drained. Convalescence was uneventful. Besides these cases, there was one of ruptured pus tube and one of perforation, both operated on and ending in recovery.

New York Medical Journal, December 10, 1904.

A Comparative Study of Idiopathic Epilepsy in Man and Animals.—L. Pierce Clark gives an interesting series of descriptions of epileptic seizures in different animals. He notes that it appears that the nearer animals have approached to man by domestication, the more they seem to be subject to the same diseases. This apparent fact may be explained in three ways: (1) The nearer to man the animal approaches in anatomical structure, such as the dog, cat, monkey, horse, etc., the nearer a comparison between normal and morbid function of the nervous system is possible; (2) being subjected approximately to the same condition of environment the same diseases result in animals and man; (3) finally, such animals being closely associated with man, normal and morbid acts are under close scrutiny. When considering so-called idiopathic epilepsy, it must be remembered that many remedies taken in excess bring on seizures resembling those of this affection, notably mercury, arsenic, lead, belladonna, camphor, hemlock, cocculus indicus, digitalis and aconite.

Public School Children and Preventive Medicine.—J. S. Lankford believes that the time to inculcate the lessons of hygiene is in childhood, and relates the experience of this kind of teaching in his own city (San Antonio, Tex.). A campaign on the general subject of insects as carriers of disease was begun by keeping a bottle of eggs and wigglers in every schoolroom, so that the children could watch the development of the organism up to the matured mosquito. The proper literature was provided for the teachers and suitable illustrations for the scholars. Thus the work was begun, and much has been learned by all about this particular insect, and it is proposed to take up in due time and in a similar way studies on tuberculosis, typhoid fever, and various contagious diseases.

Superannuated Trolley Cars for Consumptives.—W. H. Peters calls attention to the fact that discarded trolley cars make excellent shelters for consumptives, and can be purchased and set up for less than the cost of an equally substantial cabin or tent. The car bodies are taken from the trucks and set on a foundation eighteen inches high and furnished with a cot bed, stove, table, and chairs. The cars are well built, have heavy frames, can be easily ventilated, and afford a maximum of sunshine, owing to the windows on each side.

Medical News, December 10, 1904.

The Immediate Repair of the Pelvic Floor and Perineum.—Edward P. Davis says that the attention of the obstetrician is usually drawn to a laceration by the occurrence of hemorrhage. Lacerations of the posterior segment of the pelvic floor naturally divide themselves into tears of the pelvic floor and those of the perineum. These injuries may be closed immediately, or after some delay. If the tear be extensive and the condition of the patient bad, the operator may wisely delay such repair for twenty-four to thirty-six hours. No considerable tear of the pelvic floor can be satisfactorily repaired with the patient upon a low bed and in a poor light. The patient should be placed

upon a table or high bed in a good light, and sufficient assistance should be obtained to give the patient the care necessary for an important surgical operation. The most important stitches in closing lacerations of the pelvic floor are those placed at the highest points in the tears in the sulci. A fully curved needle is usually necessary for placing them. In all cases muscle and connective tissue should be brought together by a firm and carefully applied stitch. Several stitches may be used if they are properly placed, and the catgut be not too large. In repair of the perineum, the wound should be attacked nearest the anus, the skin edges and underlying facia being brought together with silkworm-gut stitches, a considerable portion of tissue being taken, but without tension. The perineum should be closed up to the point where the posterior vaginal wall begins. No effort should be made to repair the fourchette, as too close an approximation of tissues in this region will produce a pocket favoring the retention of lochia. Complications may follow this operation. Hemorrhage is of rare occurrence. The stitches sometimes tear out. In the presence of infection, the stitch at the site of infection must be removed as soon as possible and the parts thoroughly irrigated with an antiseptic solution. The after-treatment of these cases consists of surgical cleanliness, so applied as least to disturb the tissues and parts which are healing. The average patient, after an operation where union occurs without infection, is convalescent in from three to six weeks.

The Care of Fractures from the Standpoint of the General Practitioner.—Wm. S. Newcomet declares that fractures cause the physician more trouble than any other trial in his professional life. In such cases, if the proper precautions were always taken, many of the difficulties would be avoided. The *x*-ray is of great value in giving a graphic description of the exact amount of damage. A green-stick fracture is often unrecognized. Although such an error is not likely to lead to any serious consequences, the patient is made more comfortable when the proper dressings are applied. A most troublesome class of fractures are those which occur about the joints, as at the wrist, elbow, shoulder, or ankle. In these cases a small bit of the bone is torn off, and is often bound so firmly by the ligaments that the ordinary signs of fracture are absent. These injuries are often treated as sprains. Such an injury causes more inconvenience to the patient on account of the joint involvement than does a fracture of the shaft of the long bones with considerable displacement. The writer calls attention to a bad method of dressing which should be avoided. When the bone is placed in position, the dressings are applied, and are allowed to remain on for three or four weeks. If in that time they become loose, a new bandage is simply wrapped around the old dressings. This is extremely dangerous, and one that will always give a poor result. Whenever doubt exists as to the nature of the injury, the mystery should be cleared up at once, before the bones have become united, which may result in a deformity that lasts the rest of the patient's life.

A New Method for Staining the Capsules of Bacteria.—Leo Buerger describes his technique as follows: The culture is thinly and carefully spread over a perfectly clean cover-slip by means of a drop of diluted serum. Just as the edges begin to dry, the fixing fluid is poured on, the cover gently warmed over the flame for about three seconds, rapidly washed in water, flushed once with alcohol, and then treated with iodine for one to two minutes. The iodine is in turn thoroughly washed off with alcohol, and the specimen dried in the air. Staining for two to five seconds, and washing with salt solution completes the procedure. The specimen is mounted in the salt solution and ringed with vaselin. Sputum and pus can be stained in a similar manner, the addition of serum being unnecessary, except in very mucoid, stringy purulent exudates. The method depends upon the rapid fixation of the bacteria while still alive, and when spread in a medium, which prevents dissolution of their capsules. The Müller's fluid, saturated with bichloride of mercury (*i.e.* Zenker minus acetic acid) has given the best results. The procedure, as described above, can be shortened by reducing the action of the iodine to thirty seconds. This may be done by flushing several times with fresh iodine. Good, permanent balsam mounts can be made from double-stained specimens (gentian-violet and fuchsin). With this method the specimen presents the following features: There is a refractile, deeply staining, regularly outlined, narrow, elliptical capsule membrane, separated from the diplococcus by a clear area of capsular substance, which remains unstained, or takes a faint color.

American Medicine.

"Has a Persistence of the Mullerian Ducts Any Relation to the Condition of Cryptorchidism?"—Augustus Grote Pohlman reviews the general development of the urogenital system, representing the "undifferentiated stage" and the further development of the male and female by three diagrams. The blood supply to the sex gland, the suprarenal and kidney, is not established until the kidney is at its normal height. As soon as this stage of development is reached the wolffian body undergoes degeneration. The writer declares that the wolffian body in the embryo is the source of those products of internal secretion of the aforementioned glands, which later play such an important rôle in the economy. The internal secretion of the sex gland offers the stimulus for the further development of the "undifferentiated stage" into male and female types. The writer also holds that the internal secretion of the testicles inhibits the further development of the Mullerian ducts. Thus, if the testicles be imperfectly developed, a persistence of the ducts may result and account for the condition of cryptorchidism. The abnormalities of the gubernaculum or abdominal wall, or both, are the secondary causes for retained testicles. The later atrophy of the testicles in these cases is due to displacement. This atrophy is apt to appear about the time of puberty. The writer considers such abnormalities to be the cause of monocryptorchidism and reports a case in point. He concludes with a plea for embryological material.

The Dangers of the Microscope in the Early Diagnosis of Pulmonary Tuberculosis.—H. C. Clapp emphasizes the danger of waiting for the confirmation of the microscope before instituting the appropriate treatment for tuberculosis. Patients often neglect the proper treatment until the incurable stage is reached, because of the assurance from their trusted medical advisers that no tubercle bacilli have been found in the sputum. The writer quotes from his records in the Massachusetts State Sanitarium at Rutland, showing that when tubercle bacilli have been found in the sputum of patients they are not by any means always present at each examination. They are often absent for long periods, or they are irregularly present. Often the skilled diagnostician ought to recognize the disease before enough ulceration and cavity formation have occurred to allow the escape of the bacilli from the lung tissue into the sputum.

The Relation of the So-called "Piroplasma Hominis" and Certain Degenerative Changes in the Erythrocytes.—Charles F. Craig has made careful observations concerning "Piroplasma hominis," claimed by some investigators to be the cause of "spotted" or "tick" fever. According to the writer, no such organism can be demonstrated in the blood of patients suffering from this disease. He believes that the phenomena observed in the red blood cell are not due to a parasite, but to certain changes, especially in the hæmoglobin of the red cell, produced by disease, and that further study will prove that peculiar areas occurring within the red blood cell, especially those devoid of hæmoglobin and appearing in human diseases, have been wrongly considered to be a protozoan parasite by those who have demonstrated "Piroplasma hominis." Reference is made to the report of Stiles, who was unable to demonstrate the parasite after thoroughly investigating ten cases.

Journal of the American Medical Association, December 10, 1904.

Whooping Cough Treated by the Elastic Abdominal Belt.—The belt employed by T. G. Kilmer is thus described: A stockinette band is placed on a baby with whooping cough, in the same manner as is done by orthopedists before applying the plaster-of-paris jacket. This band extends from the axillæ to the pubes and fits the baby snugly. Two muslin shoulder straps are used to prevent the band from slipping down. On this stockinette band a single width of silk elastic bandage is sewn, extending entirely around the body and covering the abdomen. This silk elastic bandage is of the same quality as that used for elastic stockings. If the child is under a year old, it will be found necessary to use but one width (five inches) of this elastic bandage; in an older child, two widths will often be found necessary to entirely cover the abdomen. This silk elastic bandage is pinned in place when very slightly on the stretch. After it is pinned in place, it should be sewn to the stockinette band underlying it, all around its entire edge; this procedure keeps the silk elastic belt flat and prevents its rolling up or becoming creased. The lower projecting portion of the stockinette band should be pinned down to the outside of the diaper, or other clothing, thus keeping the elastic belt smooth over the abdomen. Kilmer states that out of eighteen patients on whom this belt was used, cough was relieved in twelve and vomiting in all but one.

The Nervous Symptoms Produced in Children by Uncorrected Refractive and Muscular Errors.—J. H. Claiborne presents the following conclusions: (1) Nervous symptoms of a variety of kinds occur, as the result of eye-strain. (2) Eye-strain is due to refractive errors, to imbalance of the external ocular muscular system, or, more frequently, to a combination of the two. (3) Of these two, the refrac-

tive errors are by far the more frequent cause. (4) Muscular imbalance alone may cause it. (5) Headache is by far the most common nervous symptom in children, caused by eye-strain. (6) The headache is chronic or induced directly by near work, and is generally in the forehead or temples. (7) Migraine or hemicrania, due to eye-strain, is comparatively rare in children. (8) Any nervous symptom in children should arouse the suspicion of ocular defects, either as the direct or a contributory cause. (9) The refractive correction should be made under atropine. (10) Muscular defects are secondary to the refractive, and should be corrected only in certain cases.

Congenital Occlusion of the Lacrymal Canal.—J. E. Weeks notes the occasional occurrence of this condition from the third to the eighth week after birth, and states that it is often confounded with acute contagious conjunctivitis. Irritating treatment makes the condition worse and may lead to corneal infection. Boric acid may be used to cleanse the conjunctive sac, and a bland ointment to protect the skin. Probing of canal should not be tried until nature has been given a fair chance to restore the patency of the canal. If, after the lapse of two months, the passage is not free, the canaliculus may be slit up and a Bowman's probe, No. 4 or 5, passed. One passage of the probe is usually sufficient. The permanency of the patency of the canal may be determined by syringing through with boric acid. The acute contagious ophthalmias from which the condition must be distinguished are those due to, respectively, the pneumococcus, the Koch-Weeks bacillus, the gonococcus and the Klebs-Loeffler bacillus. Microscopical examination is generally necessary for an accurate diagnosis. Isolation should always be practised until the discharge has entirely disappeared.

Changes in the Salivary Secretion Affected by Systemic Disease.— From the results of the studies of H. Stern and W. J. Lederer, the following statements are worthy of note. In the saliva of 158 cases of diabetes, the amount secreted was increased in 8, decreased in 89 and normal in 63; it was acid in 47, alkaline in 92, neutral in 8, not examined in 11; glucose was found in the saliva in 85. In 28 cases of uricacidemia, the amount of saliva was not increased in any, and was diminished in only 1; reaction was acid in 5, alkaline in 52, and neutral in 2. Uric acid was looked for in 59, but found in only 21. Bile pigments were looked for in 14, but found only once. The diastasic quality in 18 examinations was normal in 13, and more or less sub-normal in 5. In 20 cases of gastritis, the quantity of saliva was increased in 9, normal in 11; reaction was acid in 8, alkaline in 12; acidity due to lactic acid in 2. Hyperchloridia showed in 182 examinations an increase of saliva in 27, reaction acid in 71; alkaline in 41, neutral in 5. In hypochloridia, the saliva was increased in but 1 out of 23 cases examined. The reaction was found to be acid in 2 cases, alkaline in 15 cases, amphoteric in 6 cases; acidity was found to be due to lactic acid in 1 case, formic acid in 1 case. The saliva in 15 cases of pyloric stenosis was found to be increased in 3 cases; balance fairly normal. The reaction was found to be acid in 5 cases, alkaline in 8 cases; in 2 cases the reaction was not determined. Acidity was found to be due to lactic acid in 2 cases, acetic acid in 2 cases, lactic-acetic-formic acid in 1 case.

The Prevention and Treatment of Heart Failure in Pneumonia.—According to S. Solis-Cohen, there are three principal and many secondary causes of heart failure in this disease. The principal causes are, first, the toxemia; second, the mechanical obstruction to the circulation in the lung, causing overburdening and dilatation, especially of the right heart; third, the alteration in the physical and chemical constitution of the blood, which, apart from the toxic effect on nervous and muscular action, central and cardiac, predisposes to the formation of antemortem clot. Among the most important of rare causes are hyperpyrexia and a sudden paralysis of inexplicable origin. Two great classes of drugs are at our disposal. One may be used to support the heart and circulation during the progress of the disease, and the other reserved for emergencies. The first class includes digitalis, barium chloride, strychnine and atropine. Digitalis may be used as soon as hepatization is present. Before this, aconite and veratrum are indicated. For emergency service Cohen recommends adrenalin, camphor, and musk. For administering the first named he prefers to employ suprarenalin triturates containing 1/20 grain active principle in a very small quantity of sugar of milk. These are preferable to solution for lingual administration. They dissolve quickly and do not fill the mouth with liquid. Such a tablet may be given every ten minutes, if needed; as a rule, one every one-half hour to two hours suffices. The drug likewise raises vascular tone —a great advantage. Camphor may be injected hypodermatically in a 10 per cent. solution in sterilized olive oil or in 10 per cent. solution in ether. Exact dosage is unnecessary, about a syringeful, say from 20 to 30 minims, can be used. The effect is prompt and usually lasts for some hours. The injection is to be repeated as needed. Five or ten drops of tincture of musk given hypodermatically exert a powerful influence in overcoming the tendency to cardiac collapse, and the action of musk is even more sustained than that of camphor. Care should be taken to secure a reliable preparation of musk. Much on the market is useless.

The Lancet, December 3, 1904.

The Treatment of Cancer.—The main point in Mayo Robson's Bradshaw Lecture is the necessity of impressing upon those who have the chance of seeing patients in the early stages of their illness that in many cases cancer can be prevented by treatment in the pre-cancerous stage; that even when it has developed, if it he seen early and thoroughly removed, it is frequently a curable disease, and, finally, that in the later stages much may be done by surgical treatment to give real relief. He believes that cancer is locally infective and capable of distribution by contact and inoculation. Hence arises the danger of an imperfect operation, which, by distributing the cancer cells, implants numerous foci of the disease. From a study of numerous cases he believes it highly probable that cancer is both contagious and inoculable among human beings, as it undoubtedly is among the lower animals. These facts are so suggestive that, although it may not be necessary to advise segregation of cancer patients, it would seem most desirable that all dressings taken from cancer patients should be burnt, that linen soiled by cancerous sores should be destroyed or disinfected by boiling, that contact with cancerous ulcers, whether of the lip, tongue or breast, uterus, or other parts, should be avoided, and that common use of beds and utensils with cancerous patients should not occur.

Relationship of "Splenic Anæmia of Infancy" to Other Forms of Blood Diseases Occurring in Infancy and Early Childhood.—H. B. Shaw dwells upon the normal blood composition at different ages up to puberty and then discusses the blood states in the severe secondary anæmias of infancy and childhood, and, finally, that in the primary anæmias. He finds no sharp line of demarcation between any of the groups which have been designated by special names. It is more in harmony with recent investigations to insist upon the close relationship of all blood diseases. Pathological considerations do not at present justify the recognition as separate diseases of what are really only different degrees of reaction of the blood forming tissues to various obscure exailants. To sum up, it may be said that this or that patient is suffering from a disordered blood forming state or blood-making tissues and that the blood examination reveals features which in part are known to exist in healthy children, but which are also met with in cases which at present are called pernicious anæmia and leucocythæmia. In the latter disease the marrow is involved in every case, whether the leucocythæmia is lymphocytic, myelocytic, or of a mixed type and shows an overgrowth or hyperplasia of the lymphoid cells which normally occur there; as the result of a process allied to the one described by Virchow as metaplasia these formative or mother cells are now believed to develop into the non-granular lymphocytes, into granulocytes of all kinds, or into both non-granular and granular cells. The spleen and lymphatic glands may or may not share in this change; as already stated in recently reported cases, the marrow alone has been found to be affected. In other cases (pernicious anæmia) the lymphoid cells appear to give rise, again by metaplasia, to various forms of erythroblasts and erythrocytes.

British Medical Journal, December 3, 1904.

Afebrile Enteric Fever.—George Jubb reports this interesting case. The patient, a girl of 20, had been nursing her sister through a siege of typhoid fever. On the fourth day of her illness, she complained of headache and pains in her limbs, loss of appetite and lassitude. There was slight abdominal pain. The tongue was moist and coated; the pulse, 90, and temperature 98.4° F. The abdomen was silghtly distended and tender. The spleen was not greatly enlarged, and there were no rose spots. The mucous membranes of the lips and eyelids were well colored. The bowels were constipated. The heart and lungs were normal. A provisional diagnosis was made that the patient was probably suffering from typhoid fever. She was put to bed and kept on milk diet. The typhoid serum reaction was positive on the seventh day of the illness. The spleen was now distinctly enlarged. The temperature remained normal till the morning of the seventeenth day, when it rose to 101.6° F. The patient complained of pain in the left leg, which was slighly swollen and tender. The temperature was febrile for the next four days, but settled to normal on the twenty-second day of the illness. The recovery after that was uninterrupted. Without the serum reaction, there would have been some hesitation in confining the patient to bed on a milk diet, for a prolonged

period. The temperature was not disturbed till the complication—thrombosis of the left femoral vein—took place.

Case of Congenital Absence of Continuity Between the Large and Small Intestines.—C. H. Souter observed this case. The patient was a boy, 48 hours old, who had vomited some foul-smelling dark stuff as soon as the head was born. It was said that he vomited everything that he swallowed. There was nothing of interest in the family history. The color of the infant was yellow. He vomited large quantities of fæcal-smelling fluid of a greenish color. The rectum was small and empty. Immediate operation was indicated by the general condition. The abdomen was opened over the right iliac region, where a swelling could be felt externally. Some more distended bowel presented. The bowel was stitched to the edge of the wound and opened. Over half a pint of foul-smelling, greenish fluid escaped. The gut was then washed out with saline and the artificial anus dressed with iodoform gauze every two hours. Artificial feeding was begun, and the child did well for a week, when dystentrypsia set in and all efforts to control digestion failed. There was no rise of temperature, and no swelling of the abdomen. The patient died ten days after operation. At necropsy it was found that the small intestine from the wound to the stomach was normal, but of greater caliber than usual, and contained green bile-stained grumous matter. Downward it extended one and one-half inches, where it ended in a cul-de-sac. There was no Meckel's diverticulum, nor any trace of an opening other than the surgical one. The large intestine ended in a small cæcum and vermiform appendix, and a diverticulum of about one-half inch in length, having no opening. The two blind ends were situated in about the normal position with respect to each other, but not in contact. Loose mesenteric tissue lay between them. The lumen of the colon world admit a slate pencil. The edge of the liver was about one and one-half inches from the costal margin. The gall bladder was distended with bile, and projected one-half inch beyond the edge of the liver. The rest of the abdominal contents were normal.

Bony Union of the Olecranon Process in a Patient Aged 73.—Ernest W. Wade attended a patient of 73 who was suffering from a simple transverse fracture through the middle of the left olecranon process, caused by a fall on the elbow three days before. The arm, elbow, and hand were very black, swollen, and painful, and the broken ends of the bone were separated about one-half an inch. The muscles were flabby, so the fracture was easily brought into apposition and kept there by strapping. The arm was put up in extended position. Within a month the fracture was healed by bony union, with no deformity and with full use of the arm. A bony union of this fracture, especially at an advanced age, is very uncommon.

Berliner klinische Wochenschrift, November 21, 1904.

The Treatment of Lupus by the Practitioner.—Dreuw describes a method of treating lupus which is especially serviceable for the general practitioner, since it does not involve the use of complicated apparatus, such as that required for the production of Finsen or *x*-rays, etc. The affected portions are first well frozen with ethyl chloride spray, and then commercial hydrochloric acid is thoroughly rubbed into the tissues with a cotton-tipped wooden toothpick. On contact with the acid the lupus tubercles turn dirty white and may readily be distinguished. It is an advantage to use hydrochloric acid saturated with free chlorin gas. In cases where the lesion is extensive, involves the lips or nose, or in tuberculous abscesses and fistulous tracts, general anæsthesia may be employed. After this cauterization a grayish brown slough forms in one or two days, which drops off after two to four weeks. Together with this, the superficial lupus tubercles come away, and the deeper ones, if numerous, are subjected to one to three repetitions of the treatment, at intervals of three to four weeks. At the end of from three to six months the lupus ulceration is transformed into a tissue covered with epidermis, and in which few, if any, tubercles persist. These isolated individuals are punctured with pointed capillary tubes filled with hydrochloric acid. The results of the treatment are said to be very satisfactory, and, when available, the Finsen light, etc., may be used in combination with the acid applications. Microscopical examination of tissue removed immediately after the cauterization shows that the acid causes a prompt and profuse emigration of leucocytes from the vessels into the tuberculous nodules. Control observations on normal tissue do not show any such accumulations of leucocytes.

Münchener medizinische Wochenschrift, Nov. 22, 1904.

The Relations Between Tonsillar Disease and Acute Articular Rheumatism.—Gürich believes that most cases of acute articular rheumatism have as a concomitant a more or less severe chronic follicular tonsillitis. The most prominent feature in this condition is the formation of the tonsillar plugs, which consist of desquamated epithelium and bacteria. Out of seventeen cases of acute articular rheumatism treated by the author, all but three had these plugs in the tonsillar crypts, and the author has been treating the tonsils in acute rheumatism with very good results in preventing recurrences. His theory is that the rheumatic poison, in entering the body through the tonsils, sets up an acute inflammation in these organs. The poison remains in the crypts in a latent but still virulent state, and sets up a chronic desquamative inflammation of the crypts, with the formation of plugs. Exacerbations of the local process may easily cause the general disease to recur.

How Shall We Facilitate the Expansion of the Lung After Thoracotomy for Empyema?—Hofman believes that the most advantageous plan of treating the collapsed lung due to exudates in the pleural cavity is by closing the operation wound as soon as possible. After performing the usual resection as low down as possible, the patient is turned on the side, so as to drain out the fluid completely. No drainage tube is inserted, and the wound is covered with a thick dressing, of which only the outer layers are renewed during the succeeding days. On the third to the fifth day, according to the amount of discharge expected, the dressing is removed, and two small rubber tubes are carried through the almost closed incision just down to the pleura. During the first days the lung has slowly been regaining its normal proportions and decreasing the size of the abscess cavity, while entry of air into the pleural cavity need no longer be feared, as the parietal and costal pleura have become adherent.

Obliteratio Uteri Totalis.—Frank gives this name to an operation he has practiced since 1887 in order to remove the diseased uterine mucosa *in toto*. To permit the typical operation, the uterus must be freely movable, so that the peritoneum need not be opened. The cervix is freed from its attachments by an anterior and posterior incision and is drawn down. The uterus is split by lateral incisions and its entire mucosa dissected up, together with a layer of the muscular walls. As one proceeds toward the fundus, the organ is inverted, and the removal of the lining of the tubal angles can easily be effected. The raw muscular surfaces are then opposed by catgut sutures, beginning from the fundus down, so that reinversion is accomplished and the entire cavity obliterated. The indications for the operation comprise intractable climactic flowing, neuroses due to disease of the endometrium, chronic endometritis, complicated with obstinate retroflexion, and some cases of submucous fibroids. The author also thinks that, carried out in the intractable cases of endometritis in older women, it would prove a valuable prophylactic against carcinoma. The author gives the histories of a number of patients who were benefited by the measure.

Deutsche medizinische Wochenschrift, November 24, 1904.

Pocket Mercury Manometers for Clinical Use, with Observations on an Improvement in the Riva-Rocci Armlet.—Sahli describes two new forms of mercury manometer designed for the pocket, in order to simplify blood pressure determinations at the bedside. One type consists of two vertical U-tubes having two of their branches joined. Each tube is half filled with mercury, the excursions of which are thus reduced to half their usual amplitude. The instrument is accurate and compact, but the scale is so short that close readings are hard to obtain, and the author subsequently developed another form, which he considers satisfactory. It consists of a single U-tube of such length as is necessary to contain the column of mercury while at rest, and a graduated prolongation fitted to one arm of the U by an accurately ground joint. This receives the rising column when the instrument is in use. The apparatus fits into a case of small size, which also serves as a standard for the manometer when put together. The improvement in the Riva-Rocci Armlet consists in several minor changes in its construction, which render it more convenient to apply.

The Treatment and Prognosis of Sterility in Women.—Bumm says the usual causes of sterility in women are two, defective development of the genitals and gonorrhœa. The tendency has been greatly to overestimate the importance of gonorrhœa as a source of sterility, and the author believes that two-thirds of the cases are due to congenital errors of development, and the remaining one-third comprise acquired sterility, which, of course, is often the result of gonorrhœa. The developmental defects may be of all degrees, and may involve only a part or the whole of the genital tract, and the pathological anteflexion of the uterus associated with dysmenorrhœa is a form of this infantilism. Poorly developed ovaries, with much contorted infantile tubes, are unfavorable to conception, as well as abnormalities of the cervix in size and direction, and in the capacity of the vaginal vault for retaining the semen deposited there. Fibrous stenosis of the internal os, with or without flexion of the corpus, is a potent cause of steril-

ity, though why this should be the case is not apparent, for the stenosis of itself is not a sufficient impediment to hold back the spermatazoa. Every case of sterility requires protracted observation, and especially microscopic study of the cervical secretion in its behavior to the spermatazoa, in order to arrive at a conclusion as to the nature of the impediment. Stereotyped treatment is usually ineffectual, and may be dangerous, as when a cervical gonorrhœa is passed on to the tubes by dilatation of the cervix. Infantilism of the tubes and ovaries alone gives a good prognosis, and if the uterus is of fair size and menstruation is normal, treatment is likely to be successful. The author believes that the rudimentary uterus and adnexa may be stimulated into growth by one plan only, and that is the intrauterine application of the constant electrical current. If the uterus remains atrophic, however, conception is not likely to follow attempts to correct the position of the usually ante or retroflexed organ. Massage and pessaries may effect dilatation of the vaginal vault, and constriction or deformity of the cervix is best treated by discission. Fibrous stenosis of the internal os is most likely to yield to gradual dilatation carried out over long periods of time. Gonorrhœal sterility also often yields to free splitting of the cervix up to the vaginal vault.

The Action of Iodides in Arteriosclerosis.—Romberg prefaces a study by Müller and Inada by saying that, notwithstanding the constantly increasing use of iodides in the treatment or arteriosclerosis, the rationale of their action is not understood. Various investigators have shown that iodide of potassium has no vaso-dilating action, and the other hypotheses advanced have also been shown to be groundless. The present authors administered potassium iodide to healthy young men in daily doses of 0.3-0.5 g. for a period of from ten to fourteen days. At the end of this time the blood was examined, and was found to have lost very markedly in viscosity, in some cases the diminution, amounting to ten per cent. when the internal friction was treated by the method of Hirsch and Beck. This observation explains most of the therapeutic effects of the drug, as its action in producing greater fluidity of the blood is equivalent in a way to dilatation of the vessels, since it causes the stream to flow more rapidly. This observation also explains why the use of the drug must be long continued in order to be of value. An interesting feature is the fact that the serum does not become more fluid to the same degree as the whole blood, in some cases even being increased in density, so that the change appears to depend on alteration in the cellular elements alone.

French and Italian Journals.

Death Due to Dental Caries.—Broca observed this interesting case. The patient was a boy of 4 years. The first sign of trouble was toothache, of which the child complained on June 22. A physician diagnosed a small dental abscess at the root of the first lower molar. But the occurrence was thought of little consequence, and was forgotten till the child's condition became serious. On July 1, after a night of fever and delirium, the patient was placed under a physician's care, 24 hours of valuable time being lost at this time, before the morning visit of the physician. On July 2 the patient was seen by the writer. In the right preauricular, parotid, and angulo-maxillary regions there was diffuse swelling, œdematous and non-phlegmonous. The skin was neither red nor puffy. There was a slight cloudy discharge from the ear. Nevertheless, the writer did not consider the trouble of auricular origin, for there was no appreciable modification in the retroauricular region, and it was not anywhere painful to pressure. There was no swelling over the tip of the mastoid. Moreover, all of the swollen part over the ascending ramus and the body of the jaw was exquisitely painful to pressure. The writer considered the trouble to be without doubt an osteomyelitis of the maxilla. Pus was found around the carious inferior molar. This was the portal of entry of the infection, and the prognosis was very grave. As permission could not be gained at once for operation, it was deferred until the next morning. Incision was made along the border of the inferior maxilla. There was no pus, but two teaspoonfuls of a very fetid, brownish fluid flowed out. The effect of the operation was negative. The local swelling was diminished, but the general infection was not relieved. Death soon followed. The writer thinks that a correct diagnosis, with early operation, would have saved the child, and he urges the necessity of careful attention to a carious inferior molar in a child. Early extraction is indicated if the cavity cannot be perfectly filled.—*Journal des Praticiens*, October 25, 1904.

Keloid of Tuberculous Origin.—A case of this nature is reported from Jaboulay's service. The patient, a boy of 16 years, is remarkable for his small stature and his infantilism, both being of thyroid origin, the gland appearing to be almost absent. But the most interesting feature is the lesion on the neck. Without hereditary tuberculosis, without any pre-existing visceral lesion, this boy has had for four years tuberculous adenitis. Two years ago, after the application of emollients and one application of iodine, which slightly desquamated the skin, a red area, elevated above the normal skin, made its appearance. From that time it has gradually increased in size to a large keloid. Keloid is rare after the application of iodine, and then only when the application is repeated till the skin is burned. The ganglions in this case never suppurated, neither was there ever any suppuration of the skin. No surgical intervention has been made. All of the ganglions are freely movable, not appearing to be caseous, and the skin is not at all adherent. The keloid has really appeared spontaneously. The writer then refers to the various experiments that have been made in order to prove that keloid is of tuberculous origin. In the reports of one observer, tuberculosis has been produced after the inoculation of keloid. In one other report, virulent, generalized tuberculosis was induced by the inoculation of keloid. The writer reports this case as a clinical demonstration of the possible rôle of the tubercle bacilli in causing keloid. He thinks that at least certain keloids may be only atypical cutaneous tuberculosis.—*Lyon Médical*, October 30, 1904.

Suprarenal Insufficiency.—G. Bossuct has observed nine cases of acute suprarenal insufficiency of variable intensity, ending not in death, but in recovery. The syndrome that has been noted in these cases is no other than that known classically as characteristic of suprarenal insufficiency, the only peculiarity consisting in its manner of development. The symptoms develop very rapidly, and besides, they can disappear spontaneously, at the same time with the illness which they accompany. For this acute suprarenal insufficiency is due to an infection or an intoxication. The writer has always noted that the insufficiency occurs in the course of a toxic or infectious malady, medical or surgical. The longest duration of this acute suprarenal insufficiency that the writer has observed was one month and a half, in a woman who was suffering from an outbreak of syphilis. This affection has yielded to the employment of suprarenal extract. The patients treated by the writer recovered from the suprarenal insufficiency in a few days. In eight of the nine patients the cure appears to be definite, for the symptoms, which disappeared with the casual illness, have not returned after an interval of several months. In one case of recurrent bronchitis, however, with every attack, the patient became asthenic and the skin became dark. But when the attack of bronchitis passed, so did the insufficiency. It would be very difficult to determine to what lesion of the capsule the syndrome corresponds. The fact that this insufficiency is secondary to an intoxication or infection is the characteristic which gives it a true clinical importance.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, October 30, 1904.

A Case of General Paralysis.—Dufour and Brelet have had under their care a patient suffering from general paralysis of the melancholic type. His intellect is affected, and amnesia has developed. There is exaggeration of the knee-jerk, and Babinski's sign is present in both feet. The cerebrospinal fluid contains a large number of lymphocytes. The beginning of this paralysis dates back to only three years after a syphilitic infection. This infection began five years ago. For the last six months incapacity for work has been complete. The first changes in disposition date from about two years back. The case is one of syphilis, which three years after the chancre, has produced nervous lesions which are not ordinarily manifested till after the lapse of from ten to sixteen years. It is a very unusual case. The explanation is not known, although various suggestions may be made without proof, such as hereditary or acquired predisposition of the subject, the quality of the syphilitic virus, the failure of specific treatment, and the alcoholic factor which exists in this instance, but which was only a consequence of the cerebral troubles, and did not precede them.—*Gazette des Hôpitaux Civils et Militaires*, November 8, 1904.

Therapeutic Considerations in Two Cases of Phlebitis of the Lower Extremities.—Raffaello Ottolenghi details two cases of phlebitis of the lower extremities, which would have seemed like puerperal phlebitis, had there been any fever present. The absence of fever denoted that the phlebitis was non-infective. Favre considers such phlebitis as due to the increase of mineral matter in the blood, especially calcium salts, diminished oxidation, lessened elimination of urea, lessened alkalinity of the blood, and increase of fibrin forming materials in the blood due to the puerperal state. In both cases described the pain and tenderness of the inflamed veins was great. The author used an ointment of oleosulphonate of soda, or tigenol, and had it applied lightly over the inflamed surface several times a day. In the course of twenty-four hours the pain was greatly relieved, the tenderness passed away after some days, and in one case the patient was entirely well after ten days.—*La Riforma Medica*, October 26, 1904.

Ups and Downs of a Virginia Doctor. By his lifelong and personal friend, Clarence A. Bryce, M.D. Ashland, Virginia: Ashland Printing Company, 1904.

The "local color" of this little book is purely southern, as the author is a Virginian. He gives in the opening chapter a description of his graduating exercises. The narrative then continues with the experiences of his daily life, and describes the "ups and downs" of a physician's career. The style is colloquial, and some of the experiences recounted are quite amusing.

De l'Artérite Syphilitique. Par Le Dr. J. Darier, Médecin de l'Hôpital de la Pitié. Avec 18 figures dont 16 hors texte. Paris: J. Rueff, 1904.

The writer's long experience has qualified him to write with authority and he presents in this little monograph a very clear, complete, but concise résumé of this subject. The chapter on the clinical diagnosis of arterial syphilis in its various phases deserves special mention. The different questions concerning differential diagnosis, often so difficult of solution in practice, are examined in detail. Treatment also is discussed with admirable precision.

Qualitative Analysis Brief. By Allard Memminger, M.D., Professor of Chemistry, Hygiene, and Clinical Urinary Analysis in the Medical College of the State of South Carolina, etc. Second Edition, Revised and Rewritten. Philadelphia: P. Blakiston's Son & Co., 1904.

In the second edition of this little book no changes have been made in plan and scope, but additions have been inserted, rendering the treatment of its subject more complete. Dr. Memminger's "brief" is a very simple, elementary syllabus of qualitative chemical analysis which will prove useful to freshman students in colleges and scientific schools. The insertion of tests for the principal drugs, such as salol, carbolic acid, etc., makes it useful to medical students. The author's English will stand a little trimming and polishing here and there, but the book has the great merit of brevity.

Practical Dietetics with Reference to Diet in Disease. By Alida Frances Pattee, Graduate Boston Normal School of Household Arts; Instructor in Dietetics, Bellevue Training School for Nurses, Bellevue Hospital, New York City. Second Edition. Revised and Enlarged. Published by the Author, 52 West Thirty-ninth Street, New York City.

The importance of a knowledge of dietetics is so paramount that a book of this nature, written by one so experienced in this field, will fill a need felt by many classes. The original purpose of the author was to offer a manual and textbook for the use of the nurse in the classroom. But this little volume has much of value for many others. Diet in infancy forms an important section and must prove of use to mothers. Physicians also will find the book very helpful. The original matter has been carefully revised, and important additions have been made to this second edition.

Blood Pressure as Affecting Heart, Brain, Kidneys, and General Circulation. A Practical Consideration of Theory and Treatment. By Louis Faugères Bishop, A.M., M.D., Physician to the Lincoln Hospital, New York; Late Chairman of the Section on Medicine of the New York Academy of Medicine; Member of the New York Pathological Society, the Neurological Society; Alumni Association of St. Luke's Hospital, etc. New York: E. B. Treat & Co., 1903.

The author here pleads for clinical observation, and objects to a blind reliance on laboratories and apparatus. Although these latter are valuable, still it must not allow us to neglect other powers. The work treats of the alterations, physiological and pathological, in the blood vessels, and the writer divides his cases into primary low pressure, secondary low pressure and high tension cases, and points out the prevalence, the fortunate response to treatment, and the advantages of general management of these conditions.

Hare's Practical Therapeutics. A Text-Book of Practical Therapeutics; With Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. With special chapters by Drs. G. E. de Schweinitz, Edward Martin, and Barton C. Hirst. New (10th) edition, much enlarged, thoroughly revised and largely rewritten. Philadelphia and New York: Lea Brothers & Co. 1904.

The tenth edition of this deservedly successful book appears to have undergone thorough revision and pruning where needed, while the addition of new material has considerably increased the number of pages. Its merits have been so frequently pointed out in these columns that it needs no further commendation at this time. It is undoubtedly one of the most practically useful books of reference that a busy man can have on his shelves.

Manual of Serum Diagnosis. By Dr. O. Rostoski, University of Würzburg. Authorized Translation by Dr. Charles Bolduan, New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1904.

This is a little volume of eighty-six pages which summarizes in truly admirable fashion what is known concerning the practical application of serum diagnosis for clinical and forensic purposes. In addition to a discussion of the theoretical considerations concerning the nature and value of the Gruber-Widal reaction, working directions for carrying out the test are given, and in an appendix a series of diagrams illustrate the pitfalls likely to entrap an inexperienced observer. The use of dead formalin cultures of typhoid bacilli for macroscopic reactions is said to yield reliable results, and directions are given for the preparation and application of such diagnostic media. The diagnostic value of agglutinating reactions in other diseases, such as tuberculosis, glanders, plague, cholera, dysentery, and paradysentery, etc., is discussed, but set down as very doubtful, and the medico-legal applications of precipitin reactions are briefly outlined. The information is all concisely given, and of the most practical nature, while the translation is exceptionally well done.

A History of Columbia University, 1754-1904. Published in Commemoration of the One Hundred and Fiftieth Anniversary of the Founding of King's College. New York: The Columbia University Press, the Macmillan Company Agents; London: Macmillan & Co., Ltd., 1904.

Columbia College, since its founding, in 1754, by George II., has had an eventful and interesting history. The development of this important seat of learning is intimately connected with the growth of the colony in which it had its birth, and the youthful vicissitudes of the one were shared by the other. The present attractive volume is the work of various hands, about half of the text being contributed by Dean Van Amringe, and the remainder by numerous other members of the teaching and administrative staff. The rise and growth of the School of Medicine is set forth by Professor F. S. Lee of the Department of Physiology in most interesting fashion, and the progress of medical instruction is traced through the hundred and thirty-seven years that have elapsed since Dr. Clossy and his five associates founded this—the second school of medicine in the new world. Since then it has flourished under the successive names of King's College, Columbia College, the College of Physicians and Surgeons, again Columbia College, and lastly Columbia University, but has steadily advanced in all desirable directions and always has represented the highest type of medical endeavor. At present it has due part in the prosperity of the university, and is continually gaining in completeness of equipment and facilities for effective instruction. Dr. H. H. Rusby, Dean of the College of Pharmacy, contributes an admirable sketch of the history of that institution, which is the latest addition to the affiliated colleges of the university.

The interest of the volume is much enhanced by many reproductions of old prints and photographs showing the college buildings at various periods and by the excellent collection of portraits of those who have contributed to its development.

A Text-Book of Quantitative Analysis by Gravimetric, Electrolytic, Volumetric, and Gasometric Methods. With seventy-two laboratory Exercises giving the Analysis of Pure Salts, Alloys, Minerals, and Technical Products. By J. C. Olsen, A.M., Ph.D., Professor of Analytical Chemistry in the Polytechnic Institute of Brooklyn, formerly Fellow of the Johns Hopkins University. New York: D. Van Nostrand Company, 1904.

The present very satisfactory volume seems well adapted to fulfill the requirements of an adequate working exposition of modern quantitative analysis. After an introductory section on general working methods, etc., the determination of metals is discussed in four chapters, and that of acids in two more. Three chapters are allotted to the analysis of alloys and four more to the analysis of metals. An essentially modern section is that devoted to electrolytic methods, which are described with full technical details and illustrations of the apparatus required. Volumetric analysis is given the prominence it deserves, and occupies nine chapters divided under a general discussion of the method, oxidation and reduction methods, and precipitation methods. About a fifth of the volume is devoted to technical procedures, and the analysis of iron, steel, coal, water, fats, and oils, and gases is described on practical and modern lines. The mathematics of analytical work, including the application of logarithms, receives special treatment in the last chapter, and the book closes with twenty pages of tables and a fairly good index. The illustrations are all outline drawings of excellent execution, and are freely introduced to show the most approved plan of setting up apparatus. The volume should prove equally useful as a laboratory handbook or as a work of reference, and will no doubt find many friends.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held December 1, 1904.

DR. ANDREW H. SMITH IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Otology, and the subject of discussion was that of "Diseases of the Ear in Childhood."

The Anatomy of the Child's Ear, Emphasizing Points of Practical Importance.—Dr. WM. SOHIER BRYANT read this paper, illustrating important points by use of stereopticon pictures. In a composite photograph it was shown that, taking the labyrinth as a center, the temporal bone developed peripherally almost entirely. The meatus did not develop fast during the very early years of life, but was completed in growth about the fifth year. The antrum was nearly full size at birth, and the mastoid cells were present in the upper, but not the lower part of the mastoid process until the fifth or sixth year, and they did not attain any size until nearly puberty. The lower wall in the infant was very thin and easily perforated. The axis of the meatus in an infant was directed slightly upward. At birth it had no lumen, *i.e.* its upper and lower walls were in apposition, but a few days after birth changes occurred which made the canal patent. The Eustachian tube in an infant was placed at a different plane from an adult's; in the latter it went at an angle of about 45° downward, inward, and forward; in infants it lay more nearly horizontal.

Dr. CHURCHILL CARMALT presented some specimens showing channels in the parotid gland. He said the lymphatics of the middle ear and mastoid as yet had not been properly worked out from the pathological standpoint. The superficial lymphatics of a child at the seventh month were demonstrated. These had been injected through the umbilical vein and lymphatics. The injections were also given in the pinna, external auditory canal, and base of the drum membrane. In the specimen one could see the channels below the parotid gland, passing down the neck to the clavicle, without a gland being interposed in some cases. In some instances these channels passed from gland to gland readily. Similar preparations were shown with the parotid gland cut away. Large channels were shown passing down the jugular to its junction with the subclavian. In adults the distribution of the channels was proportionately not much greater than in children; the size was about the same, except in pathological specimens.

The Pathology of the Infant's Ear Underlying Aural and General Disease.—Dr. JOSEPH A. KENEFICK referred to the various ways of escape of purulent secretions from the middle ear, through sutures or foramina, sometimes upward and outward to the antral roof, or backward and behind and above the ear. Purulent secretions might go through an imperfectly closed roof of the antrum and tympanum, and might set up a meningitis, or brain abscess, or abscesses in the neighborhood of the temporosphenoidal lobe. Extension might be through an imperfect floor of the tympanum, or along the lymphatics or blood vessels. Again, extension might occur to the meninges directly through the labyrinthine wall. When the mastoid antrum was present thrombic involvement of the sigmoid sinus was rare; but in older children extension might occur from the antrum into the neighboring cells. One should bear in mind the possibility of a purulent meningitis, the extension of infecting microorganisms passing along the sheaths of nerves and along blood-vessels. Deafness and deaf-mutism were very common in scarlet fever. Cerebrospinal meningitis was the next most important cause of otitis media. Of 100 infants, two years and under, in whom there was a latent otitis media, 44 died of gastrointestinal disease. Of the 200 tympanic cavities examined, exudates were found in 154, 33 of which were sterile. Among these 154, the tympanic membrane was found to be perforated only nine times. This was the form of otitis media described as otitis concomitans of infancy. Whether of the fulminating or latent type, it had the same complications and terminations. If bronchopneumonia caused the death of one-third of all children under two years of age, then the relation between this disease and otitis must challenge our attention. The association of cerebral complications in pneumonia was brought out in statistical tables.

The Inflammation of the Ears of Children, Original or Derived from Other Diseases.—Dr. ABRAHAM JACOBI said that otitis media might be a merely surface affection of the mucous membrane, or it might be very complicated with suppurations, facial paralyses, meningeal disorders, etc. Purulent otitis was frequently found at autopsies. In 100 infants who had died from a variety of conditions, otitis was found in 81; but eight were unilateral; therefore, there were 154 diseased ears among the 100 infants. A latent otitis media had been found in 75 per cent. of all children examined. Among 38 children who had been excluded from school, nine were found to be suffering from inflammatory ear disease. In another series of 225 children excluded because they failed to make sufficient progress in their studies, 80 were found with previous or still persistent middle-ear inflammations. A normal nasopharynx contained many germs; in catarrhal conditions there occurred a relative increase of these germs, and, with the attendant lowered vitality, an increased possibility of a pneumococcus, a diphtheritic, or a streptococcus infection. A direct cause of diphtheritic otitis media was to be found in cases of nasopharyngeal or nasal diphtheria. In diphtheria there might be a slight swelling of the mucous membrane of the throat, accompanied by a slight diphtheritic deposit, which might close the Eustachian orifice. In other cases the diphtheritic membrane invaded the tube and caused ultimately a perforation of the drum membrane. One of the most frequent causes of otitis media was scarlet fever; but the disease was not so frequent after measles, diphtheria, etc., as after scarlet fever. He believed that the influence of hypertrophied tonsils had been much exaggerated. The relation of the tonsils in many other diseases as a cause had been greatly overestimated; it seemed to have been forgotten that the tonsil was surrounded with a firm capsule. He wished to emphasize the influence of coughing, vomiting, and sneezing in forcing infections to the middle ear through the Eustachian tubes. Reports regarding the frequency of tuberculous otitis media differed. One man had reported 127 cases of tuberculous otitis media out of 17,087 ear cases examined. Another reported that it occurred in 4.4 per cent. of chronic ear cases. The middle ear was often involved in cerebrospinal meningitis. The importance of prevention was dwelt upon, and Dr. Jacobi said that catarrhal conditions should be treated before doing harm. No operations should be attempted unless absolute cleanliness was obtained. Reference was made to the methods employed by the speaker in the treatment of certain conditions, and he claimed that sprays could not take the place of irrigations when properly done. Children with otitis media should be in bed, and no feather pillows should be allowed. Purgatives should be given. The severe pain should be controlled by cocaine dropped into the ear. Warm fomentations, with or without antiseptics, should be tried. If incisions were required, they should be made posteriorly and inferiorly. The expulsion of the pus through the incised wound might be facilitated by the use of the Politzer bag. The pus should be carefully wiped from the external auditory canal, and then boric acid introduced; when the latter became saturated with pus it should be wiped away and more introduced. After referring to various methods of treatment, as found in the recent literature, he said that chronic diseases of the mucous membrane of the ear would never get well until any accompanying chronic trouble of the nasal or nasopharyngeal mucous membrane had received attention.

The Surgical Treatment of Diseases of the Ear in Childhood.—Dr. EDWARD B. DENCH said that whenever

patients suffered from an acute otitis media which gave rise to high temperature, operative treatment was demanded, and an early and free opening was indicated. When about to incise the drum membrane he always used a general anæsthetic. The incision was made free. Great care should be taken to sterilize the canal and drum, as well as instruments and hands. This treatment was applied to the prevention of recurrent attacks. If an examination revealed adenoid vegetations of the pharyngeal vault they should be removed; hypertrophied tonsils should receive proper attention. By attention to adenoids and hypertrophied tonsils, recurrent attacks of otitis media might be entirely prevented. Whenever there was a chronic suppurative inflammation of the middle ear, an acute condition might be engrafted upon it and give rise to very alarming symptoms. In mastoid involvement occurring in children, the speaker was inclined to operate early. Free drainage was of the utmost importance in childhood. In all cases of middle-ear inflammations the mastoid should be opened and the typical mastoid operation done if the temperature was not relieved by free incisions into the drum membrane alone. In dealing with epidural abscesses, he advised against breaking down all the adhesions, which were Nature's way of limiting extension of the abscess. In cases of a diffuse meningitis of purulent or serous variety, the condition was different. If a diagnosis was made early and the cranial cavity opened, the infection might be packed off by means of iodoform gauze and the patients might recover. Almost all cases of suppurative and diffuse meningitis proved fatal; in serous cases better results might be expected. Non-suppurative cases occurring in young life called for an examination of conditions within the nose and nasopharynx and their correction, which would tend to prevent an extension of any chronic inflammatory process to and within the tympanum. Prompt operative measures were indicated in chronic purulent otitis media. The ears should be cleansed thoroughly with some antiseptic solution, such as bichloride of mercury, before paracentesis was performed. Hypertrophied tonsils and adenoids should be removed. The general hygienic surroundings of the patient should be looked into, as well as diet, baths, etc. In tuberculous infection of the middle ear the most radical operation was needed to remove all the diseased area and to prevent systemic infection. A large and patent meatus should be obtained.

Dr. L. Emmett Holt said that there was no argument regarding the necessity of early incision in the drum membrane in these cases; paracentesis did not add to the patient's danger. One of the most interesting questions was whether or not the mastoid operation was not done more frequently than was absolutely necessary, and, if done, whether the patient would not have done better if it had not been performed. All practically agreed that the tendency was to carry the thing farther than real conservative medicine and surgery indicated. The continuation of the elevated temperature after incising the drum membrane was a sufficient indication for mastoid operation. Young children did not bear operations well. The statistics at the New York Foundling Asylum for five years, where there had been extensive epidemics of measles, scarlet fever, grippe and pneumonia cases, diphtheria, etc., showed there were as many as 535 cases of otitis media of acute form, and 15 cases of mastoiditis. There had been performed 880 autopsies during those five years, and there had been found the following: Abscesses from otitis, none; meningitis from otitis, 2 cases; meningitis from either acute infections not associated with mastoid disease, 12 cases; pneumonia with otitis, 8 cases; pericarditis with otitis, 2 cases; diphtheria with otitis, 1 case, and empyema with otitis, 1 case. The mastoid operation was performed in infants 9 times, with 5 recoveries and 4 deaths. He believed that too many mastoid operations were done in infants and young children.

Dr. Kipp emphasized the necessity of an ophthalmoscopic examination in cases of ear disease, and said it was astonishing to see the large number of cases, especially in children, in which symptoms of optic nerve irritation existed.

Dr. Emil Gruening said he had been attending at the Mt. Sinai Hospital for twenty-five years, in charge of the children's service, and had examined the eyes and ears of all cases coming into the institution. In the aural service at present there were twelve cases of mastoid disease in children. He did not believe that all the deductions made by Dr. Holt were correct; they did not perform operations without positive indications. Many of these patients did get well without operation. He referred to cases of illness in children existing for long periods of time, an apparent bronchopneumonia or gastroenteritis, for instance, in which absolutely nothing would be found in the lungs or in the gastrointestinal tract, but there would be found an otitis media. He could not explain the connection, but such cases did exist.

Dr. Gorham Bacon emphasized the importance of investigating the pus of the middle ear and learning whether it was a streptococcic, a pneumococcic, or a staphylococcic infection; the question of operation on the mastoid depended upon the kind of germ that was present. In reference to Dr. Dench's statement that after doing a paracentesis without the occurrence of a fall in temperature, a mastoid operation should be performed, Dr. Bacon said that it seemed to him that one could afford to wait if it was a simple staphylococcic infection and with not much elevation of temperature. But if it was a pneumococcic or a streptococcic infection, one could not afford to wait long. He called attention to some latent pneumonias that might exist which would not develop symptoms until three or four days after incision of the drum membrane, and yet would keep the temperature up after the liberation of the pus. It was important when the temperature was high to be very careful about giving anæsthetics.

Dr. Francis J. Quinlan said that up to 1872 middle-ear disease received but little attention, and since the pathological conditions attendant upon Waldeyer's tonsillar ring had been studied, more attention had been given the middle ear. Operations were done every day for lymphoid hypertrophies of the pharyngeal vault. More often was tonsillotomy done and not tonsillectomy, adenotomy, and not adenectomy. With regard to irrigations of the nose, one should bear in mind that there were a great many forms of bacteria present, and, in a struggling child, there was danger of infection being carried through the Eustachian tube. With regard to the use of boracic acid, if there was a small perforation and boracic acid was packed in, it would be hard for the pus to escape. With regard to the question of operating for adenoids or hypertrophied tonsils in children with middle-ear disease of acute form, it seemed to him that the depletion of the parts and the removal of substances which might be reeking with infection was the better method. Seldom was the external auditory canal properly cleansed before the operation of paracentesis; this canal should be rendered perfectly sterile, and then no danger would result from forcing germs into the middle ear.

Dr. Lewis, referring to early operative measures in otitis media, believed it was not advisable to be too conservative; if one waited too long before operating it would possibly mean more than a simple mastoid operation.

Dr Toeplitz spoke of glandular swellings of the mastoid not all being due to mastoiditis; they might complicate certain infections, might result from trauma of the scalp, etc. It should not be stated that all glandular swellings of the mastoid were always of mastoid origin.

Dr. A. Jacobi referred to an old saying of his, that a good way to kill babies, the subjects of diphtheria, was to force open their mouths, make them struggle, and then to use irrigations; words to this effect he had printed a dozen times during the past forty years, and he did not wish to be misunderstood regarding the use of irrigations. Irrigation of the nose was the only ready means of getting at the child's nose and throat. He preferred the warm saline solution for this purpose. When he introduced

boracic acid into the external ear it soon became moistened and soft, and then could be readily removed. He never packed it in.

Dr. DENCH said that in performing operations of the kind referred to, general diseases should always be excluded of course. He was much interested in Dr. Holt's statistics, but the statistics of the New York Eye and Ear Infirmary, also those taken from private practice, showed the number of fatal cases from otitic meningitis, cranial complications, and otitic suppurations was very much larger.

Dr. HOLT said that the patients referred to were not admitted to the hospital, but were inmates of the institution.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 25, 1904.

Dr. A. PALMER DUDLEY, CHAIRMAN.

Large Lipoma of the Labium Majus.—Dr. ARNOLD STURMDORF presented this specimen, which was shown simply as a gynecological curiosity. The speaker quoted the statement of Kelly that lipoma of the labia majora was one of the rarest gynecological affections, no writer having as yet recorded more than a single instance in his own practice. In the Johns Hopkins Hospital Reports, Vol. III, page 321, that author collected twenty cases, as embraced in the whole scattered literature on the subject.

Sarcomatous Degeneration of a Uterine Fibroid.—Dr. STURMDORF presented this specimen, together with microscopical sections. It was a typical example of this form of degeneration, and the speaker said that the occurrence of sarcoma as a direct degenerative change in uterine fibroids seemed to be established, but the genetic relation of the malignant to the benign elements of these tumors was still the subject of controversy. It was scarcely necessary, Dr. Sturmdorf said, to emphasize the grave prognostic bearing of the possibility of such a degenerative process.

Dr. HERMAN J. BOLDT referred to the case of a woman who had been operated on about three months ago for what was supposed to be an ordinary fibromyoma. She had a large tumor filling the lower abdomen, which the speaker supposed was a pelvic abscess, and probably due to infection from one of the ligatures. Instead of an abscess, he opened into a hematoma of immense size, and on evacuating this he found large masses of sarcomatous tissue.

Dr. RALPH WALDO said he had seen a number of cases in which fibroid tumors of the uterus had undergone this variety of degeneration, and operative interference had been postponed simply because the patients were fairly well along in life, and it was thought that after the menopause there would be no further trouble from the growths. He could recall at least two cases in which these degenerative changes took place after the menopause.

Dr. HARRIS recalled a number of cases in which the sarcomatous growths were located on the posterior surface of the uterus, and the question had arisen in his mind whether these growths had a special predilection for that region, and if so, whether there was any anatomical reason for it.

Cystic Papilloadenocarcinoma of the Ovary.—Dr. STURMDORF showed this specimen, which had been removed from a widow of forty years who had presented herself merely because of the increasing prominence of her abdomen. The growth had never given rise to any pain or discomfort. Upon opening the abdomen, this mass was found, consisting of the uterus and both adnexa. It was universally adherent, and contained a large number of cysts. The peritoneal cavity, which contained an enormous quantity of serosanguineous fluid, was studded with metastatic implantations.

Primary Carcinoma of the Omentum with Peritonitis Carcinomatosa.—Dr. STURMDORF presented this specimen (see MEDICAL RECORD, November 26, 1904, p. 874).

Dr. A. PALMER DUDLEY said he had seen quite a number of these cases in which operation was followed by recovery. After free incision of the abdomen, washing out with saline solution, and allowing the entrance of air he had seen these patients get well and remain so indefinitely. Why this type of mixed growth, which was essentially a malignant disease, should be affected beneficially by this method of treatment was a question for the pathologist to answer.

Dr. BOLDT said he could recall a number of cases of so-called carcinoma of the omentum in which recovery took place, but he doubted the accuracy of the pathological report in those instances. In a case of true carcinoma he did not believe that mere incision of the abdomen and the entrance of air and saline solution would effect a cure.

Dr. WALDO said that almost two years ago he operated on a patient at the Post-Graduate Hospital, removing a large intraabdominal mass which was submitted to Dr. Brooks, who pronounced it unquestionably an endothelioma. No signs of a recurrence could be found up to the present time.

Dr. GEORGE H. BALLERAY said he quite agreed with Dr. Boldt that carcinoma of the peritoneum could not be cured by the use of saline solution or by air. In those cases in which a cure followed this method of treatment the disease was not carcinoma, but tuberculosis. True cases of carcinoma in this region were probably incurable by any method of treatment.

Dr. Sturmdorf said the apparent frequency of sarcomatous growths on the posterior surface of the uterus, to which Dr. Harris had referred, was perhaps due to the frequent involvement of the retroperitoneal glands. He referred to the difficulties surrounding the pathological diagnosis of growths involving the ovary or omentum, and stated that the cases of so-called carcinoma of the peritoneum that had been cured by simple incision were probably either inflammatory pseudoneoplasms or tuberculosis.

Simultaneous Cholecystectomy, Appendectomy, and Removal of Ovarian Cyst with Twisted Pedicle.—Dr. L. J. LADINSKI reported the case of a woman, a widow, 42 years old, who had had ten children and three miscarriages. Menstruation had ceased six months before. For the past ten years she had been subject to attacks of cramp-like pain in the right upper abdomen, which had become more frequent and more severe during the past year. Six years ago she was jaundiced for about two weeks, but not since then. During the past two years the abdomen had gradually increased in size. On June 17, 1904, when Dr. Rabinovitz saw the patient for the first time, she complained of severe pains in the right hypochondriac region, which radiated downwards to the right pelvis and thigh. There was incessant vomiting of a greenish-yellow material. She was not constipated. On examination, the gall-bladder could be easily felt; it was distended to about the size of an orange, and tender on palpation. The rest of the abdominal wall was somewhat tense and tender, and there was a suspicion of a cystic mass on the left side. Temperature, 101°; pulse, 96; respirations, 20. The vomiting and abdominal tenderness increased, and when Dr. Ladinski saw the patient on June 19 the vomiting was almost constant; there was marked abdominal distention, with general tenderness, pain, and tympanites. The patient was restless and had an anxious and drawn expression. The temperature was a fraction below 104°; the pulse was rapid and feeble, the respirations shallow and labored. There was evidently a general peritonitis, and owing to the marked distention of the abdominal wall, nothing definite was revealed by palpation. The vaginal vault was tense and bulging, indicating the presence of fluid in the peritoneal cavity. A diagnosis of general peritonitis due to cholelithiasis or appendicitis was made, and an operation was advised. In view of the statement of Dr. Rabinovitz that he had felt a cystic mass on the left side several days before, torsion of the pedicle of an ovarian cyst was also suspected. Operation, June 20, 1904. Through a median incision extending from above the symphysis to the umbilicus considerable ascitic fluid was evacuated, and a large discolored cystic mass was revealed. This proved to be a cyst of the left ovary, with torsion of

its pedicle. This was removed, and the abdominal cavity explored through the wound. There were numerous recent intraperitoneal adhesions; the gall-bladder was found to be very much thickened, distended with stones, and adherent to the surrounding viscera. The wound was then closed entirely, with the exception of a small opening at the umbilicus, from which a second incision was made extending to the free border of the ribs on the right side. The gall-bladder was exposed, freed from adhesions, and removed. Further exploration of the abdominal cavity revealed a large indurated mass in the right iliac fossa, which proved to be an elongated adherent appendix, with the mesoappendix much infiltrated and discolored; this was removed and the entire wound closed by the layer method, and without drainage. The incision, extending from the symphysis to the free border of the ribs, healed by primary union. The jaundice disappeared within forty-eight hours after the operation. Excepting for a complicating bronchitis and nephritis, which continued for a few days after the operation, the patient made an uneventful recovery.

Dr. Joseph Wiener called attention to the danger of completely closing the abdomen after cholecystectomy in the presence of deep jaundice. The recognized surgical procedure under such circumstances was to drain; otherwise, if the *vis a tergo* did not prove sufficient to dislodge the stone or other obstruction and force the bile into the intestine, the end of the ligated cystic duct was bound to burst.

Dr. Ladinski said he was not operating for stone in the common duct, and he did not remove the gall-bladder until he felt assured that there was no obstruction in the common bile duct. The jaundice in this case he attributed to the peritonitis surrounding the gall-bladder and the resulting adhesions. Dr. Ladinski said he had repeatedly removed the gall-bladder without drainage in cases in which there was no suspicion of obstruction in the common bile duct, and with excellent results.

Three Cases of Tubal Pregnancy.—Dr. L. J. Ladinski reported these cases. The first patient was twenty-nine years old, married seven years, and was the mother of three children. Seven weeks prior to her admission to the hospital she first noticed bleeding from the uterus, which she regarded as normal menstruation. Four weeks ago she had been seized with cramps in the left lower abdomen, which lasted two days. These attacks recurred several times at irregular intervals. Examination revealed a somewhat enlarged uterus and a characteristically enlarged left tube, which was tender and sensitive to the touch. There was no bleeding from the uterus at the time. The diagnosis of tubal pregnancy was made, and an operation advised. The enlarged tube, with its fimbriated extremity very much dilated and presenting a large blood-clot from which the hemorrhage had occurred, was removed. The case was therefore one of tubal abortion. The tube might have been saved, but as the attachment of the sac was close to the uterine end, it was not deemed wise to do this.

In this case, as well as in the two others, which Dr. Ladinski reported in detail, the history was of no aid to the diagnosis. In two false history was purposely given, and yet in all three cases a positive diagnosis was made entirely from the physical signs. The speaker said that the positive diagnostic signs in early tubal pregnancy were: (1) Enlarged uterus. (2) Bleeding from the uterus; the blood was dark and grumous in character, and differed from the light red blood of menstruation, with its peculiar odor, nor was there profuse bleeding, with clots and membranes, as in abortion. (3) The distention of a part or the whole tube produced a fusiform, peculiarly elastic, sensitive, movable mass; there was no other pathological condition excepting hæmatosalpinx that would present a similar feel to the palpating finger. (4) Pain, paroxysmal in character, was always present. (5) Amenorrhœa was invariably present, although a history to that effect was not always obtainable. The negative diagnostic signs were: (1) Absence of intrauterine pregnancy; early intrauterine pregnancy could invariably be diagnosed or excluded by the presence or absence of the characteristic sign of early pregnancy in the anterior wall of the uterus. (2) In tubal pregnancy, before rupture of the tube, there was never any rise of temperature, any more than there was in intrauterine pregnancy.

Dr. Harris said he had seen a few cases of tubal pregnancy in which the cervix was so soft that it raised the suspicion of an intrauterine pregnancy.

Dr. Waldo said he thought the common belief that extrauterine impregnation was apt to occur only at a long interval after a normal pregnancy was entirely erroneous. Recently, he had reviewed the records of a large number of cases, and he had found that in quite a proportion of them the patients had undergone a normal uterine pregnancy within two years.

Dr. John O. Polak asked Dr. Ladinski how he positively excluded intrauterine pregnancy before he did his preliminary curettage.

Dr. Ladinski said the sign of pregnancy that he considered absolutely infallible was an elastic feel in the anterior wall of the uterus, just above the cervix. This could be felt about the fifth or sixth week of pregnancy. He did not refer to Hegar's sign, but to a depression in the anterior wall of the uterus, which gave an elastic, fluctuating feel.

Indurated Ovarian Cyst.—Dr. Philander A. Harris showed a polycystic tumor of the ovary almost as large as two fists, which had been placed in a solution of formaldehyde of a strength unknown to him three or four years ago. Some time afterwards the bottom of the sealed jar in which it was placed became fractured and the formalin solution escaped. The specimen was as hard as oak or hickory when removed from the jar three months ago, and possibly in consequence of further drying, it had since become still more indurated. He had tried to have a hole bored through the tumor with an ordinary twistbit used by machinists for boring steel and iron, but had to desist for fear that the bit would become broken off.

The Cystoscope in Gynecology.—Dr. Sidney D. Jacobson presented this paper. After a brief review of the history of cystoscopy, the author stated that in order satisfactorily to inspect the bladder by this method, three conditions were necessary: (1) The urethra must be of sufficient calibre to permit passage of the instrument; (2) the bladder must be distensible to a certain extent; (3) the bladder must be filled with a clear and transparent medium. A saturated solution of boracic acid in water answered every purpose. Patience, the utmost gentleness in manipulation, and the strict observance of the rules of surgical cleanliness or asepsis were essential to success in cystoscopy. In vesical stone not only would cystoscopy enable one to see the stone, but also to make out its size and shape and often to determine its composition. It was the only way by which an encysted stone could be correctly diagnosed, because the bladder sound might pass over it and fail to elicit the expected click. The existence of tumors in the bladder could be demonstrated and their nature as to malignancy or otherwise judged, although such judgment should not be based solely upon evidence obtained in this manner. Cystitis, Dr Jacobson said, was no longer regarded as a disease, but a symptom-complex pointing out that there was something wrong with the bladder. Merely to treat the symptoms of cystitis was quite as unscientific as to treat vomiting or headache as a disease, and without first determining the cause. A cystitis might be due to gonorrhœa, tuberculosis, malignant disease, stone, foreign body, parasites, a retroverted gravid uterus, etc. The author reported some cases to support his contention that cystoscopy was the only positively rational and reliable method of examination of the female bladder. Perhaps the most interesting and useful chapter of cystoscopy was that relating to catheterization of the ureters. In conclusion, Dr. Jacobson said that by cystoscopy light had been thrown upon a subject which heretofore lay in the obscure region of mystery and speculation.

He expressed the hope that the day had gone by, never to return, when a female ureter was dilated until it ruptured, to permit the finger of a surgeon to penetrate the bladder in a clumsy if benevolent attempt at exploration for diagnostic purposes.

Dr. Sturmdorf did not think cystoscopy should be employed to the exclusion of other methods of diagnosis. In order to show that cystocopic findings might sometimes prove misleading, the speaker mentioned a case in which a bit of tissue became attached to the fenestra of the cystoscope after its introduction into the bladder, and gave an enlarged picture of what was supposed to be a papilloma. When the bladder was opened, nothing was found. The suprapubic wound healed very slowly, and the patient finally committed suicide.

Dr. Ladinski said he had used the Kelly cystoscope in women with very gratifying results. He regarded catheterization of the female ureters as a safe procedure which could readily be done by any one, whether a specialist or not. For this purpose, he preferred the Tilden-Brown instrument.

Dr. Harris thought that bilateral catheterization of the ureters should be avoided, on account of the possibility it involved of infecting the healthy kidney of a patient who already had one kidney diseased. In most instances, other diagnostic methods were available by which the same information could be obtained. In certain cases in which it was difficult to locate the ureteral orifices, Dr. Harris had swabbed the region of the trigone with a solution of methylene blue sufficiently heavy to discolor the bladder, and then, with the patient in the exaggerated knee-chest position, the urine was seen as it emerged from the ureters and left a distinct downward line on the discolored bladder-wall.

Dr. Jacobson said that while an inexperienced operator might readily misconstrue the cystoscopic picture, he did not think it would be difficult to differentiate between a bit of floating coagulum and a papilloma, as there was little resemblance between the two. Besides, by rotating the instrument, the adherent coagulum would rotate with it, whereas a papilloma would remain stationary. The Kelly cystoscope, to which Dr. Ladinski had referred, was an excellent instrument, but the speaker thought that women rather objected to the knee-chest position. The danger of carrying infection to the ureter with the ureteral catheter was very slight if proper precautions were taken, which included thorough cleansing of the bladder itself.

Chicago Surgical Society.

At the November meeting, Dr. L. A. Greensfelder reported a case of thrombosis of the superior mesenteric artery in a man 47 years of age, and presented a pathological report on the organs after removal from the body. He also reported a case of intussusception in a patient aged 18. A successful operation was performed in this case. Dr. A. J. Ochsner exhibited a specimen of a case of intussusception. Dr. Jacob Frank mentioned a case of intussusception of the ileum into the cæcum in a child 9 months of age, in which he made use of the button, and the child made a complete recovery. He also read a paper on "Perineal Prostatectomy by Young's Technique," and reported a case. This operation was destined, on account of the improved technique, to become as prominent an operation as that of hysterectomy. An excellent result was obtained in this case. Dr. M. L. Harris stated that Young's method of approaching the prostate was not materially different from that employed by most surgeons in using the perineal route; in fact, after having read the description of Young's technique, he did not see anything in his method of approaching the prostate which could be claimed as new or original. Personally, he had opened the capsule transversely rather than longitudinally, but not across the mid-line. However, if he found it facilitated the enucleation of the prostate, by making the incision in a longitudinal direction, he would do it. Of late it had not been his rule to pack the capsule after removing the gland, but to suture it. He had brought the walls together by catgut sutures, and by so doing he thought the period of convalescence was shortened. Dr. E. Wyllys Andrews concurred with the author relative to the general improvement which takes place after prostatectomy.

Dr. D. A. K. Steele read a paper, entitled "Gall-Bladder and Biliary Duct Surgery." Reference was made to the early history of this class of surgery, and the author stated that in no branch of the healing art had the American mind left its impress in a more forceful manner than in the development and progress of the surgery of the gall-bladder and bile ducts. Gallstones were present in about seven per cent. of all people, and proved fatal in about ten per cent. of this number. Over twelve per cent. of all gallstone cases manifested symptoms of common duct obstruction. The symptomatology and indications for operation were discussed at considerable length, and the author closed his paper with the recital of seven illustrative cases in which early operation was declined, or was not possible for some reason. Dr. A. J. Ochsner stated that the wisdom of early operation in these cases could not be emphasized too much. There was no doubt but that in the vast majority of all patients suffering from gallstones, cholecystitis, or disease of the duct, there was a time when the condition could be safely and permanently relieved by an operation, and that the serious conditions which the essayist had emphasized in the narration of his cases were the result of late conditions. Dr. Daniel N. Eisendrath said the more he saw of gallstone cases the more he was impressed that surgeons were apt to forget complications on the part of the liver itself. In a paper read by him three years ago he investigated, made sections and cultures of a case that was operated upon by Dr. Greensfelder. In this case he found scarcely any of the liver cells stained, practically nothing but the inner third around the central vein. If one investigated the liver in cases of cholecystitis and gallstones varying degrees of liver necrosis as a result of infective cholangitis would be found, particularly when there was an associated cholangitis with or without pus formation. Dr. M. L. Harris said that gallstones were always preceded by infection. They were a secondary condition of infection. He believed the infection was a descending one. The microbes were eliminated by the liver and gained access to the biliary passages. Infection being the primary and chief condition, the surgeon should operate to relieve or cure the infection.

Dr. Jacob Frank reported a case of infection of the liver. Recently he operated upon a patient for multiple abscess of the liver following appendicitis. Six weeks after the operation for appendicitis there were fever and other symptoms, and he suspected an abscess of the under or upper surface of the liver. On opening the abdomen he took a culture from the gall-bladder, then punctured the liver, and took cultures from it. In the fluid there were a few small flakes that looked unnatural, but he did not know what they were. The patient died, a post-mortem examination was made, and multiple abscesses of the liver were found. The bile from the gall-bladder was sterile. Dr. Steele said it was difficult to convince the general practitioner of the necessity of early operation, even if an early diagnosis was made. He hoped the discussion would be of service in helping general practitioners to make earlier diagnoses and refer their cases to surgeons for early operation. Dr. James M. Neff exhibited for Dr. John B. Murphy a case of cervical rib, and in the discussion other cases were reported by Drs. E. Wyllys Andrews and Daniel N. Eisendrath.

Chicago Medical Society.

At a meeting, held November 30, 1904, Dr. D. N. Eisendrath presented a paper on "The *X*-ray as an Aid in the Diagnosis of Strictures of the Œsophagus." He stated that when the *x*-ray was first introduced it was found that certain metallic substances, as mercury, bismuth, etc., threw a distinct shadow when the skiagraph was taken. Taking advantage of this bismuth subnitrate had been used during

the past few years in diagnosing, for instance, dilatation of the stomach, by giving the patient a certain amount of bismuth to swallow, and then taking an *x*-ray picture of the abdomen, showing the bismuth at the lower level. During the past year there had appeared an article on this subject, but the author did not see it until he began his own work on the use of bismuth in a case of idiopathic dilatation of the œsophagus, in which bismuth was swallowed by the patient, and the *x*-ray showed a beautiful shadow given by the bismuth. He reported the case of a man 41 years of age, who during the past nine months had had difficulty in swallowing. This difficulty had been so great that the patient was compelled to have a gastrostomy performed on him in New York. Both in New York and in Chicago physicians were unable to pass an œsophageal bougie beyond the œsophagus, but the speaker succeeded in passing a bougie through the strictured portion of the œsophagus, after which bougies were passed daily. The patient fed himself exclusively through a gastric fistula. The author instructed his patient to swallow some bismuth, allowing it to collect in the dilated œsophagus, and he then obtained an excellent skiagraph of the bismuth, which helped him in his diagnosis of the position of the stricture. This and several other skiagraphs were shown, for the purpose of demonstrating the value of the method. Its chief value was said to be confirmatory, and it was considered accurate and scientific in determining the location of the strictures. Dr. J. Rawson Pennington said the first work of this kind was done in Chicago by Dr. Metcalf. Personally, he had also experimented some with bismuth in trying to locate the sigmoid and colon by injecting the substance through the rectum, and at the meeting of the American Medical Association at Atlantic City in June, 1900, in addition to showing a number of photographs, he exhibited a specimen showing the location of the sigmoid by the *x*-ray, taken after bismuth solution had been injected into the rectum and sigmoid, but he did not consider it of any special value at that time. Dr. Henry F. Lewis showed a specimen of "Fœtus Papyraceus." The woman was delivered a few days before of a normal child. One placenta, the larger one, was practically normal, except the cord was short, being not more than 15 inches long; the other placenta was entirely detached from the large one. He showed the placenta of the small fœtus, the fœtus papyraceus, which was degenerated. This fœtus was flattened against the side of the uterus and against its own placenta. From its size it was judged to be a three or four months' fœtus; therefore, the child must have died at about that time and was pressed against the uterine wall by the growth of the other fœtus, which was born alive.

Philadelphia Neurological Society.

At a stated meeting held November 22, Dr. Wm. Pickett exhibited "A Case of Arteriosclerosis of the Nervous System." The patient was a man, 67 years old, who without loss of consciousness, gradually lost power on the right side of the body, with some thickness of speech, impaired mental activity, and increased reflexes, in the absence of symptoms or signs of disease of the heart or kidneys. The peripheral vessels were stiff and tortuous, and it was reasoned that a similar condition existed in the vessels of the brain and spinal cord, resulting in impairment of nutrition and sclerosis.

Dr. Chas. S. Potts read a note upon "A Case of Hemiplegia Following Typhoid Fever." In addition to motor weakness on the right side of the body, with aphasia, there was a history of delirium at the onset, so that while it was thought that the condition might be due to cerebral hemorrhage or thrombosis, the possibility of encephalitis could not be excluded. Dr. C. D. Camp exhibited a boy in whom following an attack of typhoid fever weakness developed in the right upper and lower extremities, with loss of knee-jerks. The patient presented also choreic movements, and the relation of events was therefore not perfectly clear.

Drs. Wm. G. Spiller and Herman B. Allyn reported "A Case in which the First Left Temporal Convolution Was Destroyed in an Adult Without Causing Word-Deafness." The patient was an intelligent man, who had had an attack of right hemiplegia with aphasia some nineteen years previously, with a large measure of recovery, and a second attack of milder degree fifteen years later. Speech was but little affected, being somewhat muffled at times and some difficulty occasionally being observed in enunciating the correct word. Errors were rarely made in speech or in writing, and the spoken word was perfectly understood. Post-mortem examination disclosed a condition of atrophy and sclerosis in the first temporal convolution on the left, with preservation of the second and marked development of the first temporal on the right. In explanation of the preservation of the faculty of word-hearing it was suggested that this had been taken up either by the left second temporal or by the well-developed right first temporal, perhaps early in life. So far as could be learned the patient had been right-handed.

Drs. F. X. Dercum and Alfred Gordon presented a communication entitled "A Case of Multiple Cerebrospinal Sclerosis, with Remarks upon the Pathogenesis of the Affection." The patient was a young colored woman with a history of miscarriages and a fall upon the buttocks, who presented motor incoordination, increased reflexes, jerky speech, nystagmus. Post-mortem examination disclosed the presence of widely disseminated foci of sclerosis in brain and cord, including the nuclei of cranial nerves.

Dr. Joseph Sailer reported "A Case of Convulsive Tic in a Girl of Six," the onset being attended with convulsions in connection with some febrile disorder. The convulsions were thereafter repeated frequently and were attended with a peculiar grunting sound. Recovery speedily ensued upon the administration of two grains of trional after the child had been removed from her home in the country to a hospital in the city. It persisted for six months, when the previous symptoms recurred. Although there were no other stigmata of hysteria discovered, it was concluded that the disorder must be of this character.

Dr. F. X. Dercum exhibited the spinal cord from the body of a young colored man who had been struck on the back of the neck by a bucket falling from a great height. There was at once palsy in all four extremities with anesthesia up to the level of the nipples, diaphragmatic breathing, loss of control of the sphincters and abolition of the knee-jerks. Bedsore developed, the palsy became marked and the anesthesia more extensive, and death ensued. On post-mortem examination it was found that the fourth, fifth and sixth cervical vertebræ had been fractured and the underlying spinal cord crushed.

Prognosis and Treatment in Certain Localizations of Osteoarticular Tuberculosis.—Adelchi Sandulli has collected nine cases of tuberculosis of the wrist and ankle, in which he considers that the prognosis and treatment are somewhat different from that of the disease when localized in the other articulations. He outlines the treatment of the disease in other joints and then compares it with that indicated in tuberculosis of the wrist and ankle. Independently of the usual factors in prognosis, such as pure or mixed infection, presence of suppuration, general condition, etc., the prognosis is always grave in disease of these articulations. This results from the anatomical structure of the joints, the number of bones that enter into them, the areolar structure of the bones, the number of synovial membranes, the numerous tendons, and the many complications which are liable to occur. Consequently, the period of conservative treatment should be short; if the infection is spreading, operation should be undertaken early, and there should be no hesitation in removing all the diseased structures, if we would avoid amputation in the end. The prognosis should be reserved if not actually unfavorable.—*Giornale Internazionale delle Scienze Mediche.*

Surgical Suggestions.

Genital Papillomata and Excrescences.—

Aronstam recommends: (1) Cleanliness; (2) a drying powder, such as:

℞ Acid. salicyl. ..... gr. x
Zinci oxidi ..... 5 j
Amyli ..... 5 ij
Pulv. talci ..... 5 v

or painting twice a week with—

Acid. salicyl. ..... gr. xx
Ext. suprarenalis ..... gr. x
Resorcin ..... gr. xx
Liq. gutta perch. ..... ad 5 ij

—*Canada Lancet.*

Ointment for Hemorrhoids.—

The following ointment is used very largely in the Department of Charities, New York:

℞ Morphine oleate (10 per cent.) 1
Camphor 2
Oil of sassafras 4
Resin 8
Yellow wax 16
Benzoated lard 24

M. To be applied on lint.

The foregoing is best compounded by melting the wax, resin, and benzoated lard together at a gentle heat and digesting the camphor in this until it is dissolved. While the mass is cooling, and before it solidifies, add the morphine oleate and the sassafras oil, and mix thoroughly.

Vaginal Discharges.—In treating diseases of women always remember that the normal secretion of the vagina is acid and that of the uterus alkaline.—Burnett.

Paraphimosis.—L. H. Prendergast recommends this course of procedure: 1. Dry the organ with absorbent cotton or bits of gauze. 2. Apply vaselin to the everted posterior part of the preputial mucosa, but none to the glans or skin of the penis. 3. Pass the index and middle fingers of both hands behind the deep sulcus, and lock these fingers together. Hold the hands so that their dorsa present to the patient's pubis, and the palms toward the operator. 4. With both thumbs endeavor to crowd first the upper margin of the swollen corona behind the constricting mucocutaneous band, while the tissues of the penis are being drawn forward by the locked index and middle fingers. Variation. If 3 and 4 fail, again dry the entire organ and annoint it as indicated under 2. Then place a bit of gauze about the organ, take it firmly in the left hand, and support the deep sulcus with the outer margins of the left thumb and index finger. With the right thumb and fingers, knead the glans into the prepuce, as it is being drawn forward. When both of these manipulations fail, division of the constricting band is imperatively necessary. To this end a slightly curved bistoury is pressed with its right flat surface parallel to the axis of the penis, upon the second mound, until the knife's point has traversed the constricting band. The knife is then turned to a quarter circle upward, and the constriction cut from below upward. Ordinarily, this incision suffices to permit slipping the prepuce forward. Occasionally, however, several lateral incisions are required in addition to the above central dorsal one.—*Memphis Medical Monthly.*

Hypertrophy of the Prostate.—A. T. Cabot sums up his views as follows: 1. I consider a perineal prostatectomy the method of choice for the treatment of the prostate causing obstruction so great as to require the constant use of the catheter. 2. In patients too old or enfeebled to bear this operation safely, a Bottini operation under cocaine may often be safely done, or if even this seems too severe, the catheter life may be entered on. 3. It is still too early to be sure that all of the good results reported soon after the operation will show themselves to be lasting. 4. The cases in which functional failure seems most probable are those with small contracting prostate and with distended atonic bladder.—*St. Louis Courier of Medicine.*

Diaphoresis.—

According to Chas. Winn, this may be produced by: (a) Application of external heat (hot air, vapor, water or sand baths); (b) prevention of loss of body heat (protecting from external temperature, prevention of evaporation); (c) artificial through internal means (hot drinks); (d) dilatation of cutaneous vessels (alcohol, hot punch, nitrites, spts. etheris nit.; also opium in Dover's powder, and by dilatation of cutaneous vessels, *e.g.* aconite in small doses, (sinapisms); (e) by production of a mild degree of nausea (any of the emetics or Dover's powder); (f) by the stimulation of the sweat center (camphor, or, better, liquor ammonii acetatis); (g) by stimulation of the peripheral secretory nerves (pilocarpine).—*The Medical Standard.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 10, 1904:

	Cases.	Deaths.
Measles	138	8
Diphtheria and Croup	368	31
Scarlet Fever	208	14
Smallpox	.....	.....
Chickenpox	112	.....
Tuberculosis	345	160

Delayed Chloroform Poisoning.—Harold J. Stiles and Stuart McDonald briefly review the literature on this subject. Casper, in 1850, was the first to direct attention to the dangerous after-effects of chloroform. The history of a typical case is given. The patient was a healthy looking girl aged 8 years. There was no evidence of organic disease. The operation was performed for genu valgum. It was successful and there was no shock. The total duration of anæsthesia was 22 minutes. There was a little nausea after the operation, about 11 A. M., but no more until the evening. Vomiting then set in and continued at intervals till the following morning. There were periods of excitement, but in the intervals the child complained of no pain. The pulse became rapid and feeble. At 1 P. M. the child had a drink. An hour later she was slightly cyanosed. The pulse could scarcely be counted, unconsciousness supervened, and at 2 P. M., twenty-six hours after operation, the patient suddenly died. On opening up the wound there was no evidence of septic infection. The pneumococcus was cultivated from the hemorrhagic areas in the lungs. An intense degree of fatty change was uniformly distributed through the whole liver. In the kidneys was seen an intense degree of degenerative and fatty change in the parenchyma. The whole organ practically suffered. The writers state that the cause of death in such cases has been variously attributed to chemical poisoning from antiseptics, to fat embolism, to sepsis, and lastly to delayed chloroform poisoning. As to the effects of carbolic acid used as an antiseptic, the writers declare that it is evident from investigations that, apart from the carboluria, the symptoms of a toxic dose absorbed by the skin bear a close resemblance to those which are supposed to be due to delayed chloroform poisoning. Fat embolism, according to the writers, is not such a potent cause of death as many believe. They also think that it is quite possible that the fatty change in the liver may be entirely due to the chloroform acting on a previously healthy liver. Organic disease can be definitely excluded in some of the fatal cases. An important predisposing factor in such cases seems to be some special idiosyncrasy to the action of the drug. The most reasonable explanation of the condition is to be sought for in some intoxication, though the exact manner in which this acts has not yet been made clear. It has been shown that chloroform is an intense protoplasmic poison, capable of producing changes in the organs sufficient to interfere seriously with their function. The most striking histological feature is a fatty change, involving especially the liver, kidneys and heart, and probably other tissues. The symptoms in cases of delayed chloroform poisoning closely resemble those met with in other auto-intoxications, such as diabetic coma. Many observers have noted a great increase of acetone in the urine after chloroform anæsthesia. The writers regard the analogy between delayed chloroform poisoning and diabetic coma merely as a working hypothesis, and they believe the question is worthy of

further investigation. They think that if an excessive acetonuria be shown to exist in delayed chloroform poisoning, we might hope to find in it the means of recognizing milder degrees of the intoxication, and possibly also of differentiating the condition from such post-operative complications as delayed shock, sepsis, etc.—*The Scottish Medical and Surgical Journal.*

The Pneumonia Problem.—Arnold C. Klebs has made a careful study of this subject. He shows that it is necessary in comparing the total death-rates of successive years to analyze the distribution of deaths in the various age groups and for the two sexes. He has found that a very considerable increase of the death-rate from pneumonia has occurred in early childhood (especially under one year of age) and also in old age, but that between the ages of five and sixty-five, there has been a decrease. By the term pneumonia is meant bronchopneumonia and capillary bronchitis, and probably other ill-defined pathological conditions of the respiratory organs, especially in childhood and old age. The writer presents charts which show a constant interrelationship between the death-rates of tuberculous and non-tuberculous respiratory diseases; as tuberculosis decreases the other class increases, and in the same age periods. The writer calls attention to the distinct increase of the death-rate in childhood from non-tuberculous respiratory diseases, the group of pneumonia being about 75 per cent. of these. He does not think it probable that pneumonia will soon threaten uniformly all age periods, and especially adult life. Great results have not yet been achieved in the treatment of respiratory diseases. The writer concludes by urging the necessity of direct specific preventive efforts. Only further investigations into the indirect causes of the disease may suggest the best methods to pursue.—*The Illinois Medical Journal.*

Prophylactic Use of Antitetanus Serum.—E. S. Alexander reports these cases. The first patient was a boy, aged 6. He exploded a "cane-cap-cracker" with the ball in the palm of the hand, wrong end up. The fleshy part of the palm of the hand was literally ground to pieces, as was the palmar fascia, but the tendons were practically unharmed. Thirty minutes later the boy was anæsthetized, and the hand and forearm was thoroughly cleansed with hot water, soap, and bichloride solution. The wound was then swabbed out with 95 per cent. carbolic acid, after all the loose tissue and tags had been removed. Hot sterile water was then used, and finally hydrogen dioxide. The wound was then dried and packed loosely with iodoform gauze and dressed. The following morning 10 c.c. of antitetanic serum was injected at the inner angle of the right scapula, it being the right hand that was injured. Healing was complete within a month. There had been no local disturbance at the point of injection, nor any noticeable constitutional disturbance from wound or serum. The second patient was a woman, aged fifty-five years, who stepped on a nail which penetrated the ball of the foot to a depth of two or three inches. She suffered greatly for twenty-four hours, at which time the wound was examined. The wound was then closed, and the patient was suffering with severe headache and pain and rigidity of the neck muscles. Under anæsthesia the wound was laid open, and curetted and swabbed with 95 per cent. carbolic acid and packed with iodoform gauze. The recovery was uneventful. Twenty c.c. of antitetanic serum was used while the patient was under the influence of the anæsthetic, the best time for its use. It cannot be stated that either of these patients would have developed tetanus without the use of serum, but the writer is convinced that it is just such kind of cases which do develop it, and he declares that in the future he will use the serum at the earliest moment in such emergencies.—*The Medical and Surgical Monitor.*

Hemorrhagic Disease of the Newly Born.—Martha Wollstein states that aside from cases of traumatic hemorrhage, and those in which the "constitutional fault" of hæmophilia can be proved to be present, there still remain under the head of hemorrhagic disease of the newly born the cases of multiple hemorrhages into the skin and viscera, occurring as morbus maculosus neonatorum, epidemic hæmoglobinuria, or Winckel's disease, acute fatty degeneration or Buhl's disease, and syphilis hæmorrhagica neonatorum. Our present knowledge tends to prove that the process in these cases is one of infection, and that morbus maculosus, Winckel's disease, and Buhl's disease, represent different varieties of the same disease. Cases are far more numerous in institutions than they are in private practice. As yet no specific microorganism has been found in these cases. The bacteria almost invariably found have been the pyogenic cocci and the colon bacilli. Generally, the source of infection and its point of entrance are demonstrable, although in some cases they are obscure. The mouth, the gastroenteric tract, and the umbilicus are the main points of entrance for the infection. The umbilicus does not necessarily show any inflammatory lesion. Pus may be found in one or both hypogastric vessels within the abdominal cavity when the umbilicus appears to be normal. The question of the significance of syphilis must for the present remain an open one. The writer refers to the recent discovery of hemorrhagin, a substance found in rattle-snake venom, and which proves to be a cytolysin for endothelial cells of blood vessels, causing hemorrhage by a solution of the lining cells of the vessels. It is probable that other poisons, and the pyogenic bacteria as well, may be proved to produce a similar toxic body. The writer concludes that it is along these lines of modern pathology that enlightenment on the subject of the hemorrhagic disease of the newly born is to be looked for, other conditions, such as heredity, being given due consideration.—*Archives of Pediatrics.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 9, 1904:

THE ANTITOXIN TREATMENT OF TERTIAN MALARIAL INFECTIONS.

BY JOSEPH HERBERT FORD, A.M., M.D.

CAPT. ASST. SURGEON, U. S. ARMY. PROFESSOR OF DISEASES OF THE TROPICS, MEDICAL DEPARTMENT, COLUMBIAN UNIVERSITY.

RECENT observations on the etiology of various specific infectious diseases indicate that protozoölogy will eventually become almost if not quite as important a branch of medical science as is to-day its similar, bacteriology. Among the human maladies already attributed to infection by microorganisms belonging to the animal world may be mentioned malaria, yellow fever, dengue, amœbic dysentery, trypanosomiasis, and the spotted fever of the Rocky Mountains, while not a few pathologists suspect that carcinoma, sarcoma, molluscum, contagiosum, syphilis, kala-azar, variola, scarlatina, etc., are also caused by specific protozoa. Since plants, however, are simpler organisms than are animals, and, as a rule, do not offer in the lower forms of life such protean morphology with alteration of life cycles as do the latter, it was natural that bacteriology should precede protozoölogy in its development. The difficulty attending the study of sporozoa (to which class most pathogenic microorganisms having animal characteristics belong) is further enhanced by the fact that attempts to cultivate them outside the bodies of their respective hosts have heretofore been futile. Pure cultures, as ordinarily understood, have not therefore been available, and the attempted development of antitoxins against protozoan human infections has been uniformly unsuccessful.

It has become evident that the methods now accepted as suitable for the study of bacteria are not altogether applicable to similar work with protozoa, and that they must be modified in some details to meet altered conditions and requirements. Thus, in the observations here recorded, the "cultures" employed were those obtained by the withdrawal of blood from the veins of patients suffering with malaria or from the salivary glands of infected mosquitoes.

These observations were made at Fort Reno, Okla., a military post situated on a slight eminence one mile south of the North Fork of the Canadian, and at an altitude of two thousand three hundred feet above the sea. The configuration of the adjacent terrain is that of a gently rolling plateau intersected by numerous watercourses. During the greater part of the summer, however, these streams are represented by pools of stagnant water, which form admirable breeding places for the anopheles. As the oil requisitioned for use upon such pools was not received until late in the season, mosquitoes multiplied abundantly, and sixty cases of malaria appeared in the garrison. At this time the troops stationed here consisted of four companies (colored) of the Twenty-fifth U. S. Infantry and two companies (white) of the Thirtieth U. S. Infantry. The members of these organizations lived under identical military conditions, while their food, clothing, quarters, recreation, and general hygienic circumstances were as nearly identical as military precision could effect. The only differences between them, aside from race, were that the men of the Twenty-fifth were better developed physically than were those of the Thirtieth, and that the barracks which the former occupied were more exposed to the southern winds. These winds blew almost constantly throughout the summer, carrying mosquitoes into the post from their adjacent breeding places, and from an epidemiological standpoint probably more than nullified whatever advantages the colored soldiers enjoyed because of their better physiques. Yet the influence of race was quite evident. Twenty-two cases of malaria developed in the four colored companies and thirty-eight cases in the two white ones—*i.e.* the white troops were, pro rata, 3.45 times as subject to this disease as were the colored.

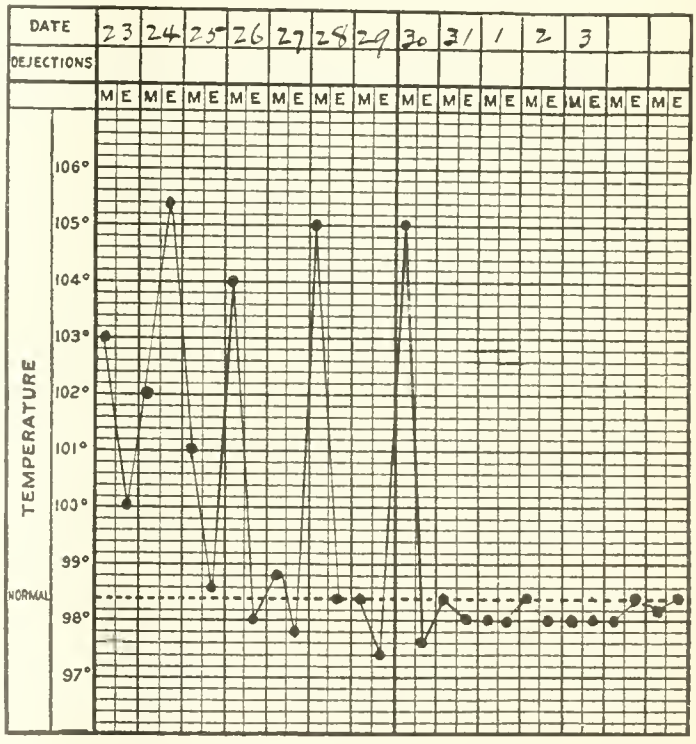

CHART I.—T. D. S., admitted August 23, 1904.

The animals employed in these experiments for the development of a malaria antitoxin were the brown rabbits, indigenous to the southwestern States, and the domestic white rabbits. The former did not prove so suitable for this purpose as did the latter, for not only were they much smaller, but most of them died shortly after they were captured or injured themselves so severely by fighting that,

for humanitarian reasons, it became necessary to anæsthetize and kill them. Of eleven such animals only two eventually furnished blood for use in these observations, and as that obtained from one of them became infected before it could be used, my experience with them was not encouraging. Of the twelve white rabbits employed, however, all but two either came to the anæsthetizing table or remain on hand for future use. These two died within ten minutes after the injection of malaria-infected human blood into their posterior auricular veins. As this blood had not been defibrinated it is surmised that they died of pulmonary thormosis—a supposition supported by the symptoms exhibited. All rabbits were kept in mosquito-proof hutches from 5 P.M. until 8 A.M.

Before this course of experiments was begun I had intended to inoculate the animals employed by the bites of infected mosquitoes only, but as no anopheles larvæ were obtainable until August, and as none of the insects developed the malarial merozoits

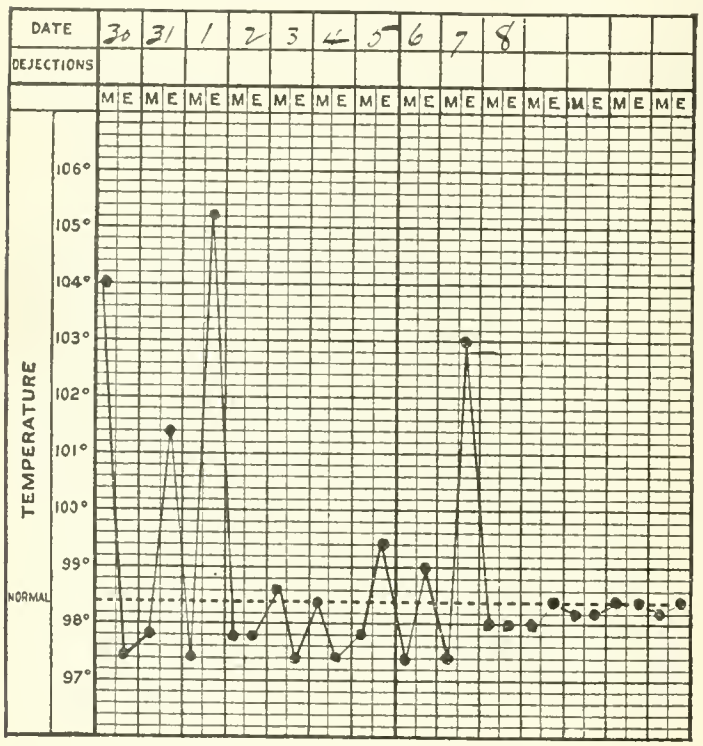

Chart II.—G. L. F., admitted August 30, 1904.

until late in that month, six rabbits were inoculated, meanwhile, by the intravenous injection of human blood, in which the plasmodium malariæ* had been found. Of these the two above alluded to died shortly after the operation. In all these cases the blood used was injected as soon as drawn, without defibrination. Since all inoculations, whether by this method or by the bites of infected insects, consisted of the introduction of the living parasites into that system (*i.e.* the circulation) wherein they naturally develop, I surmised that one such inoculation would be sufficient for the development of the antitoxin. In all cases, however, where mosquitoes were utilized inoculation with two insects was attempted, as even under the most favorable circumstances the *Anopheles maculipennis* does not always develop and convey the disease. But this attempt was not fully successful. White rabbits number nine and ten were kept uninoculated for control purposes. It remains to be demonstrated whether repeated inoculations with living organisms will develop a remedy of greater potency than that obtained by one inoculation only.

The insects employed were the *A. maculipennis* (Meiger) and the *A. punctipennis* (Say) raised from the larva. The time allowed for the development of the merozoits was from eleven to fourteen days. The average temperature of the laboratory during this time was about 78° F. The one attempt to inoculate by the bite of an *A. punctipennis,* supposed to be infected, was repeated by the use of an *A. maculipennis,* as it was found on subsequent examination that none of the former variety of insects had developed the disease.

Blood thought to contain the antitoxin was first obtained from two brown rabbits after the manner recommended by Novy, and allowed to clot. In subsequent exsanguinations it was drawn from the femoral artery through a glass tube into a mortar, where it was defibrinated with an egg-beater. Of course all instruments and implements employed had been previously sterilized. The blood obtained in each case was kept in the ice box at an average temperature of 67° F. until utilized or dessicated. As I had some difficulty in keeping it from becoming infected, I eventually dessicated the blood as soon as it was drawn and centrifuged. Serum and erythrocytes were usually dessicated separately.

In view of the fact that the first serum available had been developed by injecting into rabbits human blood containing the plasmodia malariæ, and that such serum, therefore, possessed hæmolytic powers for human erythrocytes, it was employed only in minimum doses and with the greatest caution. Fortunately no accident occurred, though in several cases its use gave rise to a local reaction, which persisted for several days. Subsequently I have learned that Metchnikoff has injected hæmolytic serum, similarly prepared, without permanently deleterious results, in several cases of leprosy, giving much larger doses (7 gm.) than those here employed.

The first case of malaria which I sought to cure by antitoxin treatment received 0.75 gm. of serum obtained from brown rabbit number two.* This was injected subcutaneously twenty-three hours before the expected chill. It recurred, however, as usual (Chart I), and as soon as the temperature commenced to fall quinine was given in doses of 324 mgm. every four hours. In view of the small amount of serum given, and especially in view of subsequent observations, this case did not prove of much value except in so far as it suggested another line of treatment.

* Under the existing laws of zoölogical nomenclature, the name first given an organism is retained, whether it prove to be scientifically correct or not. The inextricable confusion that would result from numerous observers giving to the same organism the different names which might appear to each of them most appropriate, is thus avoided, but usually at the expense of scientific accuracy. Thus, the plasmodium malariæ, so named by Laveran in 1883, retains that name, though it is now generally recognized that the taxonomic position of this organism is among the hæmosporidia, a subclass of the sporozoa, and not among the plasmodia, as was originally supposed. Plasmodia are forms of microorganisms which at one stage of their existence present animal characteristics, at another, vegetable ones. The myectozoa, to which the plasmodia belong, are by some naturalists placed with rhizopods, etc., among the sarcodina (a variety of unicellular animal organisms), while by others they are classed with low forms of vegetable life.

* These rabbits were numbered according to the sequence of their receipt, and not according to the dates when they were infected, though these were made to correspond as far as practicable.

It now occurred to me that the antitoxin might be closely associated with the corpuscular elements of the blood, especially the erythrocytes. With this idea in mind I poured the clot and remaining serum obtained from brown rabbit No. 2 from the Novy tube into a Petri dish and dissociated the clot as well as possible with sterilized glass rods. Of the defibrinated blood thus obtained, 1.50 gm. were injected subcutaneously on August 31, into a patient suffering with benign double tertian malaria (Chart II). One brood of parasites in this case was much less numerous than was the other. This injection did not prevent the recurrence of the chill on the following day (September 1), but no chill nor fever occurred on September 2 or 4. On September 3, 5, and 6 slight elevations of temperature were noted, and on September 7 a distinct chill, showing that the progress of the disease was re-established. Quinine was now administered.

This case led me to believe that a curative agent was actually present in the defibrinated blood, but that in the dosage employed it was unable to destroy the entire broods of parasites, though it diminished both of them to such an extent that the symptoms of the disease were temporarily in abeyance. From the fact that a chill occurred on September 1, and that none occurred for six days thereafter, I also believed that the antitoxin was far more toxic to the plasmodia malariæ free in the blood than it was to these parasites when developing in the red blood corpuscles. In the latter situation they appeared to enjoy some degree of protection. This conclusion is in line with our knowledge of the action and efficiency of quinine, and I yet hold it, though somewhat modified by a later observation noted below.

In the next case (Chart III) two grams of defibrinated blood from white rabbit No. 2 were injected subcutaneously on September 1, but without apparent effect. When, however, a second injection of one and one-half grams of blood from the same animal was given on September 7, the temperature, after an interval of twenty-four hours, fell to normal and there remained.

The next patient who received this treatment (Chart IV) was given hypodermically, September 4, one and one-half grams of blood from white rabbit No. 2, but, as in the former case, no clinical effects were apparent. A repetition of the injection of this quantity of blood from the same source (September 7) caused the disappearance of all symptoms after the usual interval.

The fifth case treated also failed to respond to the injection of one and one-half grams of defibrinated blood from white rabbit No. 2, but the injection of an additional quantity of the same amount from white rabbit No. 4, made one week later (September 11), caused the symptoms to disappear after September 12. The rise of temperature on that date illustrates that, as in other cases, the effects of an injection of a small quantity of defibrinated blood are postponed (Chart V).

An antitoxin which can be dessicated by exposure to moderate heat, and whose efficiency is not impaired thereby, evidently possesses peculiar advantages both for facility of shipment and for preservation in the tropics. In order to determine whether that developed in these inoculated rabbits possessed this quality, I dessicated separately on September 29 the erythrocytes and serum obtained from white rabbit No. 3. The temperature at which this was effected ranged from 47° C. to 53° C., the exposure continuing for fourteen hours. Each of these substances was then finely pulverized and kept for use in sterilized vials.

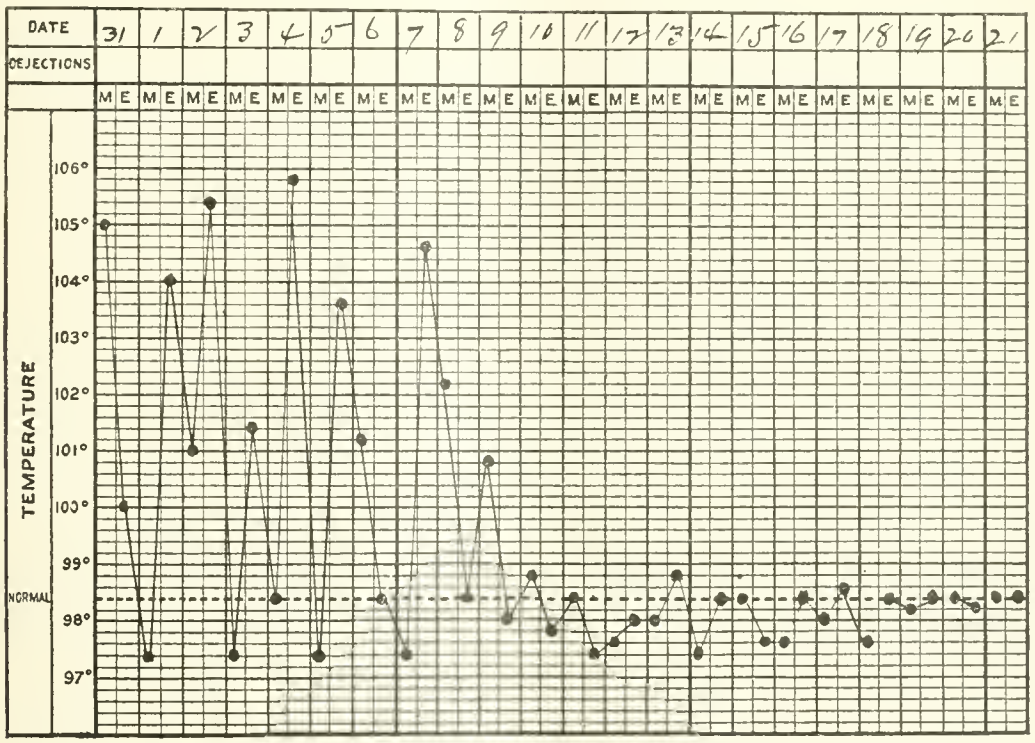

Chart III.—D. P., admitted August 31, 1904.

The first patient (Chart VI) who was treated by the use of dessicated erythrocytes was quite cachectic, and gave a history of seven attacks of malaria within the past year and a half. The original infection (if indeed there was more than one) had been contracted in the Philippines. On September 28 he received one-half gram* of these pulverized, dessicated red blood corpuscles from white rabbit No. 3, suspended in five grams of isotonic salt solution.

*Since the erythrocytes constitute 39.7 per cent. by weight of fluid blood, it is apparent that the weight of those moist corpuscles in three grams of blood would be 39.7 per cent. of three grams or 1.19 gram. Further, since the moist erythrocytes contain 36.7 per cent. of solids, it

A chill recurred September 29, and some fever was noted September 30. This fever, however, was, I believe, due to an abscess which had developed at the point where the injection had been made. This contained about eight grams of grayish, foetid pus and about one-fourth gram of black grumous material resembling a blood clot, being apparently the unabsorbed residue of the erythrocytes injected. When the pus was evacuated the patient's temperature fell to normal, and recovery was uneventful.

I now hoped that by the injection of a large quantity of dessicated erythrocytes I might cause an immediate fall in a patient's temperature to normal, without that postponement of its action noted in all cases yet cured. It was this hope that led me to inject into another patient (Chart VII), on October 1, one gram of dessicated erythrocytes from white rabbit No. 3. These were suspended in four grams of normal salt solution. As in Case VI, however, an abscess formed at the point of injection, though in this case it was so deep seated that it escaped detection for several days. It was opened October 5, and eighteen grams of pus, in all respects similar

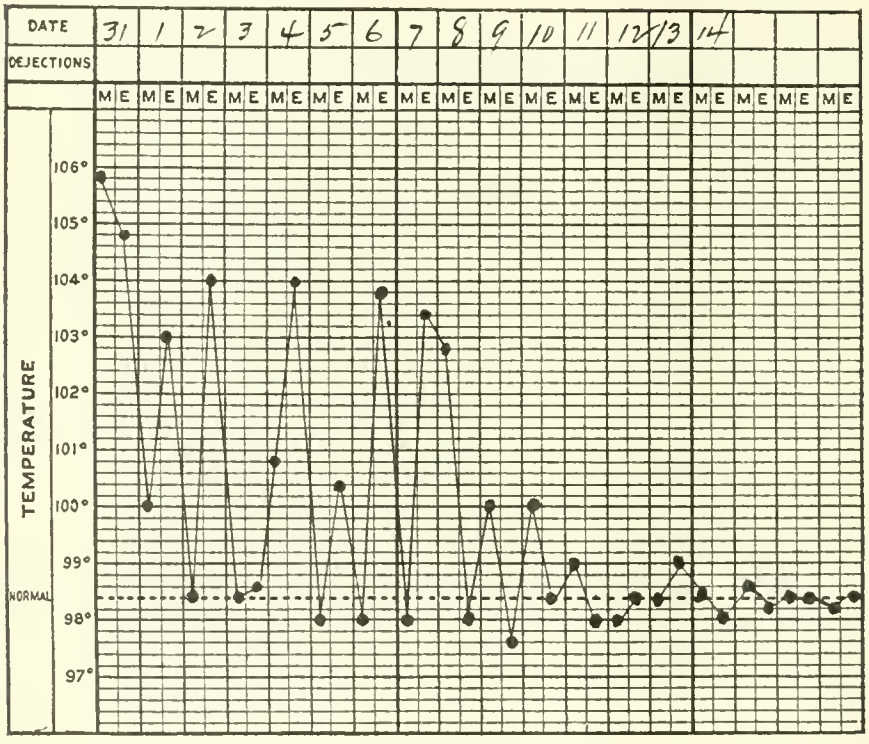

Chart IV.—S. T., admitted August 31, 1904.

to that found in Case VI, were evacuated. The wound discharged quite copiously for several days, and the temperature assumed a sapremic type. The malarial parasites disappeared from the blood after October 2, but the chill on that date was not averted. No subsequent chill occurred, but evidently the use of the antitoxin contained in the erythrocytes, even when given in much larger quantity than that which had previously proven necessary, did not relieve the symptoms promptly. While I yet believe that the antitoxin acts more energetically upon the unprotected sporozoits when these are free in the plasma, I am also led by this case to suspect that the postponement of the action of that antitoxin found in the erythrocytes is due to the fact that these must be disintegrated, physically, before they can be absorbed and the antitoxin become efficient. It will be noted that in both Case VI and Case VII the temperature showed a tertian type of temperature before the injections were made, and a quotidian type afterward. This fact, conjoined to the observation that the parasites disappeared from the blood in both cases within forty-eight hours, suggests that this postoperative fever was sapremic, after that interval.

The next case (Chart VIII), from a chronological standpoint, should precede Case VII, but is more conveniently discussed in this sequence. This man received, September 30, one-half gram of dessicated serum from white rabbit No. 3, in solution in four and one-half grams of sterile water. This fluid represented five grams of serum. Apparently no effects followed the injection, and on October 5 the use of quinine was begun, 324 mgm. being given three times daily.

The last case of this series (Chart IX) gave a history of five attacks of malaria in the past eleven months. He was quite cachectic, and the malarial parasites were found in his blood more abundantly than in those of any other patient who came under my observation during the past summer. He received October 10, a hypodermic injection of 0.75 gm. of desiccated serum from white rabbit No. 7, in solution in four grams of sterile water. This represented seven and four-fifth grams of rabbit serum. Daily examination of the patient's blood showed the parasites yet present on October 12, but none were discoverable after that date. The serum employed in this case had been developed in the largest and most active rabbit in my warren, and it is possible that this may have had some influence in determining its strength. It is a well-known fact that in the development of other curative sera some animals are much more useful than are others of the same species.

In all these cases the injection was given near the great trochanter of the femur, and a hot-water bottle kept at the place of injection for twenty-four hours in order to expedite absorption. It was noted that the serum injected caused much less local reaction than did the erythrocytes. From Case IX it would appear that the action of the serum (if it be at all curative), moreover, is much more prompt than is that of the erythrocytes, though in this case, with the dosage employed, it was not strong enough to cause the immediate disappearance of the parasites or to abolish the symptoms of the disease, it *apparently* exercised some effect within six hours after it was injected. This patient experienced his chills at about half-past three in the afternoon, and though the serum was not injected until 11 A. M., October 10, it will be noted that the rise of temperature that afternoon was just two degrees less than it had been the day before this treatment was instituted.

It would appear that dessicated erythrocytes, containing the malarial antitoxin, will find their chief usefulness in injections given to confer immunity, and it is possible that we will find the corresponding serum, in much larger doses, more suitable for curative purposes.

This case brings me to control observations—*i.e.*

follows that the amount of solids in 1.19 grams of moist corpuscles is 36.7 per cent. of that quantity, or 0.44 gram. This quantity by weight of dessicated corpuscles therefore corresponds to three grams of fluid blood.

those cases in which benign infections have disappeared spontaneously. Of thirty-one cases treated at Fort Reno during the past summer, on the expectant plan, with the use of phenacetine 150 mgm. q. 4h, for from five to seventeen days, four showed a tendency to spontaneous cure. In all of these control cases there was a gradual, generally progressive disappearance of the fever—not the abrupt cessation of it found in those cases reported in the table as cured. It was also noted that in all cases where erythrocytes were used in adequate quantity, and when no abscess formation occurred, that the condition responded decisively, after a definite interval, to the treatment employed, whereas only four out of thirty-one control cases showed any tendency to recovery under expectant treatment, and in these there was no definite uniformity. The temperature curve in Case IX, however, is so highly similar to that of one case that underwent spontaneous recovery (Chart X) that I am disposed to classify it as inconclusive, despite the severity of the infection in the former patient and the promptitude with which the parasites disappeared from his blood after serum was injected. I cannot regard the curative powers of the serum employed as fully demonstrated when his symptoms followed a course so similar to

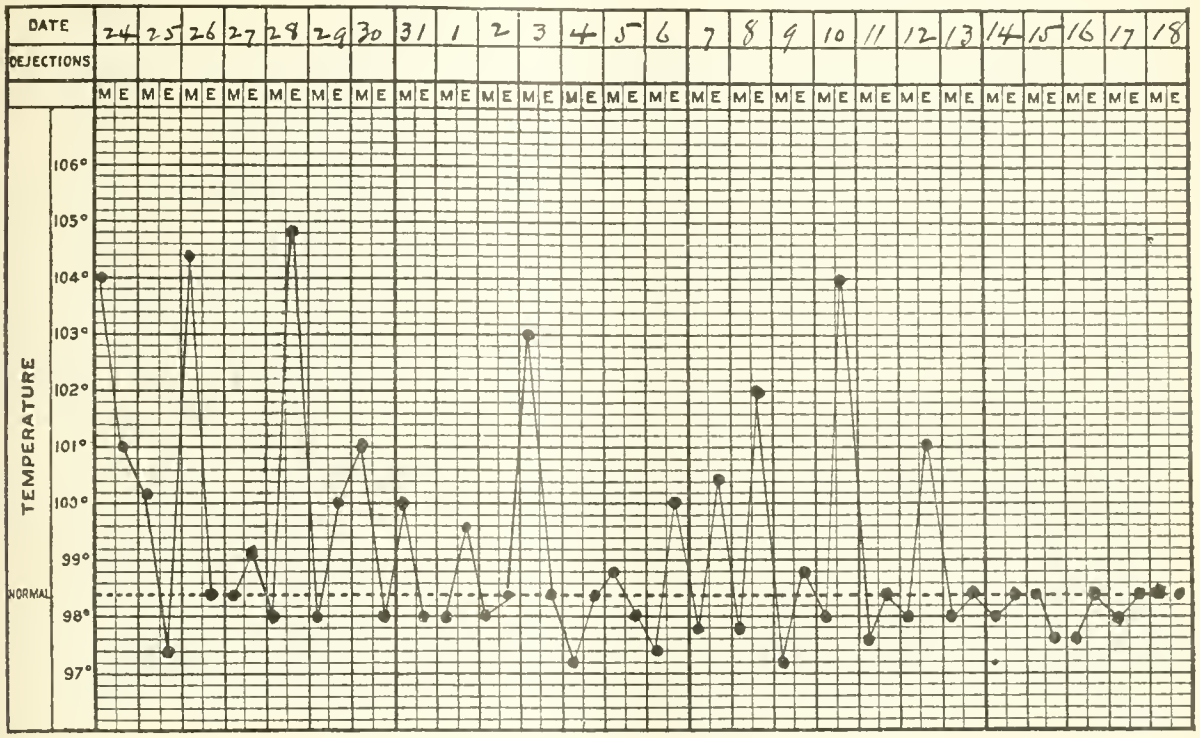

Chart V.—C. S. M., admitted August 24, 1904.

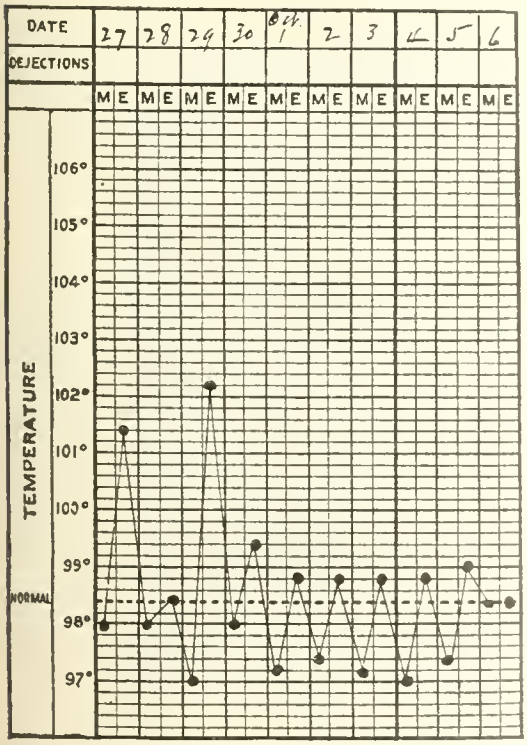

Chart VI.—C. J. C., admitted September 26, 1904.

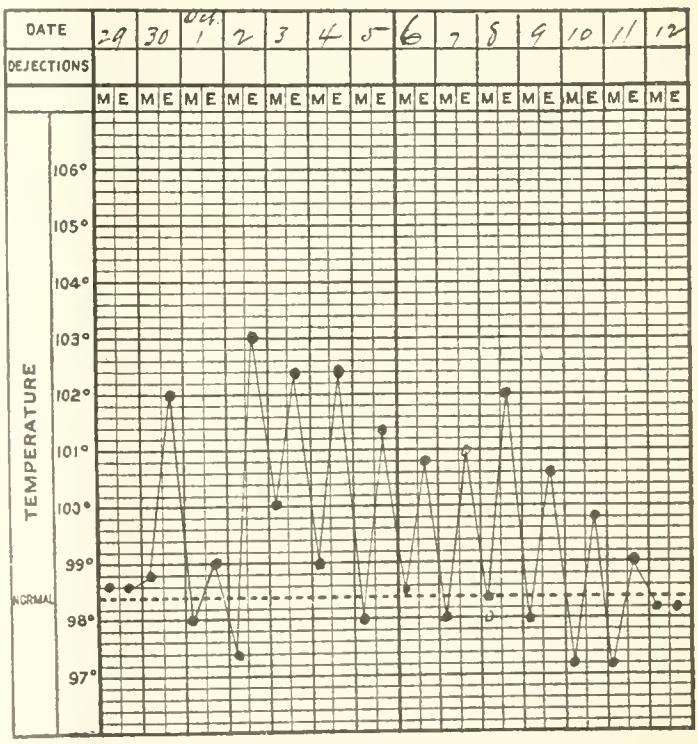

Chart VII.—D. J C., admitted September 29, 1904.

that of another case which underwent spontaneous recovery. The coincidence between the injection and recovery is interesting, and may be significant, but cannot properly be regarded until further investigated, in the light of other observations, as an illustration of cause and effect.

I am not prepared to discuss fully at this time control observations made upon tertian malarial cases with the blood of uninoculated rabbits, though this phase of the subject is evidently of the greatest importance. It will be discussed in a subsequent paper. Repeated examinations of the blood of infected rabbits failed to demonstrate the malarial parasite therein.

An analysis of the cases shows that the quantity of defibrinated blood that should be injected varies, but that about three grams is the minimum quantity that can be relied upon.

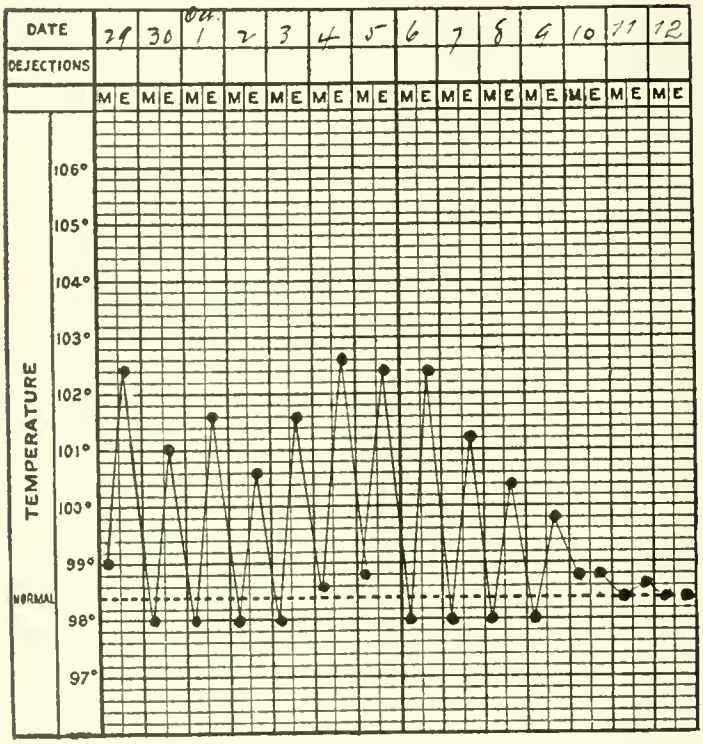

Chart VIII.—L. J., admitted September 29, 1904.

The chief purpose of these investigations was the discovery of an agent, which, when injected, will confer temporary or permanent immunity. Certainly, the discovery of a specific antitoxin is a long step in that direction, and we have reason to hope that we here possess the key which will unlock the tropics. It is a matter of general knowledge that the antitoxins now in general use possess immunizing as well as curative properties, though the duration of the immunity conferred is variable. If the immunity conferred by the injection of this antitoxin should continue as long as does that which follows vaccination its value would be established. By its universal, simultaneous use throughout a community the malaria therein would be practically exterminated. The effects of general vaccination in Porto Rico are yet before us. Vaccination is mentioned in this connection because it is the only established method of personal prophylaxis which, supposedly, makes use of the products of protozoal activities. Such an agent as that here developed should also have an important influence in clearing up the etiology of blackwater fever, and of those unclassified fevers of the tropics whose existence Manson, Crombie, and others, so earnestly and so reasonably maintain. Its influence or lack of influence in kala-azar would also be of interest.

Though the most hygienic, and therefore the best,

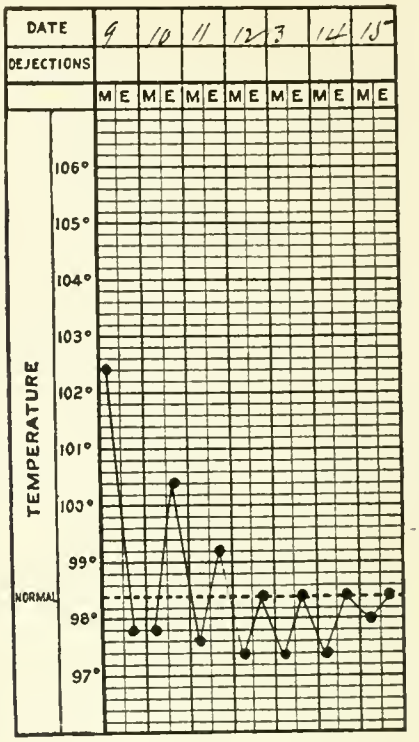

Chart IX.—R. C. U., admitted October 9, 1904.

method of preventing malaria rests in great degree* upon the extermination of anopheles, this measure is generally so expensive† that communities are unwilling or

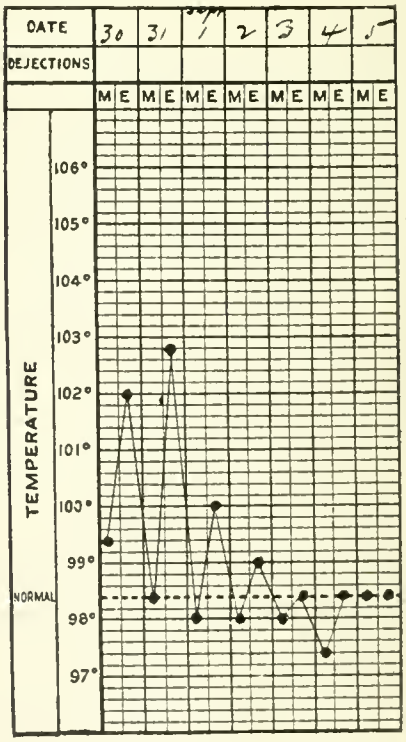

Chart X.—L. L. J., admitted August 30, 1904.

*It has never been demonstrated that malaria may be caused naturally by the bites of infected mosquitos *only*. There are strong grounds for suspecting that there exist other, but, as a rule, less important, sources of infection.

†Ross states that in Lagos the cost of the antimosquito campaign is about £10,000 per annum; in Klang and Port Swettenham, £3,225 and £8,600 for the first year's work, respectively, and that Taylor spent £1,000 for a preliminary drainage of the waste puddles of Freetown.—*Jour. of Trop. Medicine*, Vol. XVI, p. 225.

unable to undertake it, and in many districts, *c. g.* those in which rice is cultivated, it is utterly impracticable. Despite their potential wealth, tropical and subtropical countries are less prepared financially to wage war against mosquitoes than are the healthier countries in colder climates. Indeed, their poverty is due in no small degree to the prevalence of malaria in the richest parts of their territory. When we consider that this disease prevails especially in rural districts, and that the Caucasian pioneers of civilization in the tropics, whether they be civil or military, cannot hope for protection against it because of the wealth and enterprise of those communities wherein they may reside, it becomes apparent that specific individual prophylaxis, better than that conferred by quinine, has an important field of usefulness.

The scope of the observations here recorded is broader than is at first apparent. Though malaria is the chief bar to the commercial development of our southern States,* Italy, Africa, and other subtropical and tropical regions generally, the discovery of a specific antitoxin for one type of the disease is of less importance, *per se,* than is the principle whose existence that discovery implies. This principle is the fact that other human diseases of protozoal origin may, like those caused by some bacteria, prove amenable to antitoxin therapy. To practitioners resident in cool climates where malaria is neither prevalent nor, as a rule, severe, observations on its specific treatment must prove of academic rather than immediate practical value, but their experience with other less tractable infections, caused or believed to be caused by sporozoa, gives at least ulterior importance to the principle here enunciated. It is the basis of a natural, working hypothesis which, there is reason to hope, will contribute greatly to the successful treatment of diseases of this class.

In this connection it may be mentioned that Sternberg has suggested that the serum of a calf inoculated with vaccina might possess curative properties against variola. He also mentions the fact that Kinyoun, utilizing this suggestion, has found that such serum did possess curative properties to a limited degree in two cases of this disease in which it was employed. In the light of Councilman's discoveries, it is suspected that the organism causing variola may be a protozoan, though the exact nature of the bodies described by him, and their etiological importance in relation to that disease, cannot as yet be regarded as established. So far as I am aware, indeed, Councilman has never stated that the bodies which he found in variola are the specific cause of it, but his silence on this point and his well-known conservatism by no means negative the suspicion that this may actually be the case. Though Kinyoun's observations cannot as yet be regarded as a conclusive demonstration that protozoal infections may be cured by antitoxin treatment, they are highly important, and a noteworthy contribution to our knowledge of the subject. It would be interesting to learn whether the erythrocytes of a calf inoculated with vaccinia possess curative properties analogous to those resident in the red blood corpuscles of rabbits inoculated with malaria.

In this connection it may be mentioned that Sternberg has suggested that the serum of a calf inoculated with vaccina might possess curative properties against variola. He also mentions the fact that Kinyoun, utilizing this suggestion, has found that such serum did possess curative properties to a limited degree in two cases of this disease in which it was employed. In the light of Councilman's discoveries, it is suspected that the organism causing variola may be a protozoan, though the exact nature of the bodies described by him, and their etiological importance in relation to that disease, cannot as yet be regarded as established. So far as I am aware, indeed, Councilman has never stated that the bodies which he found in variola are the specific cause of it, but his silence on this point and his well-known conservatism by no means negative the suspicion that this may actually be the case. Though Kinyoun's observations cannot as yet be regarded as a conclusive demonstration that protozoal infections may be cured by antitoxin treatment, they are highly important, and a noteworthy contribution to our knowledge of the subject. It would be interesting to learn whether the erythrocytes of a calf inoculated with vaccinia possess curative properties analogous to those resident in the red blood corpuscles of rabbits inoculated with malaria.

* It has been estimated by competent authority that in the states south of the Potomac, Ohio, and Missouri rivers, malaria costs the laboring class in loss of wages alone, between ninety and one hundred and five million dollars annually. These figures are thought to be conservative.

REMARKS ON MELANCHOLIA.*

By JOSEPH COLLINS, M.D.,
NEW YORK.

PROFESSOR OF NERVOUS AND MENTAL DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO THE CITY HOSPITAL, CONSULTING NEUROLOGIST TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, MANHATTAN STATE HOSPITAL, WEST, LONG ISLAND STATE HOSPITAL, AND THE MONTEFIORE HOME.

We are told by some writers on mental diseases that melancholia is a very uncommon disease, and that whereas formerly it was encountered more frequently than mania, to-day melancholia is much less common. Others maintain that there is no such disease as melancholia, that that which we call melancholia is a symptom of a diagnosticable condition, which, being the real disease-process, should be entitled to the name. Personally, I am in sympathy with such writers insofar as their position compels them constantly to seek for the dependency of melancholia, but I am unwilling to accept their statement that there is no such disease as simple melan-

*Read before the New York Neurological Society, November 1, 1904.

cholia, *i.e.* melancholia (without any reference now to its intensity or its clinical display) which is not a constituent of other disease, physical or mental. The general practitioner is likewise loath to accept such statements, because they seem to him to be at variance with his experience. It is unlikely that there has been any radical change, either in the relative frequency of melancholia, or in its clinical display, within the past twenty-five years, so we must account for the altered attitude of psychiatrists in some other way. My purpose now is to set forth my own position in the matter, and to substantiate it by a recital of a few illustrative cases. The difficulty in discussing the subject is that the term melancholia is used by writers with great latitude and without specificity.

Melancholia, or mental depression, coupled with moral insufficiency, sadness, and anguish, is of common occurrence. We encounter it in certain toxic states, such as alcoholism, and states of insufficient oxidation and deficient elimination. We find it associated with neurasthenia, hypochondria, general paresis, cerebral and diffuse arteriosclerosis, dementia præcox, and mania, and we find it occurring without any of these associations. The question is, it seems to me, is there a form of insanity in which mental depression, coupled with moral insufficiency, is the conspicuous symptom, which has, in addition to the depression, something individual in its delineation, course, and outcome that justifies us in using the word specifically? In other words, is the depression merely a phase of some disease, or some stage of retrogression in the economy, such as the so-called involution melancholia, *i.e.* symptomatic, as it were; or is it in reality the disease itself? To this question the answer must be, there is such a disease. That it is of frequent occurrence compared with manic-depressive insanity, *i.e.* insanity characterized by attacks of depression and excitement, which may be but often are not coincident, cannot, I think, be maintained. As to the nature of this disease and its dependency, that is another question, and one to which an answer cannot be given. But in another way it may be said that melancholia = a percentage which has not yet been accurately determined, of general paresis, manic-depressive insanity, intoxicative conditions, involution melancholia, etc., and = x, which is as yet an unknown quantity. That the problem is resolvable is to be sincerely hoped, but the surest way of not solving is to deny its existence. As Dr. Johnson once said in talking of those who denied the truth of Christianity, it is always easy to be on the negative side, and very difficult to reduce those who take such position to an absurdity. Every neurologist sees a great many cases which he diagnosticates as melancholia, without being able to satisfy himself of the dependency of the melancholia, just as the general practitioner or consultant in internal medicine must often still make the diagnosis of indigestion without being able to satisfy himself that it is dependent upon any one or more of a number of disordered conditions that are sufficient to cause it. When the neurologist has the opportunity of observing these cases for a protracted time he is enabled to classify them more specifically and from an etiological standpoint more correctly. It is these cases that he should use with great effect in a discussion on the classification of the melancholias.

In 1902 I had under observation fifteen such cases of melancholia. This number does not include any of those cases that I saw once or twice in consultation with other physicians, or that I saw casually a few times in my clinic or the hospitals which I served. Of these, five were between twenty and thirty years, five between thirty and forty, and five between forty and fifty. In five cases the cause could not be assigned, in four it was attributed to fright, in two to religious worry and disappointment, in two family frictions and worry. In one, to worry over a red and swollen condition of the nose, and in another to the depressing effects of disagreeable and terrorizing dreams. In other words, the attributed cause in the majority of cases was what might be called moral or emotional. Considering the fact which is thoroughly established, viz., that a psycopathic heredity is one of the most important etiological factors in insanity, it is worthy of remark that in these fifteen cases there were but three whose antecedents had nervous or mental disease. There is less likelihood of finding a history of insanity in the ancestry of patients with melancholia than in almost any other variety of insanity. Of these fifteen cases four eventuated in manic-depressive insanity, one developed general paresis, and one dementia præcox. Another case later seemed to be more properly diagnosticated neurasthenia. Four of the fifteen were cases of involution melancholia, and the remaining four were simple melancholia from start to finish, and have all eventuated in recovery.

Another point worthy of note is the age at which the psychosis developed in these cases. There is a tendency at the present time to put all cases of melancholia that cannot be referred to organic disease and manic-depressive insanity under the head of "involution-melancholia," *i.e.* melancholia associated with retrograde changes in the tissues and occurring at a time of life when such changes of the tissues set in physiologically, and therefore directly or indirectly dependent upon them. It is my experience that considerably less than one-half of all the cases diagnosticated as melancholia, using the term in the specific sense mentioned above, can be placed in this category. And this includes those cases in which the depression and anxiety may be called "pre-involution" attacks. That is, attacks which terminate in recovery, but the patient later develops involution melancholia. It goes without saying that some of the cases occurring in the young which I diagnosticate as melancholia, may be the initial depression of dementia præcox, which does not reveal itself in a way to permit diagnosis until a long time afterward, but I am not inclined to this view. A very considerable number of cases occur before "involution" begins, and are not episodes of other disease. These cases are of particular interest because of their eventuation, which is almost always in recovery. As an illustration of this class, the two following cases may be cited:

Mrs. X., 24 years old, whose ancestry showed geniuses, average persons, and derelicts, began to be depressed, without attributable cause, one week after the birth of her first child. She had a fairly hard labor, and had experienced a laceration of the perineum of the second degree, which was immediately repaired. She soon became suspicious, self-accusatory, and uncommunicative. She refused food, and had to be tube-fed. The character of her delusions were not readily elicited at that time, for mutism and absolute uncommunicativeness were very conspicuous, but after her recovery, they, as well as the hallucinations which she had, were described in detail. She reasoned, she says, in as logical a way when she was in the attack as she did before. The conclusions were no falser than the premises. She became convinced that she had committed the most heinous crime, and that, although she could not expiate it, she could do something toward keeping the results of it from

being visited upon those whom she loved, by dying and giving herself over at once to the monarchs of perdition. The wind rustling through the trees, the sound of a distant locomotive whistle, the clang of a neighboring school-bell, all conveyed definite statements, expressed in articulate language, telling her of her sin and of her duty. In addition to this, she manifested a most pronounced repulsion toward her husband and toward her child. She afterward explained this by saying that it was her desire to spare them from contamination. Later, she mistook identity, occasionally confounding those about her with sacred personages, to which she made appeal to be let die, that she might begin her atonement. Although she was extremely noncommunicative, there was no psychomotor retardation. Her physical condition soon showed the effects of the disorder, in rapid loss of weight, deeply furrowed, tremulous tongue, foul breath, collection of sordes on teeth and lips, scant secretion of concentrated urine, sluggishness of the bowels, and sleeplessness. A large part of the time the patient was very suicidal, and was keenly alert to anything approximating an opportunity of taking her life. After six months she began to recover, and at the end of ten months was quite well, and has remained so now for eight years, during which time she has borne three children.

In a case such as this, it may be said we are dealing with a puerperal psychosis due to infection of some sort. For several days, in the beginning of the attack, there was a considerable rise of temperature and perceptible enlargement of the spleen, which led the physician in attendance to suspect typhoid fever. But my purpose here is not to discuss the etiology of acute melancholia, but the actuality of its existence. Here is a case in which the most distinctive features of acute melancholia, disorder of feelings, will power, and intelligence, were displayed. The insidious way in which it began, each day her views of her relationship to the environment becoming more distorted, the slow crystallization of her self-accusatory ideas, the agonizing belief of culpability, the gradually developing conviction of the necessity for self-immolation, the distressing hallucinations and the reaction to them, the attempts at suicide, and the physical symptoms, all go to make up a most typical picture, and one that, in my experience in private practice, is not very common.

There is little danger that such a disease as this will be confounded with manic-depressive insanity, or with involution melancholia. Nor can it be looked upon as a state of amentia and confusion. It is, in reality, a type of mental disorder of which I have seen many cases, and which, so far as my experience goes, does not form a part either of manic-depressive insanity or involution melancholia. In some cases the distinction is not, however, so easy. For instance, in the following case, it was not easy to say whether the patient had simple acute melancholia, or involution melancholia. Mrs. X., 42 years old, has had a life of hard work, worry, privation, and struggle, for many years. Her husband had been ill and incapacitated by tabes for a long time. Recently he developed mental symptoms, and had to be sent away. The small business which she was conducting had to be given up, and she soon found herself succumbing to a depression that could not be shaken off. To add to this, she was taken with a bronchitis or grippe, and the doctor told her he was afraid her lungs would be affected, and sent her to a hospital. This made her more apprehensive, and she gradually became convinced that she was going to be killed. The following is a stenographic report of an interview with her after she was taken from the hospital, many of the remarks being responses to questions: "I remember you well. You used to treat my husband (which was true). I am so glad to find you again! They abused me dreadfully up there. They put electricity on me. They put gas over my head at night. They were a hundred times going to throw me into the river. They let the water come in through the back of the hospital. They throw the patients in, and out they go into the river. Some they take back again after they immerse them. They choked me, thumped me, and pulled my hair. When I was under the gas they did operations on me—something to my stomach. I can't cough any more. I can't pass my bowels. They did something to them which prevents me from doing anything, so when I want to have a passage they send someone else to the closet. They give someone else the bed-pan, so I can't have a passage. To-day I had a passage, and the people outside called me all sorts of names. They said, 'Throw it on top of her.' I asked them if I could go to the toilet, and they said 'No.' They said, 'She has killed two up in the hospital.' When I want the bed-pan, there is a woman who uses it instead of me. There was a woman in the ward, and when I used to go to the chamber they'd give her the bed-pan, and she would do what I wanted to do. She had her stomach out. They had my bowels so hard they'd never open. One day I had to change, and they said I had killed her. I saw her dead, and I saw them take blood and clothes out of her. I heard them say, 'We will give it to her to-night,' meaning me. When I wanted to urinate, a French woman down at the bottom of the ward would do it. There was a lovely girl there, an Irish girl, and they were going to kill her last night. They were going to do it because she was a Catholic. It isn't a hospital, it's a place to plunder people and kill them. There are a lot of those women they call nurses from up there, down here. They said I had two husbands. They said I was Lowenstein's whore, that I had another man in Ireland, that I was rotten with disease, and that I was falling apart. I seen them killing, I don't know how many, up there, doctor."

"What place is this?

"This is —— Hospital. (Correct.) But it is all —— Hospital that is around me."

"When did you come here?"

"The night before last, Saturday night, in the ambulance. It took about three-quarters of an hour, perhaps less. I was so glad to get away from ——. I used to see you at the Post-Graduate clinic about ten years ago, when I would get powders for my husband. These ideas I have are not delusions. I am sure I will be killed, as soon as you leave. If you will take me to your hospital, I will not say a word. People listen, so I am afraid to say a word. I dare not open my lips. When I was here this afternoon." When I start to go, she says, piteously, "Please don't leave me behind! They'll kill me just as soon as you go. I know they will."

Five days later: "They said they were going to benzine me. They have a machine out there in the corridor that they are going to use on me, and then throw me into the river. They are all here from ——; a whole lot of them. Now I'll be killed entirely, when you leave! When my bowels moved, this morning, they all said, 'Pitch her out, throw it on her; she is good for nothing.' I have been here since Saturday. I am not out of my mind; you think I am, doctor? I asked for a priest, and they said, 'When he comes in, you can see him,'" etc., much as before.

She is very much emaciated and anæmic. There is no tenderness on pressure over nerves, and there are no sensory disturbances. The knee-jerks are

present. Pupils equal, and respond to light. No tremor of the hands or face; fine tremor of tongue. Three months later she said that my assurance that nothing would happen to her helped her very much. She thinks she must have been out of her head, delirious. She knows now that those were delusions. She has no fear of being killed or injured. She can have a movement of the bowels when she takes medicine. Has now no suspicion that people talk about her, or depreciate her. She has gained in strength, flesh, and color. Her progress toward recovery was gradual and uneventful. She has now been quite well for a year.

Fear and apprehension were the most conspicuous features, and dependent directly upon the delusion. That she was not confused, in the ordinary sense of the word, was shown by her recollection of me, by recognition of her surroundings, by relation of her past experiences, *i.e.* before she was taken ill, and in general, by her correct orientation. In two months her delusions became less dominant, and her general health began to be restored, and in four month's time she was able to return to her work. That she may be a case of pre-involution melancholia I do not deny. She has no physical signs that indicate beginning senile degeneration, though she is entering the involution period. By some writers, this case would be classified as delusional insanity, on an exhaustion basis, but it is cited here for the purpose of showing that it presents all the features of an acute melancholia, that terminates in recovery.

I shall cite another case, which is still more typical. It is quite clear that this case may properly belong to the group of the manic-depressive insanities, particularly if one is willing to accept that manic-depressive may exist, showing itself in several attacks without maniacal manifestations. Mrs. X., 36 years old, has one child 7 years old. Since the birth of her child, she has never been in robust health. Five years ago, she had cholecystotomy performed upon her. About a month before I saw her, she began to be depressed, inactive, neglectful of her person and her work, uncommunicative, and without interest in anything objective. She quickly became self-accusatory, maintaining that she had been faithless to her husband, and that she must get out of the way. She became convinced that her friends were against her, and that they and her husband wished to get rid of her, or get her into an asylum. Every one believed she was a thief and a bad woman. At times she was hallucinatory, seeing angels and devils, and reacting to these visualizations. After a few weeks she became profoundly suicidal, and had slashed both wrists with a knife, and nearly bled to death in consequence. She was very adverse to enter into conversation, but there was no psycho-motor retardation. Once her determination not to talk was overcome, the rapidity of her psychical processes as manifest by speech was quite like that of a normal person.

She told her story in the following way, the statements being responses to questions: "I have been married seven years last October, and have one boy 6 years old. I have never been as well as I should be, since my boy was born. I have had trouble with the intestines, and constipation. During the past two years my husband had lots of trouble about positions, and that worked upon my mind. I had headaches, and my eyes hurt me. I always put the worst construction on that which anyone said. I was a pessimist, and ought not to have believed what people said. As long as I was married I was faithful, and I trusted my husband, and I know he was faithful to me. I did something wrong when I was a girl. I was afraid people would find it out. I told my husband, and he forgave me. My mind was all confused and I was—I don't know what I thought, but I thought I had to die. If we come together again, I shall change life and we'll be happy if I can. I had been worrying about the things I had done, for a month or more. There was some clothes stolen from the roof, and they accused me of doing it, and people avoided me, pointed me out in the streets, and talked about me and treated me queer (bursts into tears). I feel better since I am here. I was misguided by talk and gossip. I shall not listen to them any more. This is the first time I have been depressed." Here she becomes somewhat confused, and begins to tell of her troubles again. She made a complete recovery within six months.

These cases are to be distinguished from involution melancholia more by their clinical course and termination that by any other features. As a matter of fact, I am unable to differentiate them save from a consideration of the patient's age, the absence of arterial sclerosis, or other manifestations of retrograde change in the tissues and vitality.

For instance, the following case, which is a fairly typical one of involution melancholia, reminds forcibly of the one just cited, while it illustrates the difficulty of differential diagnosis.

Mrs. X., a German, 39 years old, is married the second time. She had six children by her first husband, and two by the present husband, an Irishman. (She tells her own story.) "He wants to make a Catholic out of me. I'd like to be one myself. I went to the Catholic church for two years. When I first saw high mass, it affected me so I cried; since then I can't go in a Protestant church. I don't know what has happened the past few weeks. It must be something with my head. Yes, I have had something like headache, and I haven't understood right what people say. I forget everything. I worked hard when my first husband was alive, and my nerves broke down. There was some bad talk around the house. People said I passed my bowels in the garbage barrel, some said I wasn't married at all, that I went out and made my living on the street, and talk like that. They said it, I suppose, because I wore nice clothes. The Catholic church had something to do with it; I guess perhaps the people in the house did not want me to join the church. They would like to have me in State prison. I heard them calling out, 'Chop wood.' I didn't know what it meant. They called me very bad names." (Here she repeats them with all specificness.) "They wanted to go in my room and take my clothes and hock them. People in the street watch me all the time. No one has tried to poison me, but one woman said she would do it. They told me my husband was here to-day, but it looked like another man, so I didn't speak to him. I heard the talk from my bedroom window. I can't tell what it was. My mind is going. I have it one minute, but the next minute I have forgot it. I have got a terrible headache, and there is a heavy load on it. My whole body is sick."

These statements are the result of patient interviewing. She has no objectivity whatsoever. She sits with her head leaning on her hands, dejection, detachment, and inaction in every feature. Some days she is apparently confused and disoriented. But this is the result of profound preoccupation, rather than want of perspection. The principal somatic symptoms are: Tongue coated, breath foul, hands tremulous, tendon jerks +, pulse 68, volume small, blood-pressure (Riva-Rocci) 185, extremities cold.

Improvement in her physical condition has brought no corresponding change in her mental

state. In fact, there has been mental deterioration. "Her mind has ceased to struggle with the disease, for she has grown fat upon it." Save for the increased blood-pressure, there were no evidences of senility, and these are by no means necessary accompanying conditions. Oftentimes we find in the most typical involution melancholia no evidence of senility whatsoever. The feeling that this patient expressed, that her strength and her mind were gone, associated with her inertness and narrowness of mental horizon, were very typical.

The following case, in which the symptoms were thought by neurologists who saw him first to be an expression of arterial sclerosis, *i.e.* a senile melancholia leading up to senile dementia, but which has proved to be a fairly typical case of involution melancholia, shows some of the most constant features of involution melancholia better than any other. They are the delusions of poverty, the fear of impending disaster, the anxious restlessness, the manifestations of fear and terror in expression and attitude, the enormous and the absorbing subjectivity.

Mr. X., 65 years old, married, is the father of four children, all of whom are in good health except one, who has spinal curvature. His family noticed the first decided symptoms after his father's death in December, 1901, although they are conscious now that an almost imperceptible change had been coming gradually for a number of years. In December, 1901, they came to a hotel in New York. He worried about the charge for the room, the price of the food, the carfare spent by the family; he was sure he was going headlong to the poor-house. Nothing could stop him. He could not afford to wear the clothes he had on. He couldn't afford to go to the barber, etc. He was apprehensive about his having done something for which he was going to be apprehended. He soon refused to go into the dining-room. He couldn't afford it. He then became sullen, restless, talked to himself, and became uncommunicative. Finally, he refused to stir from his room. He would sit all day, swaying and moaning, now and then speaking briefly of his unworthiness. He had brought it all upon himself, and his family were the sufferers. He was of no use, he couldn't do anything. His mind was gone. He was then committed to an asylum, and remained there eight months. At that time patient required forced feeding for a period of two weeks, and at intervals for several months. About February, he persisted in vomiting food after each meal, and his family feared cancer. A physician was consulted, who pronounced it a mania in the patient's presence, and advocated eating food as it was regurgitated. The habit, which had been very persistent for three or four weeks, was overcome within three or four days.

When first seen by me, he had a frightened, distressed expression. When spoken to, he would answer in yes or no after a long wait, during which time he had the appearance of debating with himself whether or not he would answer. At times, instead of answering, he grunted, and then started as if to do something purposeful, left off suddenly, and then went to do something else. As a rule he was quite taciturn, and asked very few questions unless they related to family matters, when they were likely to be about his poverty. At these times he would show great anxiety, and repeat his questions with the keenest intentness, as if his life depended upon the answer. One of the most constant characteristics was a continual forward and backward swaying motion while in repose in a chair or carriage, and at times this was coupled with moaning. This would cease while driving, eating, or reading, but not while talking. He was not only very slow in his mental responses, but in the physical acts as well. In dressing, he was always very slow, but unlike most melancholics he was methodical to a fault. All physical acts, with the exception of eating, were very slow. When he was not refusing his food, he gulped it without masticating, and looked as if his desire was to avoid being seen. At this time he was not self-accusatory, although he had been formerly, and he had no delusions of having done wrong, or no delusions of reference. He was constantly depressed, anxious, and distracted, but no formal delusions save that he and his family were going headlong to ruin and the poor-house because of some fault of his own, and that his food, and perhaps also his baths, were poisoned. At the end of a year he was vastly improved, mentally and physically. At the present time his memory is good for recent as well as for past events. At times he talks rationally and quietly about his illness, but more often refers to it surreptitiously, saying he may not live through the night, and in parting with friends he bids good-bye, saying they may never see him alive again. He often joins a general conversation, and talks with clearness and intelligence.

That this patient's mental symptoms stand in direct relationship to his arterial sclerosis, there can be little doubt. The evidences of such arterial degeneration are the enormous increase of blood-pressure determined by the Stanton apparatus, the thickened, whip-cord condition of the peripheral vessels, and the altered heart sounds. Moreover, he has made most gratifying improvement, an approximation to recovery from the mental symptoms under treatment, dietetic and medicinal, directed against this lesion. It differs in this respect from the average involution melancholia, which, as has been said, rarely shows the physical signs of arterial degeneration. Another noteworthy feature of the case is that there has been so little dementia.

In many cases of involution melancholia the somato-psychic delusions oftentimes take on very strange and weird characters. Under the dominion of such delusions the patient, in many instances, develops a stereotyped way of doing certain things, or indulges in certain gestures or habits which are many times labelled as mannerisms. Such attributes occasionally lead the physician to suspect that he is dealing with dementia præcox. This is well illustrated by the following case, which I saw many times at the Long Island State Hospital at Kings Park. She was diagnosticated there as a case of involution melancholia, but one, at least, of the physicians of the staff was satisfied that the case was one of dementia præcox.

Mrs. X., 42 years old, of common school education and temperate habits, was admitted to the Long Island State Hospital, January 22, 1902. No history of nervous or mental disease in her family. She had been healthy, and of average mental capacity, but inclined to be rather pessimistic. For many years she has been subject to headache of a migrainous character. About two years before admission, she began to fail physically, to be despondent, had "dyspepsia," and finally lapsed into a condition diagnosed by the family physician as "nervous prostration"; she became depressed, detached, uninterested in her family, and negligent in her dress, untidy, and suffered almost constantly from sleeplessness. In October, 1901, her condition was aggravated; she became restless, delusional, threatened to commit suicide, and made several attempts to take her life by throwing herself down stairs, dashing her head against the wall, etc. Soon (January, 1902) she began to express delusions of an absurd nature; said she was changed into a monkey, was all rotten inside, etc.

On admission to the hospital, physical examination showed marked emaciation, slight anæmia, very decided diminution of hydrochloric acid of the gastric juice, and a few hyaline casts in the urine. Otherwise, nothing noteworthy. She appears to be greatly depressed and anxious; she is restless and agitated, expresses ideas of self-accusation, and has absurd somato-psychic delusions, fear of torture, and a desire to be put to death; she talks a great deal, showing stereotypy in her intonation, phraseology, and gestures. She resists everything that is done for her, refuses food, and has to be tube-fed. During the visits of her husband and other relatives, she behaves in the same manner, remaining entirely unaffected by their presence; she has also grown filthy in her habits, collects rubbish, garbage, and fecal matter in her pockets, and is very negligent about her person. From her remarks, demeanor, and answers to questions, it is evident that she is well oriented in regard to time, place, and personality, and has an accurate grasp on the surroundings and a good memory for recent and remote occurrences. She has no insight into her mental condition, believes herself to be as sound mentally as she has ever been, but in spite of this she has never made any request to be discharged from the institution. She is sleepless, and often even large doses of hypnotics fail to produce any effect. She is profoundly restless and clamorous. Almost constantly she screams, in a hoarse, raucous voice and supplicating tone, to have the obstruction which she maintains is in the throat removed. She clutches the throat with one hand, pounds upon the door or floor with the other, and screams rhythmically. The following is a stenographic record of her spontaneous utterances: "I tell you I am perfectly sane, it is no delusion, everything I have taken for the past year and a half is right tight here in my throat, nothing goes to my stomach. The reason my bowels move is caused by a little fluid pushing down into my stomach. Come here, quick, quick, quick, Dr. Taddiken, what I say about myself is so. Oh, Dr. Taddiken, Miss Rock (the nurse), have mercy on me, and put me out of my terrible agony. I am a creature cursed by God. I tell you it can't go on another second, you will have to burn my body at once. Dicky, dicky, dock, slack, quack, quack, quack (an articulate sound, as if a great effort was being made to clear the throat). Dr. Taddiken, I tell you I haven't a breath. If you put your hand to my lips, you will find very little breath. I tell you, you have to burn my rotten body at once. I will never die, my body is all decayed, caused by all the food in my throat. I am the biggest devil and torment in the world." Each of these sentences interspersed with gasping, panting respiration, and frequent hawking expirations. "Miss Rock, you think I do this to annoy you, by banging doors and following you, but I tell you, you have got to get it out at once. I tell you it can't be a sheet, it must be a fire. All the strawberries, tons of candies, thousands of slices of bread, fruit, gallons of milk, tea, soup, and coffee, all the cereals, vegetables, peaches, apples, plums, pears, all the chocolate creams, and all my husband brought me, all I have taken that did not belong to me, is right, tight, tight in my throat. Oh, my God, Miss Rock, look at all the flies gathering on me on account of this food in my throat. Look at the veins in my hands and arms, all bloated on account of that food. Joe, Joe, Joe, dicky, dicky, dicky, oh, oh, oh, my voice is gone, my voice is gone, my voice is gone (each repetition pitched in a higher key). This may seem like the ravings of a crazy woman, but I tell you I am perfectly sane. I tell you it is the Gospel truth, no ten men ever put into their stomach what I put into my throat. Hear, my voice is gone, my teeth are tight, tight together. Quick, fire, fire, fire, Miss Rock, quick, quick, for the love of God. I tell you it can't go on another second. My God, have mercy on me. If the doctor puts that tube in my nose he will find it can't go down. I am a perfect fool to put all that food in and waste it, as it can't go to my stomach. I have known my terrible fate from the first, and I tell you it's got to be fire, fire, fire. Oh, tell Miss Rock to come here quick, quick, she has got to do it at once, she has got to put my body in that fire at once. Oh, doctor, come here quick, all the food I have taken for the past year and a half is tight, tight in my throat." This, freely interspersed with vain supplications for relief, and raucous, almost rhythmical, cries of distress, conveys an adequate idea of the picture she presented. It is worthy of note that, despite her clamorousness by way of shrieks and words, there was remarkably little show of emotion in any other way.

Later, it is noted that her apparent depression and seemingly extreme anxiety, on close study was thought to be superficial, her talk of the most horrible tortures being sometimes interpolated with commonplace remarks about occurrences in the surroundings, thus: "Oh, you have got to burn my body at once, I cannot stand it another minute, dicky, dicky, dock, Miss Rock, you would not like to have me tell the doctor that you are reading a novel while you are supposed to be on duty (this in a very detached way, like a loud "aside"); oh, the horrible tortures," etc.

She developed pulmonary tuberculosis, and died two years after admission to the hospital, the mental condition having remained unchanged.

A sufficient number of cases have been cited to show (1) the very great variation in onset, delineation, and course that melancholia may present, and (2) the difficulties that beset the attempt to put these cases in one of two groups: Manic-depressive insanity and involution melancholia. I have purposely restrained from discussing cases in which depression of spirits, feeling of unworthiness, morbid subjectivity, mild anxiety states, and concernment in relation both to self and others, are symptoms of sufficient importance to the possessor to lead him to consult a physician. Neurologists see many of the cases, and have much difficulty in deciding whether they shall be called neurasthenia, hypochondria, or melancholy depression. Some of these patients eventually become insane (using the term now in its legal sense), but I believe the vast majority of them do not, nor is their mental capacity so interfered with that they have to give over attention to their business. These cases do not come within the scope of the present discussion. That some of these develop involution melancholia, there is no doubt, that occasionally manic-depressive insanity is heralded by such symptoms is likewise true, but that the great majority of them do not become insane, cannot, I think, be gainsaid. Whether or not there is such a disease as acute melancholia is of the greater importance because it carries with it the matter of prognosis. The outlook in manic-depressive insanity and in involution melancholia, there is no doubt, that occasionally diagnosis of either one carries with it a serious prognosis. Not so the cases I have in mind, and that I describe in the first three histories. The prognosis in them is very favorable.

A Nonagenarian Physician.—Dr. Woods, of Birr, in Ireland, probably enjoys the distinction of being the oldest medical man in active practice. He is ninety years of age and makes his professional rounds on a bicycle.—*London Globe.*

REPORT OF A CASE OF PRIMARY LUPUS VULGARIS OF THE OROPHARYNX AND NASOPHARYNX TREATED BY X-RAYS.*

By H. S. BIRKETT, M.D.
MONTREAL.

PROFESSOR OF RHINOLOGY AND LARYNGOLOGY, MCGILL UNIVERSITY, RHINOLOGIST AND LARYNGOLOGIST, ROYAL VICTORIA HOSPITAL.

Primary lupus vulgaris of the pharynx and nasopharynx is sufficiently rare to warrant one placing another such case on record, but especially when the means of treatment are new and the results obtained satisfactory.

The following is a brief outline of the patient's history: L. T., a lad aged 15, consulted me at the Nose and Throat Department of the Royal Victoria Hospital, in November, 1902. He complained, at that time, only of difficult nasal respiration, which condition has existed, as far as he knew, for three or four months, but has become especially marked within the past two weeks. The lad is robust looking, and apparently in good health; his intelligence, however, seems rather below the average. He has always lived on a farm, and been accustomed to outdoor life. His health, from infancy up to the time of the onset of his present illness, has always been good. Regarding the family history, one brother and three paternal uncles have died of pulmonary tuberculosis. One striking feature in connection with this case is that the patient occupied the room in which his brother died of tuberculosis.

The lymphatic glands in the anterior triangles of the neck are felt to be distinctly enlarged. Examination of the heart and lungs reveals absolutely nothing abnormal, and there is no evidence nor history of either inherited or acquired syphilis.

Oropharynx.—Careful examination of this region shows two distinct growths, each situated on the lateral and partly on the posterior walls of the pharynx. The growths are distinctly nodular in appearance, each nodule being about the size of a swollen sago-grain, quite separate and distinct in the central portion of each mass, but merging into one another at the periphery. Their color is pale pink in the centre, but towards the periphery it becomes a darker hue. The infiltration on each side has invaded the posterior pillar to the extent of about two millimeters, and each is separated from the other by a superficial ulceration, 10 mm. wide, involving the posterior wall of the pharynx, the surface of which is covered with a very tenacious, yellowish-colored secretion. The structures anterior to the growths, namely, the tonsils and anterior pillars, are not in the least involved in this process. The uvula, on its palatal surface, apparently seems normal. (See figure.)

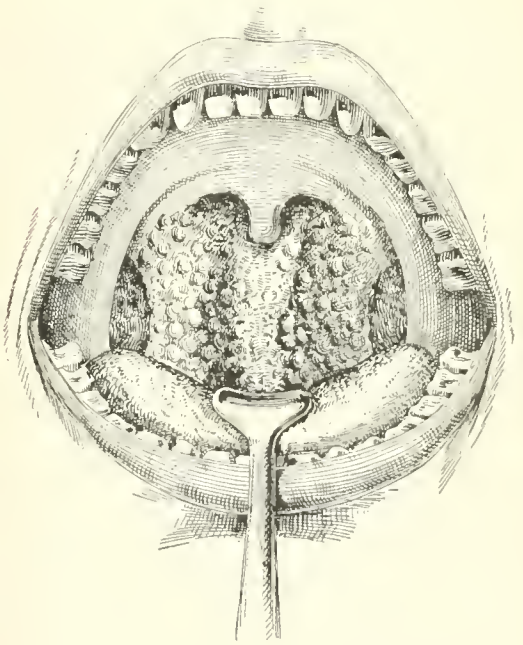
Nasopharynx.—When one examines the nasopharynx, by means of the mirror, it is ascertained that these infiltrations extend directly from their position in the oropharynx, involving the salpingopharyngeal folds, upward to the cushion of each Eustachian tube, and from here towards the center of the nasopharynx along its roof. The infiltrations, however, in the nasopharynx leave a space of about half an inch in the vault which is not involved, and are much paler in color than those seen in the oropharynx. Careful examination reveals the fact that there is absolutely no extension from here into the posterior nares.

The pharyngeal aspect of the uvula shows two distinct nodular infiltrations, each about the size of a lentil, the mucous membrane covering these being quite intact.

*Read before the Twenty-sixth Annual Meeting of the American Laryngological Association, Atlantic City, N. J., June 2, 1904.

The condition as seen at this time in the oropharynx is well delineated in the accompanying illustration.

Under ether, and by means of cutting forceps, I removed the greater portion of the masses involving the lateral walls of the oropharynx. This gave considerable relief to the difficulty in breathing, and the removed portions were sent to the pathological laboratory for examination. Dr. Keenan, who kindly undertook this work, has sent me the following report: "Sections show the specimen to consist of mucous membrane and submucous fibrous tissue. In the submucous tissue there are numerous tubercles. These consist of a central portion of young fibrous tissue with numerous typical tuberculous giant cells, and an outer part showing a small round-celled infiltration. The mucous membrane is absent in part where the tubercles have come to the surface. Tubercle bacilli are present, but few in number. Diagnosis: Tuberculosis of the Mucous Membrane. A guinea pig, inoculated in the peritoneal cavity with portions of the tissue, died in three days from septicæmia. A second one, inoculated with tissue inserted into the groin, was found at the end of ten weeks to have general glandular tuberculosis."



Further investigation of this case was now carried out, and the patient received three milligrammes of tuberculin (Koch), and the temperature, which previously was normal, now showed a definite and typical reaction to its use, rising to 101° within twelve hours, and falling practically to normal within thirty-six hours, and the affected regions showed a marked hyperæmia.

The local treatment, which was carried out subsequent to the removal of the masses under ether, consisted of curetting the infiltrated areas, and subsequently rubbing in pure lactic acid in glycerin. As this gave no encouraging results, the galvanocautery was tried with anything but satisfactory results. At this time, (January, 1903), the patient asked to be allowed to return home, which he did, and remained away until April of the same year.

Upon his return to hospital it was found, on examination, that the local conditions were practically unchanged. I now decided to try what the application of the Roentgen rays would do for this patient, and under Professor Girdwood's care the treatment was kindly undertaken and supervised. The detail

of this treatment, as carried out, is described as follows:

"The patient was treated with a Heinze regulating tube with a vacuum equal to a three-inch spark gap, which was supplied from an 18-inch coil, operated by a Heinze electrolytic interrupter. The apparatus is supplied with a direct current of 110 volts, and requires from 2 to 3 amperes. The tube was placed ten inches from the patient; treatment was begun on April 18, 1903, with ten-minute exposures and without any protection to the healthy tissues for ten treatments, when it was found necessary to stop, owing to inflammation of the surrounding parts. Treatment was suspended for three weeks, and recommenced on May 19. Since that time he has had twenty-three treatments, which have been daily. In these last treatments the face was protected by a piece of wood, which had been painted with eleven coats of white lead on each side, which was sufficient to shut out all unnecessary *x*-rays. This wood is about 12 in. x 12 in., and has a hole in the center about three inches in diameter. The patient opened his mouth as widely as possible and held the screen close to his face, and in such a position as to let the *x*-rays, which pass through the hole in the screen, strike directly on the back of the throat."

In the month of July the patient was operated upon by Dr. Garrow, who removed the enlarged cervical glands from the right anterior triangle of the neck. Unfortunately, through accident, the glands were lost before an examination could be made. After recovery from this operation the *x*-ray treatment was renewed, and at the end of July the local conditions in the throat had entirely disappeared.

The patient returned home and remained there until last November. At this time the condition of the pharynx and nasopharynx had remained so satisfactory that I regarded the patient practically as cured, and presented him before the Montreal Medico-Chirurgical Society.

I did not see the patient again until February of the present year, when upon his return I found that the disease was again showing itself by a small ulcer, a centimeter in diameter, situated in the left nostril, and involving the anterior part of the cartilaginous portion of the septum. The pharyngeal surface of the uvula, when examined, was seen to be infiltrated at its base by three small tubercles; the nasopharynx and oropharynx otherwise remaining in a healthy condition. I wish here especially to emphasize the fact that there is absolutely no extension of the disease from the nasopharynx into either nostril, and that the involvement of the cartilaginous portion of the septum seems to be separate and distinct; this being in contradistinction to the experience of most observers, that when the nose becomes involved it is always an extension forward of the disease from the nasopharynx.

The new site of invasion, as well as the oropharynx, was exposed to the action of the *x*-rays in the manner previously described. The results are, at the present time, most satisfactory, and I think there is every reason to believe that the condition will give way entirely to this method of treatment as it did on the former occasion.

It is only within recent years that lupus, as a distinct pathological condition of the mucous membrane of the respiratory tract, has been duly recognized, and this is largely through the efforts of Demme, Koch, v. Ziemssen, Rubenstein, Lange, and many others. What is necessary in all cases of this nature is to establish the circle of evidence, namely, the presence of the tubercle bacilli; definite results from inoculation; and, I think one may say, the reaction from the use of tuberculin. In the present case the tubercle bacilli were found, though, as usually is the case, few in number, and then only after very painstaking search. Again, inoculation of the material removed from the oro- and nasopharynx into the guinea pig produced a definite tuberculous condition of the lymphatic glands. Tuberculin also gave a very typical and definite reaction, not only generally but locally.

Lupus of the respiratory tract associated with skin lesions of a similar nature is not uncommon, in fact, were all cases of skin lupus examined regarding the condition of these organs it would be found that they are involved more frequently than is generally supposed. That an examination is not made as a matter of routine is accounted for by the fact that lesions of this nature, involving the respiratory tract, produce practically no symptoms in the early stages of the disease. This was well exemplified in a case of lupus of the nose, without any skin affection, which was quite recently referred to me by Prof. Girdwood; following out the usual routine examination, I found the epiglottis very extensively involved, but of this the patient herself was not at all conscious.

It is not necessary here to go over the ground regarding the part which age and sex play in this disease, or of enumerating the symptoms produced depending upon the region involved, because these points are well known and ably described in most articles upon this subject, but for those who further desire to obtain a very extensive knowledge of this subject, I would refer to the scholarly article upon these points by Mygind, as detailed in the *Archiv für Laryngologie,* Bd. 10 and 13. The question, however, which interests us mostly, is that of treatment. On reviewing the literature of the subject one finds that lactic acid, iodine solution, corrosive sublimate, permanganate of potassium, and the application of the galvanocautery, have all had their advocates with more or less varying results. It remained, however, for Eduard Schiff, of Vienna, to first treat and cure cases of lupus of the mucous membrane of the respiratory tract. In a recent communication, published in the *British Medical Journal,* May 5, 1900, he gives a detailed account of the method adopted by him with the results obtained in some of his cases.

Watson-Williams, in his recent work on "Diseases of the Upper Respiratory Tract," stated that the use of the *x*-ray as a procedure, "is worthy of trial." Beyond this work, just enumerated, I have been unable to find any further references to this method of treatment, as applied especially to lupus when attacking the oropharynx and nasopharynx; even Christiansen, in his recent paper published in October, 1903, makes reference to the use of the Finsen light as applicable only in cases where it can be directly applied.

It will be interesting to learn of the further results which may possibly be obtained through the application of the Roentgen rays to lupus when occurring in the pharynx and nasopharynx. I would here state that the patient referred to in this paper as suffering from lupus of the nose with involvement of the epiglottis, has also been placed under treatment by *x*-rays, and although too early yet to look for definite results, the progress already made has been so encouraging as to hope for a perfectly satisfactory result.

I wish here to express my indebtedness to my former house surgeons, Drs. Hannaford McKee, Newbold Jones, and McKechnie, for their careful

notes of the case, and to Dr. Roddick Byers for the accompanying sketch.

252 MOUNTAIN STREET.

INFANT FEEDING.

BY M. J. SYNNOTT, M.D.
MONTCLAIR, N. J.
ATTENDING PHYSICIAN TO ST. VINCENT'S FOUNDLING HOSPITAL.

THE proper feeding of infants is now a fairly exact science. Nevertheless, there are many instances where the judgment of the physician is severely taxed, and much depends upon its proper exercise. Innumerable lives have been needlessly sacrificed by failure on the part of the family doctor to recognize or remember certain factors in the régime of the young infant.

The days of experimental feeding, when mother or nurse was accustomed to try, seriatim, the various proprietary foods, until by chance a suitable one was found—if, indeed, the unfortunate infant survived this period, with its days and nights of torturing colic—are now fortunately relegated to the past. The present rule among the intelligent class of patients is to consult the physician promptly, and to place on his shoulders the responsibility of success or failure.

Attention to minute details is important, if we hope for success in infant feeding. The physician called upon to treat a young baby, where it is manifest that there is something radically wrong, should not be satisfied with a single visit or prescription. The case must be gone into thoroughly and scientifically, the cause of the trouble searched for until found, and the child kept under observation until there is no doubt that it is on the right track to the proper assimilation of its food. Otherwise the little patient is taken from one physician to another, or various experiments in feeding resorted to at the suggestion of relatives and friends, until it finally succumbs to athrepsia, or the starvation of inanition.

Such infants as are fed on their natural food, the mother's milk, need occupy but little of our time. There are, however, a few considerations, worthy of attention, applicable to even this fortunate class. Colic is a not infrequent source of trouble among the breast fed. It is usually due to over-feeding, or to too frequent nursing. The first thought of the average mother, if her baby cries, is that it is suffering from hunger, and if the proffered breast is accepted, this conviction becomes more positive. She does not stop to consider that the crying may be due to the discomfort of an already over-distended stomach. Crying soon after nursing, an abdomen distended with gas, and frequent stools containing ocular evidence of imperfect digestion, together with the mother's admission of improper feeding, make the diagnosis in such cases easy. If the parent possesses the average amount of intelligence, a little educational work on the physician's part is all that is required. It is well to begin the new régime with a dose of castor oil, in order to remove from the child's intestinal tract the products of past over-indulgence.

Sometimes we meet with cases of colic, with bad stools and other evidences of indigestion, although the mother observes carefully all our rules of hygiene. In such cases the question of weaning must be considered. Usually the fault lies in some defect of the breast milk. Many such cases can be corrected by careful investigation. Dr. Holt has devised a simple and inexpensive apparatus for examining human milk, and by means of this the physician can readily determine any marked deviation from the normal.

When the breast milk is found to be defective the first indication is to endeavor to restore it to the normal, by proper regulation of the mother's diet and mode of living. If our examination shows the milk to be too rich in fat she must be instructed to take more out-of-door exercise, to avoid alcoholic drinks, to reduce the amount of nitrogenous food in her diet, and to eat moderately.

When the milk is scanty and of poor quality the mother is usually found to be careworn and anæmic,

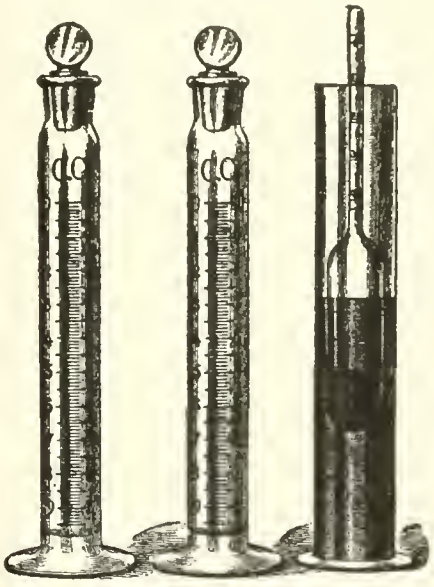

FIG. 1. Holt's Apparatus for Testing Human Milk.

very often overworked, and with vitality lowered by too frequent child-bearing. In such cases rest is, of course, indicated, with tonics and fresh air. The diet must be nutritious, and should include plenty of meat, vegetables, cereals, and fruit. Iron and malt may be given freely. Massage to the breasts with boracic acid ointment is often of advantage. Excessive nervousness on the part of the mother may be allayed by securing for her uninterrupted rest at night. This can be done by giving the baby a bottle at night, and having it sleep in another room. A milk supply deficient only in quantity may quickly be brought to the normal in this particular, by simply increasing the amount of fluids in the mother's diet, especially milk, and gruels made with milk. When, however, the quantity of milk secreted is normal or even abundant in quantity, but the quality poor, as indicated by low specific gravity and fat, very little can be accomplished by dieting, and weaning must be resorted to.

We occasionally meet with cases in which the breast milk plainly disagrees with the child, even though our examination shows it to be normal in every respect, and the mother strong and well. Some neuropsychological influence may be at work here, and if the child fails to gain in weight for a

considerable period, it must be weaned before its nutrition has been impaired.

The return of the menstrual periods to the nursing mother is not necessarily an indication for weaning the baby. Many, I might almost say most, babies, are in no way affected by this physiological process. Where, however, pronounced digestive disturbances in the infant mark the onset of the catemenia in the mother each month, and the child is seriously upset, weaning must be resorted to.

Pregnancy is usually a plain indication for weaning. Almost at once the infant will cease to gain in weight, and will show symptoms of indigestion. Every healthy infant should show a weekly gain in weight of about four ounces, and the mother should be instructed to weigh her baby regularly and to record it in a proper manner. She should be told to report promptly any failure to gain to the physician, so that he may advise her as to the cause and the remedy.

To summarize, the indications for weaning are: (1) failure to gain weight, or actual loss of weight, (2) a milk supply so deficient in quality or quantity as to be beyond control, (3) unconquerable colic and evidences of imperfect intestinal digestion, plainly manifested in the stools; (4) consideration for the mother's health, when it is clear that the strain of nursing is too much for her constitution. The decision whether or not baby is to be weaned is a serious one, and is to be reached only after careful deliberation. Having once decided, however, that the step is necessary, the physician must assume the responsibility and proceed resolutely, *Suaviter in modo, fortiter in re.*

This brings us to the subject of artificial feeding. The simplest plan of furnishing a substitute for the mother's milk is to provide a wet nurse, but a good wet nurse is hard to find. She is at the best an expensive luxury. Her character, habits, past history, constitution must be investigated thoroughly, for we must consider not only the food supply, but her moral and psycological influence over the child as well. Once secured, there is the danger ever present that she will leave suddenly. Higher wages, elsewhere, may tempt her, or her own baby—entrusted to some poor relative and fed on condensed milk—may take suddenly ill and call her away. To provide against such a contingency, where a wet nurse is employed and found to be satisfactory, her milk should be examined from time to time, and its proportions of fat, sugar, and proteids accurately determined. In the event of her leaving, we are then prepared to provide a proper substitute promptly and intelligently. Personally, I have seldom found it necessary to resort to this expedient of employing a wet nurse, except in a few instances where my directions as to milk modification were not carefully followed, or where I was hampered by overzealous relatives, or the mother's desire to experiment on her own account.

In proceeding with our substitute feeding, the mother must be instructed at the outset in the rudimentary principles of asepsis, bacteriology and sterilization, so that she may understand the importance of cleanliness as applied to her baby's food, and give intelligent care to the preservation of the milk, and the condition of bottles, nipples and cooking utensils. She should be told, first of all, to select a good milkman, and the physician should, if necessary, assist her in making a proper choice. The dairy should be visited, and its surroundings inspected to make sure of proper hygiene as applied to the care of the milk.

A dairy of moderate size has certain advantages, it seems to me, over the large stock corporations of milk producers. It is under the direct supervision of the proprietor, who is familiar with every detail in its management. He knows the condition of each cow in his herd, and when sickness occurs, or one of the animals is "off her feed," or acts suspiciously, he is aware of it at once and will not allow this cow's milk to be mixed with his dairy's output. In the large dairy, on the other hand, the details of the management are necessarily left to subordinates, responsibility is divided, and thus grave irregularities are often overlooked for considerable periods. In proof of this, we might cite numerous instances, but it is sufficient to recall the fact that two serious epidemics, one of scarlet fever, the other of diphtheria, have occurred in this vicinity in recent years, and were directly traced to an infected milk supply from a large and well known dairy. In each case the infection occurred in a manner which would have been very improbable in a smaller dairy, run under the direct supervision of an intelligent and conscientious proprietor.

The milk selected for our babies must be furnished in quart bottles, and with "gravity" cream. Some of the large milk corporations supply "centrifugal" cream on their milk. In other words, the milk is put through a centrifugal machine and separated. The bottles are then filled to a certain level with milk, and this in turn is topped off with cream. In this way a milk supply is provided in which the daily percentage of fat does not vary, but it is objectionable as a food for the young infant for manifest reasons.

The source of our milk supply having been settled, the mother must be impressed with the im portance of preserving the milk at a temperature sufficiently low to prevent bacterial growth in it, with the harmful chemical changes produced thereby. In most communities the milkman makes his rounds very early in the morning, and it often happens in the summer season that the milk is left standing in the hot sun for several hours before the household is astir. Careless domestics also frequently allow the milk to remain in the kitchen atmosphere long enough for it to become warm, and therefore unsafe for baby's use.

Sterilization or pasteurization is unnecessary except in very hot weather, or where we have reason to doubt the milk supply itself, or the mother's ability to give it intelligent care. Pasteurization, if accurately done, is preferable because it does not affect the digestibility of the milk. In certain diarrhœal disorders of the summer season, however, sterilization is of advantage. Where Pasteurization is resorted to, the apparatus devised by Dr. Freeman, and which is too well known to need any description, is simple, accurate, and inexpensive. After either process, rapid cooling of the milk is of great importance, because if allowed to cool slowly, such spores as remain undestroyed, take on new life in the warm milk, and fresh colonies of bacteria develop rapidly.

If the baby is in good physical condition when the physician is called upon to take charge of it, his task is much simplified. But if the mother has delayed calling upon professional advice until the child's nutrition has been seriously impaired, and symptoms of gastroenteritis have appeared, the selection of a proper food under these conditions, becomes more complicated. A healthy, well nourished child will digest and thrive on almost any simple modification of cow's milk. The formulæ of Dr. Holt are simple, uncomplicated and scientific, and suitable to almost every ordinary case. It is well, in starting a young baby on cow's milk to begin with a weak proteid mixture, and increase this slowly. The fat and sugar, unless very excessive, seldom give us

any trouble, but the casein in cow's milk not infrequently causes more or less indigestion when first given the young infant.

One of the simplest devices on the market for modifying cow's milk, on the Holt system, is the so-called "Sloane Maternity Milk Set," made by J. T. Dougherty, New York City.

FIG. 2. Sloane Maternity Milk Set.

By this device the sugar percentage, the alkalinity, fat, and proteids are varied easily and accurately from day to day to suit the condition of the infant.

In delicate infants, or in those who have had their digestive organs already disturbed by improper feeding before the physician is asked for advice, other modifications must be tried. Peptonized milk may be used in our Holt formulæ to advantage in some cases, where vomiting and symptoms of proteid indigestion are present.

Milk modified by peptogenic milk powder is well adapted for many cases. It gives a food very similar to breast milk, and is partly predigested. Furthermore, food prepared with it must be sterilized, and this makes it of value in certain forms of diarrhœa, and in hot weather. It is well in beginning to use it, to dilute the milk much more freely than the directions given by the manufacturers of the preparation call for.

There are infants occasionally met with who apparently cannot digest milk as such in any modification. Even a minute quantity disturbs them, vomiting ensues, curds appear in the stools, and fever soon follows. The child does not thrive and loses weight rapidly if the attempt to continue milk feeding is persisted in. These cases are usually babies who have gotten into this condition as the result of some acute illness or of a progressive decline due to prolonged improper feeding. Some substitute must be found them. Gruel, made from barley, oatmeal, or rice, dextrinized, and sweetened with sugar of milk, is of service here as a temporary food. It must not be kept up indefinitely, however, or the child's nutrition will suffer. When the stools have become more normal in character, and are free from curds, the gruel may be supplemented with whey made from fresh milk by the addition of essence of pepsin. Mutton broth and beef juice are useful also, as aids in increasing the percentage of proteids in the diet. Older children are often benefited by egg albumin, but young babies do not digest it well, and when it is given, additional discomfort is usually the result. Milk should not be resumed for a long time, in these cases, and then it is to be given experimentally and in very minute quantities. If it is digested well, it can be increased in amount, but very slowly. It not infrequently happens that several months must be tided over with some other diet, before this time is reached. Cases of this kind are the most difficult ones we have to treat.

If the proprietary foods are used at all, they must be resorted to logically and with a knowledge of their composition. Much harm has been done by them, when they have been given haphazard, and many cases of rickets and scurvy are directly due to their prolonged administration. They are all excessively rich in carbohydrates and deficient in fat. The proteids are deficient in amount and chiefly vegetable. Hence they are unsuited to sustain life without the addition of milk. They all contain more or less of unchanged starch. After the ninth month they may be used to advantage as an adjuvant to the cow's milk, when we wish to increase the amount of carbohydrates in the diet. For younger infants they possess no advantage over the less expensive cereal gruels already referred to.

The essentials for success, it will readily be seen, in the feeding of infants, are, patience on the part of the physician, together with intelligent judgment, the unquestioning confidence of the parents, and careful nursing. When these conditions are present, failures will be few, and even many of the most desperate cases may be saved to robust manhood and womanhood.

PARAPHIMOSIS IN A YOUNG GIRL.

By M. I BEEMAN, M.B.,

NEWBURGH, ONT.

I CAN find no report of a case like the following, and therefore think it may be worthy of record.

A few days ago I was called to see a girl of 13 years, on account of "something growing out of her vagina." In the region of the clitoris there was an œdematous protrusion of the diameter of half an inch, in the center of which was a round lump slightly darker in color of the size of a small pea.

The appearance of the tumor reminded me of the frequent cases of paraphimosis in boys, with the glans penis showing in the midst of the œdematous prepuce, only in this case it was in miniature.

The whole growth was very tender and painful, and careful inspection showed the ends of several long hairs which, with the aid of dressing forceps, were unwound from about the growth. Recovery speedily followed.

It seems that the patient had doubled a wisp of hair from her head and used it to tickle the clitoris, and in doing so had lassoed the organ in such a way as to cause the resulting swelling.

Antistreptococcus Serum in Erysipelas.—Giovanni Grizoni believes that the most rational treatment for erysipelas is serotherapy. The failures in this treatment are due to the technique used in the preparation of the serum used. The streptococci, producing different cases of inflammation, seem to differ in species, so that it is necessary to use a serum prepared from a case of the same type to get the desired effect, or to make one by inoculation of several species of streptococci. The use of the serum too late or in insufficient doses may account for some failures. In a very severe case of infection observed by the author the use of serum had a really marvelous effect. The patient was affected first by tonsillitis, then by erysipelas of the face, extending to the neck and scalp, then by purulent otitis media. Meningitic symptoms came on rapidly, and the patient was in coma and almost moribund when the first serum injection was given. In all four injections were made, and the improvement was immediate and rapid, ending in complete recovery. The short duration of incubation and rapid diffusion showed the gravity of the infection.—*Giornale Medico del Regio Esercito.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, December 24, 1904.

ARTERIAL SCLEROSIS.

IT is a trite saying that an individual is as old as his arteries, for the continuity of life and the maintenance of health depend, among other things, upon the proper distribution to all of the tissues of blood in sufficient amount and of normal constitution. Of course, consideration must be given also to the inherent vitality and the regenerative powers of the various cellular structures of the body. A full supply of good blood will not, however, change a defective type of cell; while on the other hand, even a perfect cell must eventually suffer in consequence of a supply of blood insufficient in quantity or improper in constitution. Therefore, apart from mere inherited qualities, the nature of which is as yet entirely unknown, the normal performance of function is dependent as an essential factor upon the blood-supply. During early life it may be conceived that constructive preponderate over destructive processes, while at a later period the two counterbalance each other, and finally, in old age, the latter predominate over the former.

There has been a good deal of earnest investigation into the process of arterial degeneration and into the causes underlying it, and it is commonly believed that, as in other structures, the principal factor resides in the blood-supply. A somewhat divergent and novel view is held by Dr. Thomas D. Savill (*Lancet*, September 24, 1904), who attaches the greatest importance in this connection to the muscular coat of the arteries, and more especially to a condition of hypertrophy of this coat, which he maintains is a common cause of increased arterial tension and one of the forerunners of arterial sclerosis, for which it is often mistaken. This view is based on observations covering a period of seventeen years, and dealing with nearly five hundred autopsies on persons sixty years of age and upward, many of whom presented circulatory symptoms during life, and some of whom died from old age.

Dr. Savill defines arteriosclerosis as a chronic generalized thickening, condensation, or degeneration of the walls of the arteries of the body, as a result of which, after death, the lumen does not collapse, as usual, and the walls are harder and less elastic than normal. In accordance with the localization of the morbid process in the coats of the vessels, three varieties of sclerosis may be recognized, namely, intimal, medial, and adventitial. Sclerosis of the intima is to be distinguished from atheroma, which is a patchy fibroplastic infiltration of the intima, while sclerosis is more generalized. Atheroma, in turn, is likely to be confounded histologically with obliterative endarteritis of syphilitic and other origin, which occurs for the most part in younger subjects. Some atheroma can always be found in the bodies of persons sixty years of age and upward, who have died without circulatory symptoms or accident of any kind. In the opinion of Dr. Savill, atheroma is of no serious pathological importance, provided the cardiovascular system is otherwise fairly healthy. The evil results sometimes attributed to atheroma, in the brain for instance, can often be accounted for by the yielding of the vessel-wall between the patches of degeneration and the resulting kinking of the artery.

In many instances it could be legitimately inferred that chronic adventitial and intimal sclerosis of the larger and medium-sized vessels was secondary in both time and importance to changes in the media or to dilatation of the arterial lumen. A distinction is to be made between intimal sclerosis in the peripheral (microscopic) arterioles, and the same condition in the medium-sized and larger arteries. The process appears to be different etiologically in the two situations, as it is also in its effect; in the former, at times it causes obstruction over large areas of the peripheral circulation, while in the latter it is mainly supporting, compensatory, and protective. The existence of intimal sclerosis in the arterioles of the kidneys does not necessarily establish its existence in other peripheral arterioles. The kidneys constitute only a small part of the whole peripheral circulation, of which the voluntary muscular system constitutes a large part.

Histologically, physiologically, and pathologically, the muscular coat of the arteries is much more important than the intima and adventitia, as it also is the thickest in the arterioles and all but the largest arteries. It constitutes the functionally active part of the entire arterial system, controlling the circulation as a whole, as well as the quantity of blood in the various areas and organs, while the intima serves as a limiting membrane and the adventitia as a supporting structure of connective tissue. The media thus forms the parenchyma, or proper tissue of the arterial system, and its imperfections affect directly or indirectly the nutrition and oxygenation of all of the organs and tissues of the body, and disturb not only the equilibrium between the different systems of the body, but also that between the heart and arteries, on which the life and health of the individual depend. The regulator functions of the arteries are also of vital importance not only to the vascular areas they supply, but likewise to the power of adaptability to the different positions of the body that is indispensable to the dynamic equilibrium of different parts of the peripheral circulation. According to the older view, old age was looked upon as a loss of balance of functions, but, according to Dr. Savill, the most important factor of incipient old age is loss of the regulator function of the arteries.

Extensive valvular disease of the heart or disease of the endocardium may exist without inconvenience, and also fat may be deposited outside the heart, and fibrosis amounting even to obliteration of the pericardial cavity may exist without seriously impairing the activity of the central organ of the circulation so long as the muscular wall remains healthy. So, too, extensive patchy atheroma, and even generalized intimal and adventitial sclerosis are quite con-

sistent with extreme longevity and with total absence of circulatory symptoms, accidents, or complications, providing the media be relatively free from hypertrophy or disease, and the balance between the heart and the arteries be not disturbed, while moderate generalized disease of the muscular coat is a serious potential evil. Thus a slight and hardly measurable increase in the muscular coat, distributed over the entire arterial system, must exert a considerable influence on the dynamics of the circulation and on the nutrition of the body generally.

The muscular coat of the arteries may undergo atrophy, hypertrophy, cloudiness, granular degeneration, necrosis, or calcification. The first four are probably due to nutritional, dynamic, and toxæmic causes, and are therefore more or less generalized in distribution, though often predominating in some vascular area, especially in the lower extremities; while the last two may be due to traumatism, or the blocking of the capillary area of the vasa vasorum, and are generally localized and limited. The former primarily disturb the dynamics of the circulation and the nutrition, for example, the elasticity and contractility of the vessels and the cardiovascular balance, while the latter lead to rupture and hemorrhage.

The term arterial hypermyotrophy is used by Dr. Savill to describe an increase in the thickness of the muscular tissue of the arteries, due to an increase in volume or number or both of the individual muscle-fibers. The condition is characterized clinically in the first stage mainly by vertigo on change of posture and other symptoms of high and unregulated blood-pressure; in the second stage by the evident thickening of the arteries, cardiac hypertrophy, and sometimes by hemorrhages into the brain and other structures; and in the final stages, by various circulatory and nutritional disturbances. Sometimes, though not necessarily, it is associated with chronic disease of the kidneys, which is one among many of its causative factors, and it constitutes in itself one of the main pathological conditions on which hemorrhages into the brain and other structures, as well as the incipient phenomena of senile decay, depend. Among other causes of arterial hypermyotrophy are hypertrophy of the heart and high arterial tension; and the consequences are mainly the same as those of increased arterial tension, namely, hypertrophy of the heart and subsequent degeneration of the cardiovascular system. The clinical phenomena consist principally in progressive asthenia, with various circulatory symptoms, and especially vertiginous sensations induced by changes in posture.

Arterial hypermyotrophy is to be differentiated especially from the changes incidental to old age, granular kidney, and arterial sclerosis, or degeneration, but it is so often associated with one or another of these conditions that the separation is at times quite impossible. In treatment the vasodilators, such as nitroglycerin, have proved of especial service in the early stages of the disorder. Finally, it is pointed out that if hypermyotrophy of the arteries, which is the first step to senile decay, could be prevented, life could be prolonged.

An Isolation Hospital for Immigrants is to be built on an artificial island in the upper bay of New York harbor, near Ellis Island.

ORGANIZATION OF THE DEPARTMENT OF HEALTH OF THE ISTHMIAN COMMISSION.

Dr. John W. Ross writes in the *Journal of the Association of Military Surgeons of the United States* on the above subject. The Isthmian Canal Commission appointed Colonel Gorgas as Chief Sanitary Officer; Dr. Ross as Director of Hospitals; Surgeon H. R. Carter, as Chief Quarantine Officer; Major La Garde as Superintendent of Ancon Hospital, and Mr. Joseph A. Le Prince as Chief Sanitary Inspector.

According to the scheme of organization, the Department of Health, with jurisdiction extending beyond the limits of the Canal Zone, is considered an administrative department of the Canal Zone Government. The affairs of the Department are administered by a Board of Health, composed of four members, namely, the Chief Sanitary Officer, the Director of Hospitals, the Chief Quarantine Officer and the Chief Sanitary Inspector of the Canal Zone. The Department of Health is divided as follows: A sub-department of hospitals, under the Director of Hospitals; a Maritime Quarantine Service; a Sanitary Service for the Canal Zone; a Panama Health Office, and a Colon Health Office.

The Ancon Hospital, although in bad repair, has a capacity of about 500 beds. A training school for nurses is to be established at Ancon Hospital, the number of student nurses being limited to 30 first year students, and to a total of 75. Colon Hospital has a capacity of 100 beds, expansible to 300 beds. A new ward building is to be added to this hospital at once. It is calculated that twenty emergency hospitals will be required along the line of the canal. Three are to be established immediately. The City Hospital of Panama contains about 150 patients. It is badly constructed and managed, but steps are being taken to remedy these defects. It is probable that an institution for lepers will soon be established. A hospital for the insane is to be built.

At first only fourteen internes, eight for Ancon Hospital and six for Colon Hospital, will be appointed. Provision has been made for forty-two trained women nurses at Ancon Hospital, fourteen at Colon Hospital, and one at each of the hospitals along the line.

The Sanitary Service of the Canal Zone is well organized. The work is in charge of a Chief Sanitary Inspector, under whom there are eight assistant inspectors. At the head of each of the health offices of Panama and Colon is a physician who will act under the direction of the Board of Health, and be in direct charge of the health and sanitary work of the city.

Taboga Island, lying in the Bay of Panama, owing to the almost total absence of mosquitos, the pure air, the abundance of pure drinking water, and the comparatively dry and invigorating atmosphere, will be utilized as a health resort for convalescents. The French erected on this island a large structure which is capable of accommodating 150 patients, but it is badly in need of repair, having suffered from the same neglect as has everything else connected with the canal during the past twelve or fifteen years. The Commission has authorized an expenditure of $6,500 to put the building in a suitable condition, after which it may, when required, be used as a sanatorium and convalescent station.

Bacteria in Grocery Milk.

Dr. N. Kruskal has recently written a pamphlet on this subject, in which some of the investigations of observers in this country and Europe are reviewed. Park and Bebb, who examined the market milk of New York at different places, and under different conditions, obtained the following results: Samples of milk from individual cows, and when all means were taken to ensure cleanliness, five hours after milking, 6,000; twenty-four hours after milking, 6,933; forty-eight hours after milking, 17,816 bacteria per c.c. From mixed milk of the entire herd under the same conditions, five hours after milking, 4,333; twenty-four hours after milking, 2,766; forty-eight hours after milking, 10,853; seventy-two hours after milking, 329,000 bacteria per c.c. Samples of milk taken in well-ventilated, fairly clean, but dusty stalls, visible dirt from udder removed at the time of milking, 15,500; after twenty-four hours, 21,666; after forty-eight hours, 57,333 bacteria per c.c. In milk taken from cans in ordinary barns, shortly after milking, 30,366 in warm weather; 16,650 in winter weather; 48,000 and 31,000, respectively, after twenty-four hours; 680,000 and 210,000, respectively, after forty-eight hours. Examinations made from milk when received at the depot contained as high as 3,520,000 and as low as 100,000 bacteria per c.c. Shop milk sold in the poorer tenement districts in midwinter contained on the average 1,977,692; in September, 13,163,600; the milk of dairy stores in the fashionable portion of the city, in midwinter, 327,500; in September, 1,061,400.

The milk of European cities has been examined by many investigators. Knochenstiern found in the market milk of Porpat in September, October, and January, in the milk purchased from milkmen, 12,200,000, in the grocery milk 30,000,000 bacteria per c.c. Clauss examined the milk of Wuerzburg, and found, in the winter months, from 1,000,000 to 2,000,000. Hohenkamp found in the milk of the same city in summer from 2,000,000 to 7,000,000. Cnopf found in the milk of Munich, five hours after milking in the winter months, from 200,000 to 6,000,000. Geuns examined the milk of Amsterdam and found in fresh milk 2,500,000, and after ten hours' standing 10,500,000. Parkes found in London's milk 3,000,000 bacteria per c.c.

Kruskal states that although the milk delivered in New York is usually forty-eight hours old before it reaches the consumer, we can still say that the milk in New York is not inferior to that of European cities, where the milk is delivered eight or ten hours after milking. In America, at least in the northern cities, there is an abundant use of ice. The milk is cooled quickly by ice and kept in refrigerating cars at a temperature not much above freezing until it is ready to be taken for final distribution. In European cities ice is too expensive, and the milk is seldom cooled by it during transit.

An Antitoxin against Fatigue.

Should the development of the study of toxins and antitoxins render possible the production of an antibody capable of neutralizing the results of muscular fatigue the consequences could hardly be predicted. Yet a German investigator seriously claims to have taken more than one step in this direction already, and publishes results that are at least surprising. Weichardt (*Münchener medizinische Wochenscrift,* November 29, 1904) says he has obtained a stable antitoxin, which, when taken by the mouth in moderate doses, permits the output of an increased amount of muscular energy without fatigue, and when taken continuously causes a sense of general *bien être* and augments the capacity for work. He commends his preparation to clinicians as a promising analeptic for convalescents, neurasthenics, etc. This fatigue antitoxin is obtained from horses by injecting them with fatigue toxin produced in the muscles of animals that have been subjected to extreme muscular exhaustion. The most rigid precautions are necessary to avoid bacterial contamination during the process of extraction, and the muscle extract, or toxin, is purified from the ordinary products of muscular activity by dialysis. It can then under certain precautions be dried and preserved for a short time, but rapidly loses its potency, in distinction to the antitoxin which may be kept indefinitely. Minute amounts of this body injected into small animals, as mice, rabbits, or guinea pigs, cause all the symptoms of fatigue, and in case the dose is sufficiently large, the substance occasions the death of the animal. Control experiments show that the extract obtained from unfatigued animals, killed without any struggling, is without physiological effect, proving that the toxin is not a product of muscular autolysis. The horse in response to injections of this toxin produces an antibody which differs from the bacterial antibodies in that it is dialysable, which perhaps accounts for its prompt absorption when introduced into the stomach. The effect of the toxin on experiment animals may be neutralized by mixing toxin and antitoxin before administration, or the animal may be protected by preliminary injections or feeding of the antitoxin. The antitoxin appears to be much more powerful than the toxin, as it requires only 1-10 mg. to neutralize 10 mg. of the fresh toxin.

The Diazo-Reaction in Other Diseases than Typhoid Fever.

Although the diazo-reaction of the urine described by Ehrlich in 1882 was at first thought to be distinctive of typhoid fever it was soon found that it occurred also in association with other disorders, while further it failed to appear in some cases of typhoid fever. Despite these facts the reaction has been shown to have a certain diagnostic and prognostic value. In a recent communication on this subject Dr. W. Taylor Cummins (*University of Pennsylvania Medical Bulletin,* September, 1904) reports the results of observations covering 436 specimens of urine from cases of typhoid fever, tuberculosis, and a number of other diseases both in children and in adults. He found, among other things, that in cases of typhoid fever the reaction is useful in differentiating between a relapse and a complication. It was further of signal assistance in separating measles from German measles, being present in the former and absent in the latter. In cases of pulmonary tuberculosis it has great prognostic significance, not appearing until late and being present usually in a rapid case. When once it appears, under such circumstances, it persists until death, the average duration of life after its appearance being about six months. The prognosis is thus unfavorable in every case of tuberculosis presenting the reaction. In a dilution of 1:40 the reaction is of some value in the diagnosis of typhoid fever, but when present with a dilution of 1:150 other conditions can be eliminated, with the exception of a small number of cases of tuberculosis, so that the test is then of considerable value.

The Plague is reported to have appeared in Russia in certain factories where fur coats are made for the troops in Manchuria.

News of the Week.

Congress of American Physicians and Surgeons.—At a meeting of the Executive Committee of the Congress of American Physicians and Surgeons, held in this city December 10, the following officers of the congress were elected: *President,* Dr. Reginald H. Fitz of Boston; *Secretary,* Dr. W. H. Carmalt of New Haven; *Treasurer,* Dr. Newton M. Shaffer of New York; *Secretary of the Executive Committee,* Dr. W. K. Simpson of New York. The executive committee is composed of one delegate from each participating association. The next congress, which will be the seventh triennial meeting, will be held in Washington, D. C., in the spring of 1907, the exact date not yet having been determined.

Fever as an Indication for Mastoid Operation.—Dr. L. Emmett Holt writes that he was incorrectly reported in the account of a discussion on "Otitis in Children," published on page 994 of the MEDICAL RECORD, the omission of a "not" making him appear to say the opposite of what he did say. He held that a continuance of high temperature after paracentesis of the drum membrane was not a sufficient indication for a mastoid operation. "So many unexplained temperatures are seen in young children that to open the mastoid for no other reason than the one given is, I believe, to do a great injury to many children."

Corresponding Members of the Munich Medical Society.—Drs. Carl Beck and Max Einhorn, of this city, have been elected corresponding members of the Aerztlicher Verein von München, an honor now for the first time conferred upon any American physicians.

The Eastern Medical Society.—At the annual election of this society, held on December 9, the following officers were chosen for 1905: *President,* Ephraim K. Browd; *Vice-Presidents,* A. Hymanson and Charles Goodman; *Treasurer,* A. Ronginsky; *Recording Secretary,* M. M. Stark; *Corresponding Secretary,* Emil Altman.

Illinois Society for the Prevention of Tuberculosis.—At a meeting of physicians, recently held at the Great Northern Hotel, Chicago, preliminary steps were taken for the organization of the Illinois Society for the Prevention of Tuberculosis. The plan is to concentrate the efforts of the State Board of Health, the Illinois Medical Society, and the Committee on Tuberculosis of the Visiting Nurses' Association of Chicago. The first work of the Society will be to secure a $250,000 appropriation for a State Sanatorium, where researches can be conducted and consumptives treated. The next step will be to establish branches. Particular attention will be devoted to out-of-door camps. Dr. George W. Webster, President of the State Board of Health, presided, and Dr. Arnold C. Klebs offered a resolution providing for the appointment of a committee of ten to draft by-laws and constitution, and to prepare a list of candidates for directors to represent all communities and interested organizations. The matter was settled by the appointment of the following organization committee: Drs. Arnold C. Klebs, William E. Quine, Charles L. Mix, J. W. Pettit, George W. Webster, N. S. Davis, Ludwig Hektoen, Frank Billings, William A. Evans, Robert H. Babcock, N. A. Graves, E. P. Bicknell, Sherman C. Kingsley, N. B. Delamater.

Milk Company's License Revoked.—Health Commissioner Darlington has revoked the license to sell milk in this city of an old-established dairy concern that supplied large quantities of milk in New York city daily. The company has several dairies, and an inspection of one of these recently showed that it was devoid of the facilities necessary for the proper care of milk. The floor was in an unsanitary condition, the drainage was improper, the wash room was used as a stable, preservatives and coloring matter were found on the premises, and skim milk was labeled as "buttermilk." The question has arisen whether the city has the legal right to send inspectors to the country dairies outside the city limits, but it is contended that the question is too serious to permit of quibbling, and for the last week inspectors have been making the rounds of the dairies in various counties in the State.

Subway Roadbed Question.—At a meeting of the Advisory Board of the Health Department, held on December 13, it was the opinion of many members of the board that the present stone roadbed is unsuitable, and that to keep the air pure a new roadway is necessary. This should be made smooth so as to permit of sweeping and thorough cleansing, which is impossible under the conditions now existing. The state of the air in the subway at present was said to be no worse than it is in crowded surface or elevated cars. The advisory board consists of Dr. Edward C. Janeway, chairman; Drs. Bates, Francis P. Kinnicutt, Abraham Jacobi, L. Emmett Holt, Henry P. Loomis, John A. McCorkle, T. Mitchell Prudden, J. Winters Brannan, and Simon Baruch.

Officers of the Society of Medical Jurisprudence.—At the one hundred and forty-ninth annual meeting of this society, held last week, the following officers were elected: *President,* Dr. Carl Beck; *Vice-President,* Mortimer C. Addoms; *Treasurer,* D. McLean Shaw; *Recording Secretary,* Charles P. Blaney, and *Corresponding Secretary,* Alfred E. Ommen.

Appointment of Dr. North.—Superintendent of Prisons Collins has promoted Dr. Charles H. North to the position of Medical Superintendent of the Dannemora State Hospital. Dr. North's predecessor in the office, Dr. R. B. Lamb, was transferred on December 1 to the Matteawan Hospital.

Commencement Exercises of the New York City Training School for Nurses.—Commissioner James H. Tully, of the Department of Charities, presented diplomas to twenty-nine nurses at the twenty-ninth commencement exercises of the New York City Training School for Nurses, on Blackwell's Island, on December 17. Brennan Hall, the new dining room, named for the late Thomas S. Brennan, was formally opened for inspection of visitors.

Report on Doyen's Serum.—Dr. Doyen has presented to the Society of Surgery a report of the committee appointed to investigate his carcinoma serum. It is written by Dr. Metchnikoff, of the Pasteur Institute, who is a member of the committee, and affirms that Dr. Doyen's alleged gem, *Micrococcus neoformans,* is habitually found in cancerous tumors, but is noncommittal in regard to the value of the serum treatment. The society appointed a new committee of five members to investigate the matter further.

Work of the Carnegie Institute.—At the annual meeting of the board of trustees of the Carnegie Institute, held at Washington on December 13, it was announced that during the year $355,070 had been expended to further research in various departments of science, and that twenty-four research assistants had received $1,000 each. The projects undertaken include the establishment of a department of experimental biology, with stations at Cold Spring Harbor, L. I., and at the Dry Tortugas, Fla.; of a department of economics and sociology; a bureau of historical research; a depart-

ment of international researches in terrestrial magnetism. Special grants were made for an archeological expedition to the trans-Caspian region, and for geophysical research. Other grants were for the encouragement of biological researches at the Marine Biological Laboratory, Wood's Hole, Mass.; also at Dr. Dorhn's laboratory at Naples; for anthropological investigation in the United States and archeological investigations in Syria, Palestine, Egypt, Nubia, etc.; for important astronomical investigations in several of the great observatories and elsewhere; for the publication of the *Index Medicus;* also for other important bibliographical work, such as the preparation of a handbook of learned societies of America, etc.; for investigation of desert vegetation; for a study of the fundamental principles of geology; for extended geological explorations in China, and for investigations in nutrition at the laboratory at Middletown, Conn.

Seney Hospital to Receive Gift.—The board of managers of the Methodist Episcopal Hospital of Brooklyn, last week announced that the $300,000 necessary to secure the gift of $125,000 from Mr. and Mrs. William Halls had been raised, and that the work of renovating and completing the buildings can now be undertaken.

Doctors Awarded Liberal Fees.—From the first account of the executors of the estate of the late William L. Elkins, of Philadelphia, it appears that the estate represents a valuation of nearly $32,000,000. Among the payments made were the following for medical attendance: Dr. Louis A. Duhring, $25,000; Dr. J. William White, $1,750; Dr. Alfred Stengel, $1,100; Dr. W. L. McCandless, $440; Dr. W. W. Keen, $150.

Clinic on Cancer of the Female Organs of Generation.—Drs. A. N. Currier and J. R. Goffe have been appointed gynecologists to the New York Skin and Cancer Hospital. They will hold a gynecological clinic at the hospital, corner of Second avenue and Nineteenth street, every Tuesday and Friday afternoon, from 2 to 4. It is requested that physicians come with their patients, or send a letter with them, in order that they may be kept informed as to the patients' condition.

The North Branch of the Philadelphia County Medical Society is now completing the fourth year of its existence, having been the pioneer "branch" in the new movement of organizing the medical profession of our American cities. The officers for 1905 are: *Chairman,* Dr. A. B. Hirsh; *Clerk,* Dr. T. T. Thomas; *Committee on Scientific Business,* Drs. W. H. Thomas, W. H. Good, and Anna M. Reynolds; *Committee on Membership,* Drs. W. H. Parke, H. B. Mills, Clara Dercum, F. C. Hammond, C. L. Felt, Rose Hirschlar, S. P. Gerhard, and Wendel Reber.

The Board of Medical Directors of the Cincinnati Hospital organized recently, elected the following officers: *President,* Dr. A. B. Isham; *Vice-President,* Dr. Louis Schwab; *Secretary,* Dr. Byron Stanton.

Dr. George B. Roessly, of Cincinnati, has been appointed district physician, to succeed Dr. H. J. Strack, deceased.

Lectures for the Laity.—The Chicago Medical Society has undertaken to deliver a series of public lectures on popular medical topics, and last week a lecture on "How to Prevent Consumption" was delivered by Dr. William E. Quine, and one by Dr. James M. Brown, entitled "Minor Accidents, Frost Bites, and Burns."

Ottawa Tent Colony.—A report has been issued by Dr. J. W. Pettit, in which he gives the results obtained by the Ottawa Tent Colony for the treatment of tuberculosis, which was established by the Illinois State Medical Society. The admissions have been 59, of which 24 were advanced cases. Of these, 6 improved, 3 are convalescent, and several are still under treatment. The incipient cases made considerable improvement from the beginning of treatment.

A New Medical School.—St. John's College, Fordham, is to take advantage of its university charter and establish medical and law departments. The dean of the medical school will be Dr. J. N. Butler, of this city, but the names of the faculty have not been announced. St. John's will hereafter be known as Fordham University.

A Tuberculosis Dispensary.—A new dispensary for the special treatment of patients afflicted with pulmonary consumption will be opened on Monday by the New York Throat, Nose, and Lung Hospital. Patients, who will be required to visit the dispensary three times weekly, will receive treatment, advice, medicines, where it is necessary, food and clothes, and will be carefully instructed how to live hygienically.

Red Cross Reorganization Bill Passed.—Mr. Cullom reported to the Senate last week the bill incorporating the American National Red Cross, and it was passed. It carries out the reorganization plan proposed by former Secretaries of State John W. Foster and Richard Olney.

Quack Advertisements Barred.—The *Boston Herald* has recently announced that it will in future exclude from its columns all advertisements of patent medicines and venereal quacks. It is to be hoped that the support which this course will receive from decent-minded folk will encourage other journals, religious and secular, to do the same.

To Save the Eyes of Small Pupils.—The instruction committee of the Board of Education of St. Louis has recommended the adoption of a plan which they hope will result in saving the eyes of first-year kindergarten pupils in the public schools, by shortening the time allotted to writing. Teachers have reported to the committee that too close attention to writing by the small pupils seems to be injurious to the eyes, and the plan is to shorten the writing periods and give the little ones some sort of manual work which will not cause a strain on the eyes, yet at the same time prove instructive.

Sanitation of Cuba.—The Cuban House of Representatives recently passed a bill appropriating $190,000 for the sanitation of Santiago, Cienfuegos, Cardenas, and Matanzas. The Senate amended this bill by increasing the amount of the appropriation to $326,000 and adding ten more towns to the original four cities where improvements are to be made in the sanitary arrangements. This action of the Senate postpones the final settlement of the matter until Congress convenes again next month. In the course of the debate on the bill some sarcastic remarks were indulged in by several of the speakers, who said the condition of the streets in many cities of the United States was worse than in those of Cuba. Many Cubans who this year visited St. Louis, they said, could testify that the streets of New Orleans were in much worse condition than those of any Cuban town.

The Rhodes Scholarship in Missouri.—Notice is given that all persons who desire to become candidates for the Rhodes scholarship in Missouri should send their application to President R. H. Jesse, of the State University, Columbia, Mo. All applications must be received on or before December 31.

Notice will be sent to all candidates making application as soon as the date of the examination is definitely fixed. President Jesse is chairman of the committee, and the other members are Chancellor W. S. Chaplin, Washington University, St. Louis; President William Henry Black, Missouri Valley College, Marshall, Mo.; Rt. Rev. Daniel S. Tuttle, Bishop of Missouri, and Rt. Rev. John J. Glennon, Archbishop of St. Louis.

Chi Zeta Chi Fraternity.—A smoker was given by the united chapters of the Chi Zeta Chi Medical Fraternity last week. Some fifty members and invited guests were present, and an enjoyable evening was passed.

First District of Ohio State Medical Association.—A meeting of this society was held in Cincinnati on December 8 and 9. The district composes the counties of Adams, Brown, Butler, Clinton, Clermont, Hamilton, Highland, and Warren. About 300 members were present. The meeting was called to order by Dr. Brooks F. Beebe, after which Dr. B. H. Blair, of Lebanon, O., was elected permanent chairman, and Dr. Magnus Tate secretary. The afternoon session was mainly devoted to the reading of papers by Dr. E. S. Stevens, Lebanon; Dr. Mark Millikin, Hamilton; Dr. Joseph Eichberg, Dr. S. P. Kramer, Dr. Charles A. L. Reed and Dr. P. S. Conner, Cincinnati. In the evening, after a dinner at the Business Men's Club, the Academy of Medicine entertained the visitors at the theater and afterwards at a smoker. The second day of the meeting was given up to specially arranged clinics at the various hospitals and to a general clinic at the rooms of the Academy of Medicine.

The Duties of a District Physician.—The jury in the case of Dr. H. Clay White against the Kenton Fiscal Court has returned a verdict in the Kenton Circuit Court, Covington, in favor of the county. The case was an interesting one, as it involved the duties of a district physician and the liabilities of the county for services rendered by such officer under the direction of the County Health Board. The plaintiff is district physician for the Visalia district. He sued the county for services in attending paupers stricken with contagious diseases, claiming he did the work under the direction of the Health Board. The County contended that it was the duty of the plaintiff to attend the cases in question as district physician for the regular stipulated salary.

New York State Hospital for the Cure of Crippled and Deformed Children.—In the fourth annual report of this institution the surgeon-in-chief, Dr. N. M. Shaffer, states that forty-two patients were treated during the year. Of this number seventeen were discharged, four cured, seven much improved, and three improved. The hospital, now at Tarrytown, will be moved in the spring of 1905 to West Haverstraw, Rockland County, the Legislature of 1903 having appropriated $50,000 to secure a site and build and equip a new hospital. The new building will accommodate thirty-five patients, the present hospital having a capacity of twenty-five only.

Ohio State Dental Association.—At the annual meeting of this society, held at Columbus, O., December 6, the following officers were elected: *President,* S. D. Ruggles, Portsmouth; *Vice-Presidents,* H. L. Ambler, Cleveland, H. C. Brown, Columbus; *Secretary,* F. R. Chapman, Columbus; *Treasurer,* C. I. Keely, Hamilton.

Dr. Thomas G. Ashton has been elected Adjunct Professor of Medicine in the University of Pennsylvania.

New Children's Hospital in Chicago.—Approximately $100,000 already has been subscribed for the construction of the Children's Memorial Hospital, Chicago, which will cost $300,000. The nucleus of the new institution will be the Maurice Porter Memorial Hospital for Children. Mrs Porter will give $75,000 towards the erection of the new institution, and another gift of $20,000 is in hand, with many smaller subscriptions.

The Cleveland Medical Library Association held its annual meeting December 10, in the Library Buildings. The paper of the evening was read by Dr. George Ben Johnson, of Richmond, Va., his subject being: "The Medical Men Contributed to the United States by the State of Virginia."

Home for St. Louis Medical Library Association.—The St. Louis Medical Library Association has recently purchased property on Pine street, near Grand avenue, which is to be utilized as a home for the Association and a meeting place for the various medical societies of the city. The Association has been in existence but a few years, but it has made great progress and is exerting a powerful influence for the advancement of medical interests in the city of St. Louis.

Obituary Notes.—Dr. William Gilfillan died December 18, at his home, in Brooklyn, after a short illness. He was born in Derry, Ireland, in 1833. His father was an assistant surgeon on the British Arctic voyager *Dorothea.* He received his medical degree at Edinburgh in 1854. In 1857 he came to this country and secured employment for a time as surgeon on one of the Cunard Line vessels. In 1858 he settled in St. Louis, and two years later came to Brooklyn. He was appointed surgeon and lecturer at the Long Island College Hospital, and held this place until 1869. He was a member of the Kings County Medical Society and of the New York Academy of Medicine.

Dr. Conrad Wesselhoeft, one of the best known homœopathic physicians in the country, died at his home in Newton Centre, Mass., on December 18, at the age of seventy years. He was born in Weimar, and came to this country with his parents when a child. He was a graduate of the Harvard Medical School in the class of 1856. He was president of the American Institute of Homœopathy in 1870, and later held the same office in the Massachusetts Homœopathic Medical Society, and was always very active in promoting the interests of that school of practice.

Dr. Charles K. Law, thirty-six years old, died at his home in Jersey City, on December 13, from peritonitis. He was a graduate of the University of New York Medical School in 1893. He was a member of the Jersey City Practitioners' Club, and of the Hudson County Medical Society.

Dr. Robert J. Barry, of Ansonia, Conn., died on December 15 of meningitis, at the age of thirty-five years. He was a graduate of the College of Physicians and Surgeons in this city, in the class of 1890, and was City Health Officer of Ansonia.

Dr. Frederick C. Cluxton died on December 17, at Bradford, Pa. He was graduated from the University of Victoria in 1871.

Dr. Levi Curtis died at Philadelphia on December 12, at the age of eighty-two years. He was graduated from Jefferson Medical College in the class of 1847, and he served during the Civil War as a surgeon in the United States Army.

Dr. Charles A. Durand, of Chattanooga, Tenn., died at San Antonio, Tex., on November 23, after a long illness. He was a graduate of the Medical College of Ohio in 1889.

Dr. William S. Hunt died at his home in Springfield, Ohio, on November 21, at the age of fifty-eight years. He was graduated from the Cincinnati College of Medicine and Surgery in the class of 1870.

Dr. H. J. Strack, of Cincinnati, was found dead in his office of heart disease, December 10. He was a graduate of the Ohio Medical College in 1901. He had served one year as District Physician, and was Examining Physician of the Catholic Order of Foresters.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BRADSHAW LECTURES—TREATMENT OF CANCER—TREATMENT OF TYPHOID FEVER—BIRMINGHAM UNIVERSITY MEDICAL SCHOOL—MR. CHAMBERLAIN'S SPEECH ON RESEARCH—MORTALITY OF THE NAVY—GENERAL MEDICAL COUNCIL, DR. MACALISTER ELECTED PRESIDENT.

London, December 2, 1904.

Last evening Mr. Mayo Robson, vice-president R. Coll. of Surgeons, delivered the Bradshaw Lecture at the College. This was the second Bradshaw within a short time, the other being at the Royal College of Physicians on the 15th ult. Some brief notes on each may interest you. Mr. Robson's subject was cancer, the cause of which he dismissed with slight consideration, to speak rather of prevention and cure. As the disease is not infectious in the ordinary sense, there is no occasion for isolation at any stage. When the ultimate causative factor in the life history of a cancer cell has been discovered, we may hope that something in the nature of preventive treatment may also be discovered, but at present nothing of the kind is known, and the serum treatments employed by certain so-called cancer specialists are utterly worthless. Many valuable lives and great suffering might be saved by the recognition of a precancerous stage. That was the period when such preventive measures as exist might be useful; they consist in the abolition of all conditions which are known to be frequently followed by cancer. Whatever other factors may exist in the causation of cancer, chronic irritation is certainly one, and the establishment of the precancerous conditions might be prevented by the removal of such irritations, *e.g.* the pipe and excessive smoking in cancer of the lips and mouth. So quite simple and apparently innocent spots and growths in and under the skin might be a source of danger. If such showed signs of irritation or increased in growth, it was safe to remove them at once. Patients might think little of them, and their medical attendants might not like to seem alarmists, but it was better to alarm and cure than to lull into false security, and have to operate under less favorable conditions. It was certainly wrong to wait for a doubtful growth to become unquestionably malignant. At an early stage it could be removed without risk, and the fears and anxiety of the patient relieved.

The lecturer proceeded to apply the principle thus enunciated to cancer of internal organs.

Passing on to the treatment of fully developed cancer, Mr. Robson advocated entire removal as early as possible of the morbid growth, together with a wide margin of healthy tissue, and, when practicable, the nearest glands. On these lines, the chances of cure, or of relief for many years, were more favorable under modern conditions than was formerly the case. Often entire cures might be obtained.

In conclusion he said: "My purpose will have been served, if I have been able, in however small a degree, to convince those who have the chance of seeing patients in the early stages of their illness, that in many cases cancer can be prevented by treatment in the precancerous stage; that even when cancer has developed, if it be seen early, and thoroughly removed, it is frequently a curable disease; and lastly, that even in the later stages much may be done by surgical treatment to give real relief. Is it too much to hope that some of the views I have enunciated may filter through the profession to the public, and serve to convince them that until a true prophylactic for cancer is discovered they will be consulting their own interests best by seeking medical advice earlier, since to trifle with their ailments in the early stages is to lose the favorable moment, and ultimately to hear the verdict—alas, too often pronounced—too late!"

The Bradshaw lecture at the Royal College of Physicians was delivered by Dr. Foord Caiger—his subject one of perennial interest to every practitioner, the "Treatment of Typhoid Fever." This, he remarked, may be conducted on one of two lines, viz., an active remedial or a passive, so-called expectant method. The active measures are (1) specific, (2) antipyretic, (3) antiseptic. Specific curative serums have not succeeded as in diphtheria. Professor Wright's preventive serum has been shown to confer a considerable degree of protection, and also to mitigate the severity of an attack. Of the antipyretic plan, Dr. Caiger does not favor the use of drugs—at any rate in antipyretic doses—as he is convinced that the pyrexia is a natural defensive element against bacterial invasion. But when pyrexia becomes excessive it must be met by vigorous measures by reason of its effect on the heart muscle and the central nervous system. Baths are the most powerful means, and the cold, the graduated, and the continuous tepid were considered. Of drugs to aid the baths, only quinine deserved any confidence. Of the antiseptic method, the lecturer recognized that the attempt to destroy bacilli in the lower bowels by drugs given by the mouth is quite futile. But he said it is not unreasonable to expect harmless doses may restrict the multiplication of organisms (specific or not). In fact, this is effected as to putrefactive organisms, as shown by diminished fetor of the stools. Of antiseptic drugs, calomel is most widely used, and in suitable cases beneficial, but in exceptional instances, even in the first week, may induce intestinal irritation; so Dr. Caiger has given up its routine employment in the early stage, restricting its use to cases with special indications. The lecturer's experience is that antiseptic drugs in frequent doses have a favorable influence on the course of the attack, but cannot arrest it or lessen the risk of hemorrhage, perforation, or relapse. Sulphurous acid, turpentine, quinine combined with nascent chlorine, and oil of cinnamon are the drugs he favors. The last he begins in doses of 2½ minims, and increases in a few days up to ¼ or 5. The results are favorable. In 147 cases meteorism did not once occur; in three instances progressive cardiac enfeeblement developed without any apparent reason, and consequently Dr. Caiger now gives a grain of quinine with each dose. So much for the active line of treatment. Now as to the passive, expectant, or symptomatic line. Dr. Caiger, as a general rule, would treat a case on symptomatic lines, but would employ in addition, and from the earliest possible period, such antipyretics or antiseptics, or both, as appeared suited to the attack or the idiosyncrasy of the patient. Considering the successes of the cold bath reported from abroad, he thought some responsibility would be incurred by those in charge of hospital cases if they withheld it, except in the rare cases in which it was obviously inadmissible. When toxæmia is prominent—dark, foul evacuations, abdominal fulness at an early stage, nervous depression, and high temperature—antiseptics are required as early as possible; at the outset 3 or 4 grains of calomel, followed in a couple of days by another dose. This is best at an early stage, but in some cases he would even give it later. If free evacuation is not obtained, and the abdomen remains tumid, a turpentine and soap enema should be given. Antiseptics should follow every few hours, oil of turpentine or of cinnamon. In cases characterized by anxiety or mental perturbation, the cinnamon treatment is also valuable. Mental rest is so important that opium may be called for until the cloud has passed. In ataxic cases quinine and chlorine every two hours. In hyperpyrexia the cold pack—or sometimes the bath—followed by quinine to prolong the effect. The lecturer did not favor synthetic antipyretics. Insomnia which does not give way to cold sponging may be treated by hypnotics; if associated with diarrhœa or abdominal pain, Dover's powder or laudanum.

Moderate diarrhœa, not above four or five stools in twenty-four hours, the feeding not being at fault, should be met by a starch and opium enema. If this is not effectual, opium may be required by the mouth. Bismuth and astringents were commended, but not mineral astringents. An ice-bag or large wet compress to the abdomen is of undoubted value, especially if the diarrhœa is associated with distinct abdominal tenderness. In cases in which definite tenderness can be elicited on slight pressure, whether diarrhœa exist or not, few measures are more valuable than continuous cold compresses. Should meteorism arise in spite of care and diet, opium; if it seems due mainly to distension of the colon, turpentine and soap enemata. Sometimes the long tube may afford relief, but by no means always.

Cardiac failure may require the cautious use of stimulants. Alcohol alone has a temporary effect; digitalis, strychnine, and quinine are more lasting. Dr. Caiger ranked himself with those who hold that in most cases alcohol is not required, and often hurtful. A few ounces will markedly increase the restlessness of a delirious person whose pulse is good and circulation well sustained, especially if the patient is young and unaccustomed to alcohol.

For hemorrhage, absolute repose of body, bowel, and

mind; nutriment reduced to the lowest possible point; deprivation of fluids to reduce blood pressure. A full dose of opium given, and an ice-bag applied, our treatment is summed up in the word prevention, and for this, deprivation of fluids, save only a fragment of ice occasionally, is most important.

For perforations, the lecturer said he agreed with those who hold that a moribund condition is the only contra-indication to operation, and in regard to the most favorable time for this, "there is no time like the present." It is a golden rule to examine the abdomen carefully every day. Accurate diagnosis must be arrived at, but in view of the improved results of late, it is better to recommend an unnecessary laparotomy than let a patient die from perforation without the chance operation offers.

Dr. C. E. Purslow presided on Wednesday at a dinner of past and present students of the University of Birmingham, which was rendered memorable by a presentation to the Dean, Professor Windle, who is leaving to take up the presidency of Queen's College, Cork, as well as by a most interesting speech by Mr. Chamberlain. The loyal toasts having been duly honored, Sir F. Treves gave the "Medical School," remarking that though it used to be thought a university should be old, and located far from the haunts of men, times had changed, and to succeed, at any rate so far as science is concerned, it must be young, and situated in a great city. Time was when the man of science was cast into prison. Now he is simply left to starve. If a young man showed exceptional promise for a scientific career, none was open to him, and he therefore drifted into medical practice, a most deplorable thing. We were told that millions were given to hospitals, but the public did not think what they got for their money. All the advances in medicine and surgery were made by men who worked for nothing and gave their discoveries to the world.

Dr. Purslow, as president, then recounted the successes of men of the school. The presentation was next made to Dr. Windle, whose reply was received with vociferous applause.

Mr. Chamberlain, as chancellor of the University, then gave "The Past and Present Students of the Medical School" in a long and most interesting speech, of which I must refer to only one point. He divided the people essential to a university into three classes, (1) students, (2) teachers, and—having done justice to these—(3) the "pious benefactor." This species he found scarce in these days; he had been hunting him for three or four years. When he found him he wanted to drink his health and offer the warmest aspirations for his prosperity. America had many who had covered their land with universities. Here they are too rare. He had heard—perhaps it was only a superstition—that sometimes medical men were consulted by patients as to the disposal of their benefactions. If it were the fate of any of them to enjoy such confidence, he hoped he would gently insinuate the undying renown and gratitude that awaited any one who so established in their university a great school of medical research. It was only a question of a quarter of a million or so. The speaker then went on to show the value and necessity of such schools of research, and pointed to the results already accomplished as an encouragement to further efforts.

The annual report of the Director-General of the Royal Navy shows that the death-rate of the force, 4.19, was the lowest recorded since 1856.

The General Medical Council closed its session on Tuesday. A good deal of business was transacted at the sitting, but not much that will interest you. Dr. Donald MacAlister was elected president in succession to Sir Wm. Turner, and was duly inducted into office by the retiring president. Sir Wm. Turner was entertained by the members of the council at a dinner on Saturday.

OUR PARIS LETTER.

(From Our Special Correspondent.)

VACCINATION INSTITUTIONS—ANEURYSM OF THE POPLITEAL ARTERY—SARCOMA OF THE ORBITAL MARGIN—CICATRICIAL CONTRACTION OF THE PALM OF THE HAND—POST-MORTEM EXAMINATION OF THE HEART SUTURED TWO YEARS PREVIOUSLY—ARTERIAL TENSION—MERCURIAL INJECTIONS—OBESITY—INTUBATION VERSUS TRACHEOTOMY—A CASE OF TETANUS CURED—POISONING BY BALLOON GAS—DEATH OF OLLIER—NEW BOOKS.

PARIS, November 22, 1904.

KELSCH read a long report before the Académie de Médecine on a commission relative to the study of foreign vaccination institutions, and on the transference of the service of vaccination to the Académie, an institution superior in view of its adaptation to the new rôle which devolved upon it by the application of the law of July 27, 1903. Kelsch passed in review the organization and working of foreign vaccine institutions. He discussed, with all the new data, the relation between variola and vaccination, and described the chief improvements which would take place in the vaccination service, under the Académie.

At a recent meeting of the Société de Chirurgie, Nélaton reported an interesting series of observations on syphilitic aneurysm of the popliteal artery, which at first improved under specific treatment, then suddenly ruptured on the thirtieth day of a severe typhoid fever, causing in a few days complete gangrene of the foot and leg. It was necessary to amputate the leg, and convalescence followed. Examination showed it to be a sacculated aneurysm, which extended to the tibioperoneal trunk, and which, in consequence, according to Nélaton, was not amenable to resection. He thought that a resection so extended, in which the anterior tibial artery was included, would lead to a fatal gangrene of the limb, and to a second amputation. Moreover, Nélaton thought that in similar cases it would be necessary to confine oneself to ligating the artery at the level of the opening in the third adductor, without attempting to extirpate the aneurysm.

Walther presented in his own name, and in that of Béclère, the case of a young man who, having already undergone several operations for a sarcoma of the inferior orbital margin, had recently had a recurrence, with lesions so extended that Walther considered further operation impossible. Béclère then treated the patient with *x*-rays. Eighteen sittings, covering a period of four months, sufficed to cause all trace of the neoplasm completely to disappear. Professor Berger treated with equal success a very serious recurrence of a sarcoma of the face, which, in spite of the most vigorous intervention, such as resection of the maxilla and ligation of the external carotid, recurred each time, with the greatest rapidity. Under the *x*-rays the tumor entirely disappeared.

Professor Berger presented a young woman who had had cicatricial contraction of all the fingers of the right hand, following a burn of the palm. Berger did an autoplastic operation, according to the Italian method, the skin being taken from the back. The result was very good, both from the æsthetic and the functional point of view.

Launay detailed the post-mortem examination of the heart of a patient dying from typhoid fever, who, two years before, had received a double bullet wound of the heart. This wound had been sutured and cured by Launay. From the specimen, one could see that the bullet entered the left ventricle at the level of the insertion of the anterior mitral pillar, and passed out of the ventricle at the level of the insertion of the left mitral valve, at the level of the auriculoventricular orifice. The obliquity of the course of the bullet explains a peculiar fact observed, namely, that at the moment of systole, the blood flow was arrested, the muscular contraction sufficing to stay its course, but as soon as the cardiac walls relaxed the hemorrhage started afresh.

The seventh session of the Congrès Français de Médecine was held in Paris in October, 1904, immediately after the Congrès de Chirurgie. The first question on the programme was "Arterial Tension in Disease." The speakers were Bosc and Vedel, of Montpelier, and Vacquez, of Paris. The last mentioned considered only hypertension, and after having studied its diagnostic, clinical, and pathological significance, concluded his address with a discussion of its treatment. In the case of cerebral lesions of this origin, he recommends lumbar puncture, and, in case of dangerous complications, as acute œdema of the lungs, it is necessary to inject morphine.

The second question discussed was "Mercurial Injections." Lannoir, of Lyons, and Balzer, of Paris, were the speakers. They agreed that injection is the most powerful method of administering mercury. But although the limit of the specific action of mercury in syphilis is reached when the method of injection is used, it is none the less true that ingestion and inunction each has its place.

"Obesity" was the third topic to be discussed. Maurel, of Toulouse, and Lenoir, of Paris, were the speakers. According to Maurel, obesity is always the result of hypernutrition. It constitutes a method of organic protection, and disappears only under the influence of hypoalimentation. According to Lenoir obesity is caused by a defect in nutrition, and to explain why one becomes obese he recalled the fact that liberation of fat is made under the influence of a special ferment, lipase, which is found in the serum. Now these ferments are probably the products of internal secretion of glands, and among these the thyroid gland plays an important part. In the discussion which followed, Javal, of Paris, spoke of cases in which he had been able to observe that the ingestion of thyroid gland extract acted almost exclusively on the albuminoids of the body, and not on the fat, hence the danger of the thyroid treatment. Leven laid stress on the constancy of dyspeptic trouble among the obese. According to him, the treatment of dyspepsia alone caused the greatest number to lose flesh, allowing them to eat only food easily digested, and to drink water, without any special treatment. He insisted also on

the necessity of causing obesity to disappear slowly, a rapid decrease depending more on a dangerous dehydration than on the loss of fat.

In a paper read before the Société Médicale des Hôpitaux, Louis Martin showed that in severe forms of diphtheria accidents must be expected, whether intubation or tracheotomy is employed. There is no necessity of immediately rejecting intubation in favor of tracheotomy, for the same mischances occur whichever method is employed. Intubation is to be preferred, and in the cases in which the false membrane is abundant and may act as a valve on the tube, it must be inspected very often, and the tube changed once or twice a day, to bring about the expulsion of the false membrane.

Jeanselme reported an interesting case of acute tetanus, treated on the sixth day after infection with antitetanus serum, and large doses of chloral. In thirteen days the patient received 1,060 c.c. of the serum by subcutaneous injection, and in seventeen days he had taken by mouth and rectum 224 grains of chloral.

Barrier told of a fatal case of poisoning by balloon gas. It is known that this gas is composed of hydrogen containing unusual and toxic gases, chiefly hydrogen arsenide, hydrogen antimonide, and hydrogen silenide. Comparative study of their characteristics shows that hydrogen arsenide is almost entirely responsible for the poisoning. This observation, added to those published previously, shows how dangerous is the manufacture of hydrogen by chemical processes, and increases the interest in substituting for them the electrolysis of water, as is now being done at the Parc d'Aérostation Militairé de Chalais-Meudon.

A monument has been erected in Lyons in honor of her great surgeon, Ollier, who is best known for his work on bone surgery, and especially for his method of subperiosteal resection, which has proved so valuable. On November 13 this monument was dedicated in Lyons with impressive ceremonies. A number of speeches were made by delegates from the Faculté de Médecine de Paris, and by several distinguished foreigners.

Among the books which have recently appeared, we cite that of Dr. Robert Proust, professor of the Faculté de Médecine de Paris: "La Prostatectomie dans l'hypertrophie de la prostate." This book is indeed a monumental work on prostatectomy, which the author has made for some years his subject of choice. It is almost superfluous to recall the considerable part played by Proust in the introduction into France of perineal prostatectomy applied to the treatment of the hypertrophied prostate. One might say that only after the work of Proust and Gosset was the place of perineal prostatectomy really recognized in France, and it has now become a classical operation, perfectly developed in all its details. One finds in this book of four hundred and ninety pages an absolutely complete exposition of the question of radical treatment for hypertrophied prostate. The anatomical and anatomopathological portions are treated with particular care. Immediately following are descriptions of the operative technique of the suprapubic and perineal methods. Numerous detailed observations and résumés in tabular form complete the work, and give to it an added value.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

NEED OF A BABIES' HOSPITAL—GOOD RESULTS OF BATTLE AGAINST SUMMER ENTERITIS IN BABIES—POLITICS AND MEDICINE—POLYARTHRITIS OF CHILDREN—DURATION OF LIFE IN DIABETES—CARCINOMA IN MICE—RARE CASES.

BERLIN, November 24, 1904.

BERLIN does not stand first among the cities of Germany in regard to the hospital care of babies. For this reason an association has been formed under the name, "Verein für Erreichtung eines Säuglingskrankenhauses." To win supporters for this enterprise Ritter delivered an address in the Hotel Kaiserhof, in which he said that there were in Berlin asylums only for well babies. The three children's hospitals have fifty beds for infants, which by no means corresponds with the existing need. These hospitals do not have separate wards, a disadvantage for all concerned. Moreover, the babies ought to have wet-nurses. The hospital in Dresden should serve as model for similar institutions. There mothers and babies who have no home are admitted, and these mothers nurse other babies. From six to nine wet-nurses suffice for forty babies. A school for nurses has also been established there. Some of the daughters of the best families live for a year in this hospital, and later extend among the people a knowledge of the proper treatment of babies.

That infant mortality has decreased is shown by a comparison of the death rate of last year with those of 1900 and 1901. Taking the hottest months, June, July, and August, the number of babies dying in 1900 was 4,425; in 1901, 4,454, and in 1904, 3,522. These figures relate only to babies fed with cow's milk. The "Gesellschaft zur Bekämpfung der Kindersterblichkeit" has existed but one year, and has sent out 60,000 papers containing rules for mothers. It has also superintended the inspection of 170 cow sheds in the city by forty-eight physicians to insure the fact that the milking is done in a clean way, and that the milk is immediately cooled. The splendid result is indeed proof enough of the activity of this society.

Politics has entered the lists against medicine, and, it is hoped, will be worsted. At the end of October the old bill requiring the examination of all meat brought into the city, whether or not it had already been examined, was repealed. The new bill, very favorable to land-owners, who are now of great political influence, offers undoubted difficulties from a hygienic point of view. This explains the stormy applause which greeted Westenhoeffer in the Medicinische Gesellschaft on the reading of a paper on the meat inspection law in its relation to tuberculosis. Last year Westenhoeffer stated that the flesh of tuberculous cows is not infectious, except in the case of miliary tuberculosis. To prove whether the flesh contained bacilli, it was implanted in rabbits and guinea pigs; none died; of the control animals inoculated with tuberculous glands, all died; of seven animals, inoculated with flesh from cows with miliary tuberculosis, all died. In spite of the results of these experiments, the speaker held that the flesh should be very carefully inspected, because of the possibility of its containing tuberculous glands. When the meat comes from abroad, the entrails should also be sent for examination. Slaughtering indoors should be forbidden, and only especially qualified veterinary surgeons should be employed for the examination.

In the same society, November 8, Baginsky spoke on "Articular Rheumatism in Children," and for those to whom it was new the paper contained much of practical value. Baginsky had observed in all 144 cases in the Emperor and Empress Frederic Hospital. Most of these cases occur in the chief periods of growth between the ages of 5 and 10, and 11 and 14 years. No influence of season can be noted, and the influence of heredity is not pronounced. Two groups of cases are to be distinguished, both beginning violently. The first is soon cured without difficulty, while the other runs a rapidly fatal course, or is severe with subacute intervals. The lower extremities are usually most affected. Nephritis is not often found as a complication, but chorea is frequently present, and the heart is almost always affected in severe cases. Only a few of the heart cases live till puberty, and their treatment is very discouraging.

In the "Verein für innere Medicin," Hirschfeld, the well-known authority on diabetes, read a very valuable paper on the prognosis of diabetes. Contrary to the old rule of Traube, that in light cases the sugar disappears with the decrease in carbohydrates, Hirschfeld recommends a more exact examination of toleration. He gives 100 gm. of carbohydrates and records the quantity of excreted sugar. When the excretion amounts to 50 gm. a day, the speaker said, the disease will never wholly disappear. The cases with an excretion of 10 gm. are light. The most important complication is nephritis, which occurred in eleven per cent. of his cases. It was accompanied by polyuria, and occurred in the younger patients. When diabetes complicates renal calculus, the attacks of pain are very slight. Every diabetic patient suffers to some extent from cystitis. Hirschfeld does not agree with Senator that the nephritis is caused by arteriosclerosis. Among the first symptoms noted are the evidences of kidney irritation. Therefore careful treatment is indicated, and a rich diet is always forbidden. Milk is contraindicated in diabetes, because of the presence of milk sugar, but cream is recommended. As causes of death in the moderately severe cases, complicating diseases cover only 7 or 8 per cent., and in the light cases, 30 per cent. From life insurance statistics and from patients observed, the average duration of a moderately severe case is estimated to be about 10 years, and of a light case, 20 to 25 years. The patient who after the ingestion of 100 gm. of carbohydrates excretes only 10 gm. of sugar in 1,500 c.c. of urine in a day, *i.e.* 0.2 per cent., suffers from a disease which does not noticeably shorten life.

Animal pathology has often done good service in the investigation of human disease. For this reason the investigations in the charity cancer hospital are of value. They were reported by L. Michaelis, October 31, in the "Verein für innere Medicin," in a paper on cancer-like neoplasms in mice. Michaelis observed three types of neoplasm: (1) The usual carcinoma; (2) the usual adenoma; (3) a form combining the two types. These neoplasms are subcutaneous, and until they are ulcerated may easily be removed. Metastasis was observed only once in the lungs, but often in lymphatic glands. Infiltration did not occur as in human beings. Infection of other mice is simple. The neoplasm mixed with water is injected sub-

cutaneously, or small pieces are implanted. The neoplasm is not infectious for other animals, or even for other kinds of mice. The liquid if filtered loses its infectious power. Michaelis himself has not observed spontaneous infection, but it undoubtedly exists, if reports can be believed. Experiments in the production of immunization have been without success.

Paul Manasse read a paper on Mikulicz' disease, namely, a symmetrical enlargement of the ovaries and lacrymal glands. Then a boy was presented who lacked the tear and salivary secretions. He was somewhat dyspnœic, but otherwise well, and his blood condition was normal, contrary to what has been observed in other similar cases. Eckstein presented a girl of 20 years who had no nose. The other parts of her head and body were perfectly normal. Baginsky reported a case of Hirschsprung's disease, namely, enormous dilatation of the colon, especially the sigmoid flexure. The case demonstrated was in a child 11 months old, and the colon was as large as that of a man.

Progress of Medical Science.

The Boston Medical and Surgical Journal, December 15, 1904.

A Case of Diffuse Encephalitis Showing the Pneumococcus.—W. N. Bullard and F. Robertson Sims sum up the chief points in this case as follows: After a month of severe bronchitis in a man of 50, there developed a group of cerebral symptoms, weakness, and mild delirium, followed by flaccid paralysis of the left side, with rigidity on the right, and incontinence. Death supervened on the seventh day of the cerebral symptoms, after gradual failure, and coma, with elevated temperature. Autopsy revealed extensive diffuse encephalitis, and bronchitis, with bronchopneumonia (pneumococcus). The pneumococcus was found by culture, free in the tissues, and within the phagocytes of the cerebral lesion. The lesions were related to branches of the cortical arterial system of both hemispheres, and were marked on the right side, where almost the whole of the subcortical projection system was acutely involved by œdema and punctiform hemorrhagic foci. The lesions were histologically simple, consisting of accumulations, within and surrounding the adventitia, of phagocyte cells of the type familiar in cerebral and meningeal lesions, and small numbers of lymphoid and plasma cells. The large cells contained vacuoles, detritus of myelin, and an occasional pair or short chain of diplococci. There was no evidence of acute leptomeningitis or of ependymal changes.

Flies and Tuberculosis.—Frederick T. Lord has performed a number of interesting experiments with flies and tuberculous sputum. He concludes that flies may ingest tuberculous sputum, and excrete tubercle bacilli, the virulence of which may last for at least fifteen days. Bacilli appeared in the stools within at least eighteen hours after the ingestion of the tuberculous sputum. The number of bacilli in each microscopic field increased from about ten in the original sputum, to 150 in the specks. Paraffin sections were made from many flies fed on tuberculous sputum, and tubercle bacilli were found in the intestinal contents of all. No invasion of other parts of the body could be determined. The bacilli in the specks were much larger than those in the original sputum, and showed some evidence of apparent branching. The writer believes that it is probable that the usual contagion of tuberculosis is not by the ingestion of infected food, but by the drying and distribution as dust of infected material through the air. The danger of human infection from tuberculous fly specks is by the ingestion of the specks on food. Spontaneous liberation of tubercle bacilli from fly specks is unlikely. If mechanically disturbed, infection of the surrounding air may occur. The writer states that he has often noted the eagerness with which flies feed on sputum, even when other food is accessible. He has no doubt that flies play a part in cases of primary tuberculosis of the intestines, or the mesenteric lymph glands in man, due to the ingestion of infected food. The writer suggests in conclusion that tuberculous material (sputum, pus from discharging sinuses, fæcal matter from patients with intestinal tuberculosis, etc.) should be carefully protected from flies, lest they act as disseminators of the tubercle bacilli. During the fly season, greater attention should be paid to the screening of rooms, and hospital wards containing patients with tuberculosis, and laboratories where tuberculous material is examined. As these precautions would not eliminate fly infection by patients at large, food stuffs should be protected from flies who may already have ingested tuberculous material.

The New York Medical Journal, December 17, 1904.

Scarlet Fever in New York, and Some of Its Therapeutical Possibilities.—A. Seibert gives a carefully compiled statistical review of the history of scarlet fever in New York, and presents several graphic tables, showing frequency, relative mortality, relation to density of population, etc. He finds that the disease is always present, and is evenly distributed each year among the different districts, in direct proportion to the number of inhabitants. It is most common among school children, and the schools are the chief common centers for contagion. He believes that direct contact is necessary for infection. Seibert believes that we can destroy streptococci in the scarlatinal throat and skin before they enter the body. He employs, four times daily, from a five to ten per cent. ichthyol lanolin ointment, which is rubbed into the entire skin. Swelling and itching are diminished, and desquamation almost entirely prevented. He also uses a fifty per cent. solution of resorcin in alcohol on the throat as soon as an exudate appears, and thus describes his method: The patient is placed upright on the lap of the nurse, as when intubation is performed, the wrists are held down, and the head is held firmly by a second attendant standing behind. A plug of absorbent cotton, wound around a curved applicator, and dipped into this solution, is quickly introduced over the handle of a tablespoon into the nasopharynx, on one side of the uvula, left there a few seconds, and then withdrawn. A second application is made on the other side. No swabbing or wiping away of exudate is resorted to, for on the introduction of the cotton the soft palate instantly contracts, and so presses the fluid into every nook and corner of the throat. The solution penetrates through the exudate and deep into the affected mucosa, and there destroys the life of every streptococcus (or any other germ) it comes in contact with.

Venesection.—G. E. Souwers advocates venesection in acute inflammatory affections, especially of the more vital organs, accompanied by pronounced rise of temperature with a pulse either bounding or of that tense, whipcord character that gives, on examination, the impression that the vessels are strained to high tension by the blood current. The same indication exists when we have a slow, full, laboring pulse, as after an apoplexy, or heatstroke, but when in these latter conditions the patient is pale and flabby, we should not bleed. The author then goes over seriatim the maladies of the various bodily organs, in many of which, he believes, venesection to be indicated.

The Relation of Diseases of the Stomach to Affections of the Mouth, Nose, and Throat.—R. Levy lays down three main propositions: first, that certain affections of the upper air passages, and the adjacent cavities, are causative, in a measure, of some form of stomach disturbances; second, that certain stomach disturbances are the cause of certain affections of the upper air tract, and third, that the relationship existing between digestive disturbances and certain diseases of the upper air passages is so close that treatment must necessarily involve attention to both conditions. Among the diseases of the nose which are more especially associated with gastrointestinal affections are vasomotor rhinitis, nasal irritation, and red nose. Various disturbances in sensation are closely allied to some digestive disorder. Particularly is this true of paræsthesia and hyperæsthesia of the pharynx. Urticaria of the mucous membrane of the throat, a serious and possibly fatal affection, largely dependent on digestive disorders. Among diseases of the larynx, certain nervous affections, such as hyperæsthesia, and laryngeal spasm, are dependent on the same general causes of gastroenteric origin.

Medical News, December 17, 1904.

Diagnosis of Disease in Children.—J. Madison Taylor believes that in this line of work we need not so much new facts as a more practical application of those already recorded and tested. Many valuable truths have been revealed, but are locked up in large treatises, which are commonly used by specialists only. One important factor in this work is the study of morbid phenomena of the mind and morals. Clinical teaching should emphasize the urgency of obtaining the earliest possible indications, omens or prefigurements of departures from normal functionation, especially in children. The evil effects of environment and training, as well as those of inheritance should be recognized and rectified. Thus, the physician should possess clearly defined standards of growth, proportion, activities, sensitiveness, functional competence, intelligence, and capacity for endurance. Wide observation, reading and experience should lay the foundations of these standards. Bohannon has given valuable data from his study of over 1,000 individuals, which, although relating more to the psychic nature than to the physical, still is very helpful in diagnosis. The psychic factor, especially in the observation of children, is more important than is generally thought. Courageous children are usually healthy and strong in mind and body. Timidity has a physical basis. The "only child" in 66 per cent. shows disadvantageous traits. The writer calls attention to Arnold's scholarly work on the clinical significance of the interrelationships between the blood supply of organs and their functional activities. The writer states that there is both a nutritional and sensory reaction exhibited

upon the erector spinæ muscles, and allied structures, caused by the disturbed circulatory equilibrium in areas depending for vasomotor regulation on certain groups of segments of the cord. There is a compensatory relationship existing between, first, the surface muscles and the skin supplied by the posterior divisions of the spinal nerves, and, second, the blood vessels of the cord and the deep structures, organs, and remoter parts innervated by fibers whose cell bodies arise in that region of the cord. A great deal can be learned from careful study of the varying conditions of the back. In most acute conditions there is more or less hypersensitiveness in the tissues adjacent to those segments of the cord which correspond to the areas in which the innervation is disturbed. In places the structures will now and then lose tone, so as to feel like dough, or they may atrophy. Alterations take place in the muscle fibers so that they feel like cords. In acute disturbances of the throat, nose, and larynx, aside from the sensory disturbances, the upper dorsal areas and neck muscles will show changes in resistance. In order to make use of this method of diagnosis, the physician must systematically read clinical facts in the light of broad physiological principles. The writer concludes his interesting paper by presenting a résumé of the diagnosis possibilities of the Roentgen rays in disease in childhood.

Overlapping the Aponeurosis in the Closure of Wounds of the Abdominal Wall.—Charles P. Noble describes the method of overlapping the aponeuroses in the closure of all wounds of the abdominal wall, as follows: The incision in the hypogastrium for operation on the female pelvic organs may be taken as the type. In closing the wound, the peritoneum is first closed with a continuous suture of fine cumol catgut. The fat is then dissected from the upper surface of the aponeurosis of the tranverse muscles on the left side of the wound from one-third to one-half inch. The aponeurosis upon the right side of the wound is then separated for an equal distance from the rectus muscle. The muscles and fasciæ are sutured with medium weight chromicized catgut as follows: Beginning at the lower angle of the wound on the left side, the suture is passed from above downward through the aponeurosis and rectus muscle. The separated bundles of the rectus muscle are united with a continuous suture until the upper angle of the wound is reached, when the suture is passed from below upward through the aponeurosis upon the left side of the wound, and then from below upward through the aponeurosis upon the right side, while an additional suture is taken from above this point to fix the suture, and take off the strain from that part which has brought the muscle in apposition. The aponeurosis is then closed from above downward by catching the aponeurosis on the left side after the manner of the Lembert intestinal suture, and then passing the needle from below upward through the aponeurosis on the right side. When this suture is drawn taut, it slides the aponeurosis of the right side of the wound upon that of the left, and holds the two in apposition. The process is repeated until the lower angle is reached, when the two ends of the suture are tied. In long wounds two or more mattress sutures are placed to take tension off the lines of continuous suture.

The Association of Cancer and Tuberculosis.—W. A. Bastedo presents the following conclusions: 1. Cancer and tuberculosis not infrequently occur together in an active state, and may be intimately associated in the same tissue. 2. There is probably neither specific favoritism nor specific antagonism between the two types of disease. 3. There are a few reported cases in which one of the affections seems to have exerted a modifying influence on the course of the other. 4. Lupus favors the development of epithelioma. 5. Cancer is more common among those with latent tuberculosis than among others at the cancer period of life. 6. The common age for cancer is not the common age for active tuberculosis (Cruveilhier, 1828). 7. The common sites of cancerous involvement are mostly not those of tuberculous involvement, and vice versa (Rokitansky, 1838). 8. A family history of tuberculosis is more frequent in the cancerous than in the general community, and there may be some hereditary relation between the two. 9. A latent tuberculous process in a lymph-node may become active when a cancer develops in the neighborhood. 10. Lymph-node enlargement in the vicinity of a cancer is not always cancerous (Claude, 1899), and may be solely tuberculous.

American Medicine, December 17, 1904.

The Value of the Physiological Principle in the Study of Neurology.—James J. Putnam calls attention to the importance of physiological conceptions and methods in the study of disease. The pathological conception of disease, fruitful as it has proved, is in reality inadequate to the completion of the task which has been assigned to it, and it needs to be supplemented by another, which recognizes, as forming an integral part of each process classified as disease, a great variety of reactions on the part of the organism as a whole, or at least of portions of the organism, not implicated in the primary lesion. It is proper to speak of these adaptive or compensatory reactions as physiological. The degree to which the organism may take part in them varies, of course, within wide limits. We cannot depend upon anatomical evidence for giving all the information needed with regard to the disease, but must study the genesis of symptoms as well, even though they are in reality evidences of healthy reaction rather than of destructive processes. Hughlings Jackson has long stood as a pioneer in this study of the genesis of symptoms, but many other physicians have started researches in this direction that demand the fullest recognition, amongst these, Janet, representing the new school of psychologists, and Meltzer, representing medical physiologists. Although the study of function is so important, we ought not to divorce our conceptions of "functional" from those of "organic" to the extent that is common. The use of these terms, as standing for radically different and antagonistic conditions, is unscientific and misleading.

The Eye and the Digestive System.—Mark D. Stevenson points out that an improperly fitting pair of spectacles produces dizziness, nausea, vomiting, headache, and even faintness; so may abnormal strengths of the eye or its muscles. He thinks that not only the above-named symptoms, but other functional digestive disturbances, and even constipation, may be due to the inadequate nerve supply to the digestive organs in these conditions, because an undue amount of energy is consumed in overcoming the muscular or refractive errors. Likewise, he considers that the nausea and vomiting of sea-sickness are chiefly due to reflexes of the eyes and semicircular canals rather than from anything in the stomach itself. He describes the anatomic nerve relationship between the digestive organs and the eyes. Disorders of the digestive system affect vision, as often witnessed after a too hearty meal, for example, disturbances of accommodation, diplobia, etc. Hemorrhages into the stomach or intestines are sometimes followed by blindness. Jaundice sometimes causes yellow vision.

Röntgen-ray Therapy.— A. P. Rainear discusses Röntgen-ray therapy as applied to malignant growths, chronic ulcers, tuberculous glands, etc. He believes this agent is especially indicated in epithelioma, lupus, acne, rodent ulcers of the neck and face, the so-called birthmarks, and all superficial diseases of exposed areas in which a cosmetic effect is desired. Rainear calls attention to the brilliant results obtained from the use of the rays in severe cases of neuralgia. In facial neuralgia, severe attacks of sciatica, acute gouty paroxysms, and rheumatoid arthritis, he has seen relief afforded in from one to three applications.

The Röntgen Rays in the Treatment of Tuberculosis.—J. Rudis-Jicinsky uses the Röntgen rays in conjunction with the regularly accepted treatment, and gives quinine sulphate internally, to insure better absorption of the rays. Of twenty selected cases of pulmonary tuberculosis, five hemorrhagic cases showed improvement in ten weeks; ten fibroid cases gave three deaths after a lapse of six weeks; in five cases of mixed infection, three patients ceased taking the treatment, but the other two show continued improvement, with steady gains in weight. In six cases of tuberculosis of the peritoneum one patient died, but the rest recovered, and there has been no recurrence. In glandular tuberculosis there were nineteen failures, eight patients cured, and six benefited; in lupus vulgaris, sixteen patients apparently cured, three failures. The greatest improvement was shown in tuberculosis of joints, eight patients with simply tuberculous synovitis were cured in six weeks; four chronic cases showed improvement in four months; one case of tuberculous dactylitis showed good results after six weeks, some deformity remaining, and in two coxalgias the sinuses healed in four months.

Journal of the American Medical Association, December 17, 1904.

Enuresis in Childhood.—M. Ostheimer and I. V. Levi report their personal experience in ninety cases, about equally divided between the two sexes. Various complicating conditions existed, chronic gastrointestinal catarrh being the most common. Nasopharyngeal catarrh, enlarged tonsils, and adenoids are frequently found. Of eight cases with adenoids, six had had the usual operation for removal performed, without more than temporary benefit of the enuresis. The treatment consisted, first of all, of the correction of all dietetic errors. No liquids were permitted after the evening meal. Cold sponging was practised daily, sleeping on the back was prevented, and occasionally the foot of the bed was elevated. In boys, the motility of the prepuce was determined, and phimosis cases were circumcised. Citrate of potash was given when the urine was hyperacid. Tincture of belladonna was given in increasing drop doses, a bitter alkaline tonic being taken before meals. If the belladonna failed to relieve by the time fifteen-drop doses were reached, it was given up, and aromatic tincture of rhus was tried, increasing gradually to 30 minims daily.

If this also failed, as it usually did, one two-hundred-and-fortieth grain of atropine, with half that quantity of strychnine, were given, the dose being increased by the amounts mentioned, daily, until full physiological effect was reached or the enuresis relieved. On this treatment, sixty-seven out of the ninety cases recovered, and in fifty-three of the sixty-seven, the recovery was permanent.

Hæmaturia as the Earliest or Only Symptom of Scurvy.—J. L. Morse records seven cases. In one, the onset of the hæmaturia was accompanied by pain and tenderness in the extremities. In one it preceded any other symptom of scurvy by three months; in another by three weeks, and in another by one week. In three others in which it had been present for one month, two weeks, and two days, respectively, without any other symptoms, recovery was almost immediate under antiscorbutic treatment. The author considers scurvy as the most common cause of uncomplicated hæmaturia in infancy.

Post-Operative Infection of the Eye.—From a study of many thousands of cases of cataract extractions, J. A. White finds post-operative infection in about one per cent. The author follows this procedure in his own cases: The night before the operation a bath and a purgative are given, eyebrow, lids, and lashes are cleansed thoroughly by soap and water, followed by sublimate solution, 1-1000, and alcohol, the conjunctival sac is thoroughly irrigated with a sublimate solution, 1-10,000, and filled with sublimate vaselin. A slerite pad and bandages are then applied to the eye, and it is not opened again until the patient is on the operating table. The bandage is then removed and the sac irrigated anew with a sublimate solution, 1-10,000. The sac, being kept filled with this sterile preparation for twenty-four hours after thorough irrigation, is much more likely to become sterile, and remain so, than if merely washed out. No organisms can live in this medium, as bacteriological investigations have proven. The only defect in the technic is that the sterilizing medium is not applied often enough. The eye does not retain a particle or sign of the vaselin in even a few hours after, expect that the lid is somewhat greasy. But if the contact for a few hours succeeds in destroying or preventing the development of germ life, there is no chance of infection from without while the eye is kept sealed, although there is always danger of infection from within, if there is any pathological condition with purulent secretion, or any affection of the lachrymal sac, or a purulent rhinitis.

Berliner klinische Wochenschrift, November 28, 1904.

Observations on Carbonic Oxide Poisoning.—Strassmann and Schulz undertook a series of tests to determine the degree of absorption of carbonic oxide gas that can take place in the blood after death. The point is an important one medicolegally, since it is sometimes necessary to determine whether an individual may not have been already dead before he was placed in the poisonous vapor. Until recently it was supposed that the detection of carbonic oxide in the blood always indicated that the gas had been inhaled during life, but lately various observers have shown that not only the gas in the pure state, but also when mixed with air or smoke, can penetrate to the interior of a dead body through the skin. The authors' experiments were made on seven bodies, which were exposed to illuminating gas for varying lengths of time in a closed box. The results are in harmony with those of other observers, and show that carbonic oxide can enter the body, and probably penetrate all parts of it if the exposure be long enough. It makes little difference whether the illuminating gas is diluted with air or not, or whether it is stagnant or in motion. A useful differential diagnostic sign is the fact that when the gas enters the blood by post-mortem diffusion the superficial muscles, such as those of the chest, show a difference in color between their upper and lower layers in proportion to their degree of saturation with the gas. The most delicate test is the palladium reaction, which surpasses the spectroscope in sensitiveness.

The Route of Infection in Pulmonary Tuberculosis.—M. Wassermann believes that in many cases of pulmonary tuberculosis the infection reaches the lung from the tonsils and pharynx through the cervical lymph glands and the pleura. Through some local inflammation, or other lesion, the pharyngeal mucosa admits the bacilli, and the cervical glands become secondarily involved. The infection travels down the lymphatics to the pleura, and sets up a local pleurisy, which causes adhesions, and enables the bacilli to enter the lung itself. Adhesions form easily at the apex, for in this situation there is least motion during respiration. Inquiry often reveals the fact that swellings in the neck and pleuritic stitches in the shoulder have preceded the appearance of the pulmonary symptoms, and the author describes several cases in which this sequence of events was observed. The greater activity of the right shoulder favors the lymphatic current on this side, and explains the frequency of apical lesions on the right side.

Münchener medizinische Wochenschrift, November 29, 1904.

Technique of the Gruber-Widal Reaction.—Stäubli describes several innovations intended to facilitate the performance of this test. In order to render it less difficult to secure the necessary amount of blood, and at the same time to make the process less disagreeable to the patient, the author uses a special mixing pipette with rubber bulb not unlike that of the hæmocytometer. An amount of blood equal to 1-20 c.c. is drawn up to the mark 1, and physiological salt solution immediately drawn to the mark 12½. The mixture is placed in a special small tube, and is centrifuged. A mixing block contains eight shallow depressions, marked with the number of the corresponding dilution that each is to contain, and the original pipette is used to measure the amounts of centrifugalized blood and salt solution. The observation slide has similar depressions, and a drop each of the diluted serum, and of the culture, is placed on a vaselined cover glass, which is then inverted over the corresponding depression in the slide, and the whole is placed in the incubator for an hour. By this method only the cover glass, and the platinum loop, come in contact with the typhoid culture, and the dilutions are made with great accuracy from 1-25 up to 1-800. The author also describes a convenient tube for collecting blood that is to be sent some distance for examination.

A Method for Constant Temperature Determinations.—Oertmann describes a form of thermometer which makes it possible to obtain definite knowledge as to the highest point reached by a patient's temperature during the twenty-four hours. The assumption that the records obtained by taking the temperature two or three times a day indicate the highest point reached by the fever, is, of course, open to criticism, and the author has devised a maximum thermometer shaped like a hemorrhoid pessary, which is intended to be kept constantly in the rectum. A modified form is equally applicable to the vagina, and the author claims that these instruments can be retained in position without discomfort. Observations on the temperature for scientific purposes can be best made by means of this instrument, and in puerperal cases the recognition of ephemeral elevations is especially important. The method is also of practical value in all diseases characterized by brusque fluctuations of temperature, such as pyemic, embolic, infectious processes, as well as incipient phthisis. The detection of malingering is facilitated by the use of the instrument.

Deutsche medizinische Wochenschrift, December 1, 1904

Experimental Observations on the Possibility of Increasing the Resistance of the Peritoneum to Operative Infection.—Borchardt describes experiments on guinea pigs undertaken for the purpose of determining the possibility of increasing the resistance of the body to peritoneal infections with the bacillus coli communis. The agents used were nucleinic acid, horse serum, and physiological salt solution. Subcutaneous injections of the two latter proved efficient to protect the animals against subsequent injections of fatal doses of the colon bacillus, but the nucleinic acid was found ineffectual, and also gave rise to severe local reactions. Most of the experiments were conducted by injecting the protecting substances into the peritoneal cavity. All three agents applied in this way sufficed to augment the natural resistance, so that two or three times the ordinarily fatal dose of bacteria could be survived, but the author gives the preference to the salt solution. It was found that the highest point of the resistance curve was reached about forty-eight hours after the injection, which is much later than the highest leucocytosis. The protection lasts about four days. The author believes that by this method the dangers of laparotomy may be diminished.

Intraperitoneal Injections of Serum and Salt Solution to Prevent Operative Infection of the Peritoneum.—Schmidt has devised a special apparatus by which it is possible to inject salt solution or horse serum into the human peritoneal cavity without danger of injury to the intestines. The skin and fascia down to the peritoneum are punctured by a short, sharp trocar, which is prevented from touching the peritoneum by a flange which impinges against the skin. The needle, which has a closed, rounded end, with lateral openings, is passed down to the peritoneum through the lumen of the trocar, and is then punched through the peritoneum by a quick push. In this way there is little risk of injury to the intestines unless adhesions have bound it to the abdominal wall, and even in this case the fluid would simply flow into the intestine. The author has employed the method in five cases, using as injection fluid 5 to 10 c.c. of sterile horse serum in 250-500 c.c. of physiological salt solution. The fluid was thrown into the abdomen seventeen to nineteen hours before the operation. On opening the abdomen the peritoneum was found congested, and but little free fluid remained. The leucocytes increased to about double their normal number up to the time of operation, after which they rose rapidly, in some cases up to four times the normal number. The increased resistance conferred by the

treatment is shown in one case in which the wound burst open on the fifth day after a gastroenterostomy, and allowed intestines to escape, but in spite of this, secondary suture was followed by uncomplicated recovery. In another case, however, a considerable quantity of pus was evacuated from the stomach in an attempt to remove a carcinoma, and this patient did not survive the infection. The author considers that the procedure might also be found useful in cases in which peritonitis is threatened, as early appendicitis, salpingitis, etc., and that by increasing the natural resistance it would assist other internal or operative measures.

Bacteriological Results in the Recognition, Prophylaxis, and Treatment of Puerperal Fever.—Döderlein says that puerperal fever is essentially a condition to be benefited by the application of the theoretical considerations that bacteriological study has developed. The reason why the practical results have lagged behind the laboratory work is because in Germany 95 per cent. of the deliveries are still conducted by midwives, whose skill in asepsis is, of course, very deficient. Two chief types of puerperal fever may be recognized, that due to streptococcus infection, and that caused by saprophytes. The first is to be combated by the most rigorous asepsis, including the use of rubber gloves, while the second must be avoided by not permitting the conditions necessary for the development of the organisms. Complete and spontaneous expulsion of the placenta and membranes is the desideratum, and long labors are more hazardous than short ones. The prolonged sojourn in the genital tract of foreign bodies of all sorts, as bougies, dilators, gauze, etc., is fraught with danger; and other things being equal, prompt, even though aggressive, procedures are preferable to less vigorous but more prolonged methods. Every effort should be made to secure as natural a labor as possible, and thus not interfere with the body's inherent powers of resistance. Puerperal infections of the saprophytic type readily yield to local treatment by irrigation, etc., while true sepsis should always be met by injections of antistreptococcus serum, as well as by antipyretics and alcohol. The operative treatment of puerperal peritonitis has not been successful, though in carefully selected cases, with localized infection, hysterectomy may save life.

Annals of Surgery, November, 1904.

The Bridging of Nerve Defects.—C. A. Powers reviews the historical development of this procedure and summarizes the findings in fifty-six cases. Grafting was done in 22, flap operations in 11, implantation in 10, resection of bone in 7, suture à distance in 5, and tuberlization in 1. He records his own experience in implanting four inches of the great sciatic nerve of a dog in the external popliteal of a man. A report on the case eight years later showed a complete failure as regarded motion, and this in the face of conditions which seemed to promise a good result. The author believes that more cases must be recorded before we can draw final conclusions as to the preferable mode of operating. At present neoplasty and implantation (anastomosis) would seem to be preferable.

Total Avulsion of the Scalp.—The patient of E. J. Mellish was a woman of thirty years, whose hair caught in a belt. As a result the entire scalp, with most of the left ear and all of the skin and subcutaneous tissues, down to the fifth cervical vertebra behind and the bridge of the nose in front, were torn off. The patient received immediate attention and skin grafting was begun the next day. Sixty days later the entire denuded area was covered with movable skin, with the exception of three spots, which soon creatrized. Considerable trouble was experienced in preventing the new skin from pressure effects and microbic invasion. The author refers to several previously reported cases. There are only about a dozen of these, and in several the avulsion of the scalp was only partial. The present case healed more rapidly than those previously reported.

Operative Treatment of Perforating Gastric Ulcer.—A. B. Atherton reports a third successful case. The patient was a man of thirty years, who was operated on three and a half hours after his initial symptoms. An opening the size of a crow's quill was found on the anterior wall of the stomach, just at the narrowest part of the pylorus. It was closed by two rows of silk sutures, the inner one including all the coats and the outer one being a Lembert. The abdominal wound was united with through and through silk-worm-gut sutures. The patient left the hospital well, three weeks later.

A New Operation for Intestinal Stenoses.—The operation is thus described by T. A. McGraw: The tumor or stricture having been found, the coil in which it is seated should be drawn out of the abdomen, and, if neseccary for this purpose, adhesions should be broken or cut, enlarged mesenteric glands should be then removed, and the mesentery repaired. At this stage the two limbs of the intestine leading to and from the tumor, at a sufficient distance from the seat of disease, should be joined together by Lembert sutures and an anastomosis made with an elastic ligature. If the exploratory opening in the abdomen should seem best adapted for the purpose, the wound should now be closed snugly around the protruding coil, the ligatured portion remaining in the abdominal cavity, and the tumor, with a length of gut of two or three inches, outside of the abdomen. If the exploratory incision is made in the median line and the tumor is found to exist at either angle of the colon, it would be better to close the median incision and make a new one over the tumor, just large enough to permit of its easy exit. In every case the tumor should be drawn out of the abdomen at that point which would most nearly permit the resected intestine to occupy its normal position. When the wound has been closed and sutured to the protruding intestine, a firm silk ligature should be tied around the efferent limb just below the tumor and the gut cut off below it, care being taken that not the least portion of its contents is allowed to come in contact with the wound. This part of the gut may now be closed with a circular suture and pushed in until its outer surface no longer projects beyond the level of the skin. It is to be held in position by Lembert sutures and the skin brought over it and sutured. Thus the efferent limb is cared for. When the gut is divided just below the ligature, the efferent posterior should be wrapped in gauze and the surgeon should examine the sutured line which fastens the proximal bowel to the integument and see that the abdomen is thoroughly closed. Layers of gauze soaked in collodium should then be placed over the whole wound so as to seal it hermetically. A large trocar, such as has been used for the discharge of fluids from ovarian cysts, in operations for the removal of these tumors, may now be thrust into the intestine and the fæces discharged. A rubber tube attached to the trocar will carry them into a proper receptacle. When the gut has been thoroughly emptied of fæces, the diseased portion should be cut off and a large glass tube inserted into the bowel and tied in place by an encircling ligature. To this a rubber tube is attached for the disposal of fæces. At the end of four or five days the fæces will find their way through the new channel of anastomosis and pass into the lower bowel. As soon as this is determined by fæcal discharges per rectum, the tube may be removed, the gut sutured and turned into itself, and the wound in the integument closed over it. In this way the abdomen is guarded from all contamination from the opened bowel, have excised the diseased portion, and made the anastomosis and completed the work in what is practically but one operation, for the final disposal of the proximal end by inversion and suture can hardly be dignified by the name of operation.

Pneumococcus Peritonitis.—F. S. Matthews reports five cases, three boys and two girls, all under five years. In one the whole peritoneum was involved, twice mainly the region of the stomach and liver, and twice the hypogastric region. In no case did the patient live long enough for a localized abscess to form. All belonged to the diffuse or spreading type of the disease. Four had empyema. In two the peritonitis followed the empyema, but in two others the process seemed to originate at the same time in the pleura and peritoneum. Pericarditis was found once. Two had pneumonia at the time of death. The author quotes Jensen as recognizing that the infection may come through the diaphragm, genitals, or a wound. Three stages may be distinguished in symptomatology: (1) Sudden onset with high fever, vomiting for a day or two, tenderness and distention. There is little muscular rigidity, and the pain and distention are not so marked as in the other types of peritonitis. (2) After a few days vomiting ceases, temperature falls often to normal. Diarrhœa, often present in the first stage of the disease, is the rule in the second stage. The amelioration of symptoms is pronounced, appetite returns, and the child looks better. (3) Then with the increase of exudate there appears a tense cystic mass in the hypogastrium, temperature rises, and shows marked morning and evening remissions and exacerbations. There is cachexia and weakness, and the case terminates in from one to four months in death from exhaustion or in recovery following operation or perforation at the umbilicus.

Treatment of the Appendix Stump in Appendectomy.—M. G. Seelig shows that simple ligation of the appendix, with ablation distally to the ligature and cauterization of the stump, is not only a rational, but also an absolutely safe method of dealing with this organ. He takes up the various methods of inversion, showing that they are all open to the serious objections of secondary hemorrhage and infection of the operative field. Cases are quoted to prove that these accidents do occur. There follows a detailed histological and bacteriological study of the appendix stump, the result of this study being that a cauterized stump is sterile and that a ligature tied around an appendix causes

a perfect stump formation, so perfect, in fact, that there is no necessity of inverting what remains of the appendix into the cæcum. The author contends that this is the ideal method of dealing with the appendix, both because it is safer than all other methods, and because it is an operation calling for the expenditure of less time than does any of the other methods. He supports his contention by the fact that he has never seen the method fail in some fifteen hundred cases of appendicitis operated upon in Mount Sinai Hospital.

Abdominal Crisis Caused by Meckel's Diverticulum.—Two cases are reported by O. C. Smith and previous cases in literature referred to. Only two of the latter have occurred in America. Both of the author's cases recovered. The symptoms in Case I, a child of 10 years, suggested a commencing general peritonitis, and on section a perforated Meckel's diverticulum was found. In Case II, a boy of 19 years, the symptoms suggested intestinal obstruction. Two coils of ileum were found constricted, the constriction being due to a twisting of the bowel around a diverticulum, extending from a point on the ileum, eighteen inches above the ileocæcal valve to the left pelvic wall. This diverticulum was also twisted upon itself to the point of obstruction. Blanc in 1899 was able to collate forty-eight cases of abdominal disease due to Meckel's diverticulum, including volvulus, invagination, inflammatory and perforative disease, cysts, tumors, and herniæ. The structure is a remnant of the vitelline duct in the embryo, which has failed to become obliterated. It is of rare occurrence in the human subject, but is always to be thought of in obscure abdominal conditions.

French and Italian Journals.

Acetonuria Elsewhere Than in Diabetes.—Beauvy says that although acetonuria has for years been studied, especially in its relation to diabetic coma, still for a long time it has been known to exist in other conditions. It has been said that a meat regime causes acetonuria, and it is well known that diabetic coma is sometimes due to an exaggerated meat diet, but according to Argenson, the acetonuria of meat diet is very slight. The three characteristics of acute acetonuria are, the peculiar fruity odor of the breath, and so penetrating at times as to be noticeable at a distance, the febrile urine, with the characteristic odor; and the fact that the reaction of Gerhardt is generally positive, while the reaction of Lieben is always so (acetonuria generally accompanied by diaceturia). As a rule, this clinical picture exists only when the acetone amounts to about 0.20 gr. to a liter, a figure frequently reached. In the condition of acetonuria, acetone exists in the blood, as Petters and Argenson have demonstrated. The kidney plays the rôle of elimination, and not of formation. But the breath eliminates as much acetone as the saliva, and the perspiration. The origin of acetone has been discussed at great length. Some authorities believe it to be derived from sugar by alcohol or aldehyde; others, from the albuminoids. Schumann has detected acetonuria in a healthy subject after feeding him on fats exclusively, and has determined the cessation of this condition after adding carbohydrates to this regime. But all of these diets cause so marked an inanition that it may itself be the cause of the acetonuria. This is the reason why none of the theories can be considered as being absolutely demonstrated. Although acetone is slightly toxic to a healthy subject, it is not so well tolerated by hepatic and diabetic patients, in whom it causes slight headache, and in whom it passes easily into the urine, as if the liver were incapable of arresting it. It is an exaggeration to say that acetonuria is a phenomenon contingent to the course of diabetic coma—*Revue Française de Médecine et de Chirurgie,* November 7, 1904.

Prophylaxis of Ankylostomiasis.—Dopter, in speaking of prophylactic measures for workmen, in regard to ankylostomiasis, says that the etiological study of the causes inherent in the individual shows the evil influence of a bad personal history—digestive disturbances, etc. General prophylaxis, for the workman, therefore, means prophylaxis against ankylostomiasis. To ameliorate the conditions of the workman, to better the sanitary conditions of his dwelling place, of his diet, to watch over his health from a general point of view, the functioning of his viscera, to treat rationally the different affections, both acute and chronic, which he presents, will give him a greater resistance to infection by the duodenal ankylostoma. It is necessary to follow up vigorously all known measures in the campaign against tuberculosis, syphilis, and alcoholism, the three plagues which depress the organism to a serious degree. The writer then emphasizes the importance of teaching the workmen pursuing trades which render him especially susceptible to this disease, the means of averting it, and of combating it. The masses must be informed as to their danger and the manner of its prevention.—*Gazette des Hôpitaux Civils et Militaires,* October 29, 1904.

Cancer of the Rectum Situated Above the Rectal Angle.—Girard calls attention to a variety of rectal cancer which, by reason of its position and its small size, and also by reason of the fact that the symptoms to which it gives rise are so slight, passes too often unperceived by physicians, and even by the patients themselves. Thus the propitious time for operating is lost. These cancers are generally inaccessible both to rectal touch and to abdominal palpation. They are not accompanied generally by the ordinary symptoms of rectal cancer. There is no sign of stenosis, no loss of blood, and no pain, or at least very little. If pain does exist, it often resembles that of a simple enterocolitis, and so precious time is lost. The growth may in the meantime invade the neighboring organs, especially the bladder, without the least intestinal trouble. When the diagnosis is at last made, intervention has no chance of success. Gerard has observed several instances of such cancers, and in the last case made the diagnosis in time to perform a successful operation. He made a resection of the rectum by the abdominal route. The patient recovered and has remained well for two years.—*La Presse Médicale,* November 2, 1904.

The Value of Fats for Tuberculous Patients.—René Laufer declares that the most definite and constant influence of fats is the same on tuberculous patients as it is on normal individuals, consisting in the retention and preservation of nitrogenous material. The author has observed the effects of the administration of fats in two sets of tuberculous patients. To the first set he gave large doses—150 gr. to 200 gr. daily. These fats were in the form of cod liver oil, butter, and plain oil. To the other set of patients he gave these fats in moderate quantities—100 to 150 gr. In the first set the curve of weight rose at first in a rapid and remarkable manner, then reaching a level and remaining stationary for a time, it finally fell, sometimes below the original weight. This was due to digestive troubles, or to the loss of appetite for other foods, or, finally, to the fact that the fat was not utilized, but was passed out in the fæces without being changed. In the second set of patients, those who received moderate doses, the curve of weight slowly rose, but in a progressive and continuous manner, so that the benefit was lasting. The dose of 100 gr. to 150 gr., according to the susceptibility of the patient, appears to be the maximum quantity that is really beneficial.—*Le Bulletin Médical,* November 5, 1904.

A Case of Perforation of the Interventricular Septum from Ulcerative Endocarditis.—Carlo Gennari observed an exceedingly rare case of ulceration of the interventricular septum, resulting in perforation, which was not diagnosed in life, but by post-mortem examination. The diagnosis had been endocarditis, with aortic ectasia and pulmonary gangrene. The disease existed for some six months before death. There was marked anæmia, daily intermittent fever, intense chills, cardiac changes and an enormous tumor of the spleen. No malarial plasmodia were found, and no tubercle bacilli, but staphylococci were found in the blood. There was gangrene of the lung from thrombi derived from the vegetations of the heart. There was during life a systolic murmur, heard at the apex and propagated toward the aortic orifice, where it was most intense. In the first, second, and third interspaces, to the right of the sternum, there was a systolic pulsation. The murmur was not heard in the great vessels of the neck. There was a systolic fremitus propagated in the same direction as the murmur. These symptoms the author considers characteristic of perforation of the ventricular septum. The pulsation was due to dilatation of the right ventricle, especially the right pulmonary infundibulum.—*Rivista Critica di Clinica Medica,* November 5, 1904.

The Changes in Arterial Pressure in Malarial Infection.—Giovanni Quadri has studied the arterial pressure in ten cases of malarial infections and gives us his results. The effects of the toxic bacteria of several of the infectious diseases on the heart have been studied, with the result that the conclusion was reached that there is a motor insufficiency of the myocardium, without any true myocarditis, and a hypertension of the arteries continuing into convalescence. The myocardium does not respond to the ordinary cardiac stimuli, the vascular dilators, like caffeine and nitrites, having more effect. The author studied cases that were not complicated by any other disease, and measured the arterial pressure with the sphygmomanometer of Riva-Rocci twice daily, at the same hour, between meals, when the processes of the body were most in abeyance. His conclusions were: 1. There is a slight rise of arterial tension in malarial infection; it varies with the length of the disease and the resistance of the individual, not with the type of the parasite. 2. The myocardium reacts to digitalis and cardiovascular remedies. 3. The effect of the cardiovascular tonics was shorter and less than in normal persons.—*Il Policlinico,* November, 1904.

Book Reviews.

Text-Book of Nervous Diseases and Psychiatry, for the use of Students and Practitioners of Medicine. By Charles L. Dana, A.M., M.D., Professor of Nervous Diseases and (ad interim) of Mental Diseases in Cornell University Medical College; Visiting Physician to Bellevue Hospital; Neurologist to the Montefiore Hospital; ex-President of the American Neurological Association; Corresponding Member of the Société de Neurologie, etc. Sixth Revised and Enlarged Edition, with 244 engravings and 3 plates in black and colors. New York: William Wood & Co., 1904.

In the present edition of this well-known standard text-book, the chapters on neurology have undergone little change. Some new ones have been added and slight corrections made. In particular, some comments on the recent method of cytodiagnosis are given.

The most important change from former editions consists in the insertion of twelve chapters in sixty-eight pages upon psychiatry. The classification of mental disorders is in general that of Kraepelin, but somewhat modified to represent the author's own experience. The matter in this division of the work is presented in a way to make this somewhat difficult subject accessible to the profession generally. To this end an excellent chapter is given on normal psychology as expressed in physiological terms and equivalents. Then follow chapters on general symptomatology, methods of examination and diagnosis, general prognosis and treatment, and, finally, those on the individual psychoses. Not the least important feature is the author's standpoint. He says: "I have thought it of especial importance to insist on a distinction between major and minor psychoses, and to emphasize the fact that one may have a psychosis and yet not be in any sense insane. In fact, I am in sympathy with the view that makes as few people insane as possible." In this respect the author differs somewhat from some other alienists, and, in our opinion, differs decidedly for the better. To make room for the chapters on psychiatry without increasing too much the size of the volume, much of the matter on general neurological therapeutics which, having now become part of general medicine, is no longer needed has been omitted from this edition.

New Methods of Treatment. By Dr. Laumonier. Translated and Edited from the Second Revised and Enlarged French Edition by H. W. Syers, M.A., M.D., Cantab. Physician to Out-Patients, Great Northern Central Hospital. Chicago: W. T. Keener & Co., 1902.

The purpose of this work is to render familiar to the practitioner the newer methods of treatment such as seem to the author of value. He does not treat of the well known or the insufficiently tried drugs and procedures, but merely endeavors to make clear the indications and the physiological action of the methods which have had a fairly extensive investigation. Many subjects are thoroughly treated and will help to clarify the rather hazy ideas which prevail concerning them. Among the less well-known remedies, we note the lecithins, the nucleins, the derivatives of venadium, the yeasts, the organic extracts, specific sera, etc., all of which are of extreme interest. At the beginning of each chapter there is a summary of pathological physiology and pathogeny which enables the reader to adapt his remedy in accordance with modern rational methods. All in all, the work is well worth reading, and although the author at times seems too hopeful of benefits to be derived, still he is alive to the dangers and contraindications, and states them plainly.

Outlines of Physiological Chemistry. By S. P. Beebe, Ph.D., Physiological Chemist to the Huntington Fund for Cancer Research, and B. H. Buxton, M.D., Professor of Experimental Pathology, Cornell Medical College. New York: The Macmillan Company; London: Macmillan & Co., Limited. 1904.

Organic chemistry, particularly in its application to vital processes, has kept pace with the innovations that have been made in other departments of natural science within the last years, and now presents much that is perplexing to the student of even a short time ago. It has been the object of the authors to detail in simple manner the modern conceptions of physiological chemistry, and the book should prove most acceptable to anyone wishing to keep abreast of the knowledge of to-day. The principles of ionization and of electrical conductivity in solutions, with the newer views as to the nature of chemical reactions, are briefly indicated, and a chapter on disease and immunity discusses the chemical aspects of these problems. The chemistry of the carbon compounds in general is simply explained, and the nitrogen derivations, proteids, enzymes, etc., are treated in detail. The text is made intelligible by an unusually large number of graphic formulæ, and the only criticism to be made of the useful volume is that the index might with advantage be made somewhat more comprehensive than it is.

Diet and Food, Considered in Relation to Strength and Power of Endurance, Training, and Athletics. By Alexander Haig, M.A., M.D. Oxon., F.R.C.P. Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women. Author of "Uric Acid as a Factor in the Causation of Disease" and of "Uric Acid; an Epitome of the Subject." Fifth Edition. With Seven Illustrations. Philadelphia: P. Blakiston's Son & Co., 1904.

Although far too little attention is yet given to the subjects discussed in this little volume, still an appreciation of their importance is gradually gaining a strong foothold. The author, a master of the science of dietetics, declares in the preface that as time goes on he is more and more convinced of the importance, both mental and physical, of the right understanding of dietary questions. The present edition is practically the same as those which have gone before, so far as the vegetarian doctrine of the author is concerned; but it contains some new matter adduced in further support of the now well-known views of Haig regarding uric-acid formation and ingestion. One who does not go all the way with the author in his dietary restrictions—and few do or will, we opine—may, nevertheless, read this little book with profit, for he will find in it many hints following which he may formulate a diet list for his gouty patients without condemning them to inanition.

The Principles of Relief. By Edward T. Devine, Ph.D., LL.D. Author of "The Practice of Charity;" General Secretary of the Charity Organization Society of the City of New York. New York: The Macmillan Company; London: Macmillan and Company, Ltd., 1904.

In the opening chapter, the author tells us that "the main purpose of the present volume is to aid the citizen who is conscious of a sense of obligation for the relief of poverty, and more especially those who look forward to active volunteer or professional service in any branch of social work, to recognize the character and extent of such service, to become familiar with its guiding principles, and to apply those principles to such practical tasks as they may encounter." The chapter on "The Elimination of Disease" is one to which the medical reader will naturally turn; and we can assure him that he will read it with much interest. In this chapter the author tells us that he has a friend "in whose opinion physicians are, on the whole, the most bigoted body of men that he knew, with a single exception." But, as we are subsequently informed that this friend was "interested in the manufacture of a proprietary remedy," readers of the Medical Record will probably consider this opinion as a very high compliment to an honest and incorruptible body of men. Further on we learn that puerperal infection "resulting in death occurs as frequently in the practice of physicians as in that of midwives." The service of medical men in the prevention of diseases is ungrudgingly acknowledged; but the author thinks that physicians ought to take the public press and charitable agencies more into their confidence.

Pathological Technique. A Practical Manual for Workers in Pathological Histology and Bacteriology, including Directions for the Performance of Autopsies and for Clinical Diagnoses by Laboratory Methods. By F. B. Mallory, M.D., Associate Professor of Pathology, and J. H. Wright, M.D., Instructor in Pathology, Harvard University Medical School. Third Edition, Revised and Enlarged. Philadelphia, New York, London: W. B Saunders & Company, 1904.

This laboratory handbook has already gained for itself a permanent place in the working library of the active pathologist or bacteriologist. It contains what is most useful of the voluminous literature of laboratory technique, expressed with sufficient fullness to make successful application of the methods described a comparatively simple matter, while the size of the volume is kept within reasonable limits through the omission of much of the obsolete material that so often cumbers the pages of books on this subject The authors are progressive investigators, who have themselves contributed many ingenious and valuable methods to pathological research, and their statements always have the stamp of authority.

The last eighteen months have been particularly fruitful in additions to this field of research, and we find that most of the innovations have been incorporated in this edition. Among them are methods for the isolation of typhoid bacilli from the fæces, sections on the bacilli of dysentery and of chancroid, containing certain improvements in the methods of their isolation, improved methods for imbedding and manipulating frozen sections by Wright not published before, the latest staining methods of Weigert, Wright's blood stain and directions for its application to blood films and malarial parasites, the methods of cytodiagnosis and inoscopy in the examination of serous fluids, Mallory's stain for fibroglia fibrils, etc. The new photographs of malarial organisms are excellent, though we believe that for teaching purposes at least photomicrographs are never as satisfactory as well-executed colored plates.

Society Reports.

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting, November 1, 1904.

JOSEPH FRAENKEL, M.D., PRESIDENT PRO TEM.

Two Cases of Bilateral Symmetrical Atrophy of the Thenar Eminence.—Dr. I. ABRAHAMSON reported these cases. The first patient was a woman, sixty-two years old, whose family and personal history was negative. Her occupation was that of a housewife, which necessitated putting her hands in water a great deal, and she also assisted her daughter at needlework. Eight years ago she first began to experience numbness and paræsthesia in both hands, with beginning atrophy of the thenar muscles, chiefly the flexor brevis pollicis. There were no trophic skin changes, and no nerve tenderness. The atrophy was symmetrical in both hands.

The second patient was a woman, fifty-two years old, a native of Hungary. Her occupation was that of a housewife. The symptoms were similar to those in the first case, but the paræsthesia was most annoying at night. There was marked symmetrical atrophy of both thenar eminences. The speaker said he regarded both of these cases as examples of acroparæsthesia with subsequent atrophy.

Dr. CHARLES L. DANA said the unusual feature of these cases was the symmetrical character of the atrophy affecting both hands. Not long ago, the speaker said, he saw a case of atrophy of the thenar eminence of one hand, with paræsthesia and evidence of neuritic disturbance. In this instance the condition had been produced by the Vardon grip in playing golf. In another case the patient was an elevator boy, and the neurosis had been produced by pulling on the wire rope of the elevator. While these occupation neuroses were not particularly rare, bilateral and symmetrical cases of this kind were extremely so.

A Discussion on the Classification of the Melancholias.—Dr. CHARLES L. DANA opened this discussion. He stated that the term melancholia indicated to the psychiatrist a combination of symptoms varying in groupings, duration, and intensity, but beneath all a dominant condition of painful emotional depression. It might occur as a symptom in various organic and degenerative cerebral diseases, but it was recognized in particular as a manifestation of two functional states: first, that occurring at about the period of involution or change of life, and later; second, that occurring in early and early middle life. No one, the speaker thought, disputed the distinctive character of melancholia of the first type as it occurred in middle and late life. The "melancholia of involution" was a chronic and incurable disorder. It was a psychosis accompanied with anxious, worrying apprehension, and was often a natural evolution of the constitutional worrier. It was characterized by hypochondriacal and obsessive ideas, dysthesia, and somatic delusions; by hallucinations, self-accusations, and at times by suicidal ideas and impulses. There was complete self-absorption, narrowing of consciousness, enfeebled attention and power of concentrated or constructive thought. There was no clouding of consciousness, nor retardation of thought, nor dementia. It was an agitated, worrying hypochondriacal psychosis.

The melancholias which were seen especially during early life, and were at least characteristic of that period, had not such a single, definite picture. That form which had been described as acute melancholia, however, was in its typical form a sharply defined condition, characterized by profound emotional depression, retardation and difficulty of thought, clouding of consciousness, and other phenomena familiar enough to all. This form of melancholia, we were told by Kraepelin and his followers, was not really melancholia, but only the melancholic phase of manic-depressive insanity, and it was proposed to substitute this term for all or most of the functional melancholias not belonging to the melancholia of involution. Hence we would have but one real melancholia, the chronic form of later life.

Dr. Dana said he had been trying to fit this scheme to his experience, and for that purpose he had looked over the histories of over 400 cases occurring in his private practice. Of these he had closely analyzed 130, which he had seen more recently and in many instances followed for a long time. From this analysis he had reached the conclusion that chronic melancholia, under the classification of Kraepelin, was indeed a special disease, but not in all cases one of the involutional period. In its milder types especially it seemed to him that we saw pictures of it that would be called anxiety psychosis, or depressive neurasthenia, and it was not unreasonable to suppose that in psychopathic individuals, or those with a special hereditary tendency, the nervous system should be subject to early chronic melancholia. He thought it possiblbe that this same worrying psychosis might appear at the period of adolescence, when the disease was less intense, the somatic and sensory disturbances less severe, but the mental state essentially the same. The sharply defined delusional melancholia of early life, with great activity of thought, clearness of memory, intense self-accusation, and powerful suicidal impulses belonged more to this type than any other. The association and alternation of mania with early, simple recurrent melancholia, was an established fact, and the term manic-depressive insanity fitted this group of cases admirably, but in the speaker's list of 400 cases of melancholia, mostly not asylum types, there was a history of mania in only 8 per cent. It seemed rather forcing the issue, therefore, to use the term manic-depressive insanity for these patients, who never had any mania. He was inclined to regard the melancholias of early life as simple melancholias of the involution type—or preinvolutional, if that seemed a better term. He would at least consciously associate their disorder to that form seen more typically and severely later in life. He would say that there were a great number of simple, functional, often recurrent melancholias that belonged to the manic-depressive type by reason of the neurasthenic and apathetic condition, the absolute loss of interest in life, and psychomotor sluggishness and enfeeblement, but he saw no reason to use the term manic-depressive insanity here. He would only use the term manic-depressive insanity when there was evidence of it.

Dr. M. ALLEN STARR said that Dr. Dana's remarks regarding melancholia would appeal to every neurologist and practitioner who did not constantly come in contact with the severer types of insanity. Those who were doing asylum work, however, might meet with considerable difficulty in grouping certain of the cases. Perhaps five per cent. of the cases in the average asylum could not be positively assigned to any definite group. The speaker said he was glad to hear Dr. Dana make a distinct protest against the term manic-depressive insanity. He had never been in sympathy with that term, for the simple reason that it did not coincide with our clinical experience in this country. He had carefully reviewed the records of about 280 cases that he had classfied as melancholia, and he saw no reason to protest in any way against the classification that was proposed by Krafft-Ebing years ago, namely, simple melancholia, melancholia with delusions, and melancholia with delusions and agitation. Those three types embraced distinct varieties of the disease. The speaker said he also agreed with Dr. Dana that the type that rose to the stage of mania was extremely rare, in his own experience probably not exceeding five per cent. of the total number of cases observed. He thought it would be very unfortunate, therefore, to label these patients with a term like manic-depressive insanity, in spite of the fact that in 95 per cent. of the cases there was no mania whatever. Dr. Starr said that a careful study of his cases of mild melancholia had impressed him with the idea that the condition was a purely toxic neurosis. The symptoms were most severe in the early morning, and passed off largely during the day. Sixty per cent. of his cases never passed beyond the simple melancholic type, which was not the

type met with in the insane asylums. The patients he had in mind were entirely conscious of their surroundings and of their own condition; they were in extreme dread of insanity, and they were not suitable subjects for an insane asylum, and to incarcerate them in such an institution would be an outrage. About 35 per cent. of his cases corresponded to the delusional type, and required watching to prevent suicide.

Dr. Starr said he would like to impress upon the Society the existence of a true toxic melancholia. In fully 60 per cent. of his mild cases he believed that he had to deal with a purely toxic neurosis, and if we could eliminate that poison we could cure the patients. He had noted that any intercurrent disease, such as grippe, pneumonia, or malaria, that produced a decided change in the chemistry and nutrition of the body, arrested the symptoms in these mild cases of melancholia, and he had produced the same effect by the use of thyroid extract. Under the administration of this agent the symptoms of melancholia would be immediately relieved and remain absent until the temperature again dropped to normal.

Dr. Adolf Meyer said that his experience with the melancholias had naturally been of a different sort from that of Drs. Dana and Starr, having been largely confined to patients who were already committed to the asylum. His observations had led him to conclusions which did not essentially differ from those of Dr. Dana, although for practical reasons he would rather favor a different classification. On the whole, he was desirous of eliminating the term melancholia, which implied a knowledge of something that we did not possess, and which had been employed in different specific ways by different writers. If, instead of melancholia, we applied the term depression to the whole class, it would designate in an unassuming way exactly what was meant by the common use of the term melancholia; and nobody would doubt that for medical purposes the term would have to be amplified so as to denote the kind of depression. In the large group of depressions we would naturally distinguish our cases according to etiology, the symptom-complex, the course of the disease, and the results. A distinction into acute and chronic forms was not consistent with experience. Dr. Hoch found that all attacks tended to become longer in advanced years. The distinction had best be made according to the intrinsic nature of the depression. From that point of view we might distinguish the pronounced types from the simple insufficiently differentiated depressions. Besides the manic-depressive depressions, the anxiety psychosis, the depressive hallucinations, the depressive episodes of dementia præcox, the symptomatic depressions, non-differentiated depressions would occur; especially the differentiation of the dementia præcox type frequently caused difficulty, where stupor and catalepsy supervened. The speaker said he was somewhat surprised that no reference had been made to the difficulties in determining the depressions of dementia præcox. He took exception to Dr. Starr's statement that mania was but a rare event and only to be expected in the most agitated cases. He could not recall a single instance where a case of the pure agitated type developed mania, while on the other hand, the type that did not show the agitation, but a great deal of inhibition and subjective inadequacy, was the form that might develop mania.

Dr. Meyer said that he would rather hesitate to accept Dr. Starr's idea that the intermission in the symptoms of melancholia produced by febrile disturbances proved the toxic origin of those symptoms, because an intercurrent disease was apt to produce a change in the symptoms of almost any mental disorder. The shortness of the time for discussion did not permit the review of about 300 cases of depressions to be reported on another occasion.

Dr. Ralph L. Parsons said that some years ago he made out a classification of the insanities that was provisional only, because the facts upon which to construct a scientific classification did not exist then nor did they exist at the present time. Different types of insanity were often very closely identified, and during the same attack the patient might exhibit symptoms of mania, melancholia, and dementia. Dr. Parsons then exhibited a table that he had devised, in which the melancholias were divided into many different types descriptive of their cause, such as adolescent, puerperal, etc.

Remarks on Melancholia.—Dr. Joseph Collins continued the discussion in a paper with this title. (See page 1007.)

Dr. B. Sachs said that in a discussion of the classification of the melancholias there was danger of going to extremes in both directions, and making the classification either too wide or too narrow. Under the inflence of Krafft-Ebing and the older French and German writers the term melancholia was much abused. It should be restricted, he thought, to those cases in which there was a slowing up of all mental processes, associated, perhaps, with some self-accusation. This formed a very definite clinical picture, and he saw no reason why it should be eliminated. On the other hand, there were various forms of depression which could be differentiated from melancholia. In private practice he frequently made the diagnosis of simple depression; this he regarded as a transitory condition, and it had never occurred to him to look upon it as true melancholia, which was a true and very often a serious psychosis. To his mind, pure melancholia had always represented a typical and grave disorder. The question arose whether to discard the older classification entirely in favor of the more recent one of Kraepelin, with its comprehensive term of manic-depressive insanity, which included all types of melancholia, circular insanity, and what not. In picturing manic-depressive insanity, Kraepelin had shown great genius and insight, and Dr. Sachs said he indorsed that writer's wisdom in putting clearly before the medical public the existence of a large group of cases that were characterized by typical symptoms. There could be no doubt about the existence of such a group, but he could not agree with the dictum of Kraepelin that all cases of melancholia were merely one stage of manic-depressive insanity.

Dr. A. R. Diefendorf, of Middletown, Conn., said he was surprised by the difference of opinion regarding the melancholias as expressed by the neurologists and those who saw these cases in asylums, as it was certain that all the cases that eventually came to the hospitals for the insane had passed through the hands of the practitioner and specialist. As regards simple melancholia, there were several groups of those cases. There was one group in which the characteristic symptoms were mental sluggishness, a feeling of insufficiency or inadequacy, a lack of energy, an increased sense of fatigue, a slowing of the train of thought, difficulty of comprehension, perhaps a few indefinite hallucinations, and possibly a few delusions. The emotional attitude of these patients was one of simple despondency. They took an abnormal view of life. There was another type of simple melancholia that occurred early in the course of senility.

Dr. Edward D. Fisher said he would certainly agree with the view that we had to deal with a simple melancholia which was distinct from that described by Kraepelin. Kraepelin's cases were those of later life, and differed from the melancholia which he found in manic-depressive conditions. There was in his so-called melancholia not so much absolute retardation of thought as in the class of cases of the manic-depressive type. Dr. Fisher said he had seen a number of cases occurring in young persons, perhaps about the age of 25, where they simply presented a psychosis which was described as melancholia, and where the patients made a complete recovery within three to six months. He could recall one case in which at least fifteen years had elapsed since such an attack, and there had been no signs of a recurrence. The speaker said he was certainly in favor of retaining the term simple melancholia, and he also believed decidedly in the manic-depressive type.

Dr. L. Pierce Clark said he was not in favor of the term

involution melancholia. He thought the psychosis of the climacteric or the melancholia of involution should more properly be called an anxiety psychosis, because that seemed to be the great predominating factor. In the differential diagnosis of manic-depressive insanity and involution melancholia, the one essential feature was the retardation.

Dr. A. J. Rosanoff said it was well known that depression was the most common symptom encountered among the insane. He thought that all forms of mental disease, without a single exception, might present this symptom. This fact perhaps accounted for the statement of the older writers with regard to the frequent occurrence of "melancholia." At the institution with which he was connected, and probably also at all other asylums, a considerable proportion of the depressed cases admitted had to be set aside as unclassified. The majority of these patients ultimately developed one or the other of the typical syndromes, but a small group still remained which could not be classified among the well-known psychoses. This group contained about five per cent. of the total number of depressed cases admitted to the asylum. This was merely a rough estimate, but the speaker said he felt assured that it could not be far from the actual figures. It had been proposed to designate these cases as "simple melancholia." It seemed to him that any generic term would be entirely inapplicable to an extremely heterogeneous group of psychoses, such as these.

With regard to manic-depressive insanity, Dr. Rosanoff said it must be remembered that many patients presented during their whole life nothing but a number of attacks of simple depression. The diagnosis was made not at all from the occurrence of manic and depressive episodes in the same individual, but chiefly from the exceedingly well-defined symptomatology. He thought that Kraepelin had selected this term for the disease for the purpose of indicating simply that its manifestations might be either depression with retardation and dearth of ideas, or elation with restlessness and flight of ideas, or a mixture of these phenomena, but not that each individual case must present all the possible manic-depressive episodes. Some of the depressed cases of this disease were so mild that the patients were not committed, and were even able to continue their occupation; but even those cases presented the characteristic features of the disease, and one experienced in making the diagnosis of manic-depressive insanity would not have much difficulty in recognizing them.

The occurrence of melancholia with anxiety and agitation at a comparatively early age had been referred to. The resemblance between these cases and those of involution melancholia of Kraepelin was only a superficial one. The speaker thought that probably almost all of them belonged to the dementia præcox group. On analysis their depression was found to be extremely shallow, it being at times but a simulated depression. Moreover, they presented mannerisms, stereotypy, neologisms, negativisms, emotional deterioration, and delusions of an exceedingly absurd or even impossible nature, contrasting with perfect orientation, intact memory for recent and remote occurrences, and a surprising alertness with regard to their surroundings.

Dr. Dana, in closing, said that, on the whole, the position he had assumed in his paper had been largely sustained by those who had taken part in the discussion. He still insisted that we had two forms of melancholia, with a third that belonged more or less to one or the other. The two forms were the involution type and the manic-depressive. Outside of these, there were many cases of simple depression, which he had learned from experience would never be anything else but simple depression, but which, if closely analyzed, would be found to belong to either the manic-depressive or the involution type. In his paper, the speaker said, he had confined himself to the functional types of melancholia, disregarding the group of simple symptomatic melancholias occurring in the course of organic brain disease. The classification devised by Dr. Parsons was very practical and interesting, especially for those working in institutions, but, of course, it was not intended as a text-book guide of melancholia.

A Case of Bilateral Facial Hemiatrophy.—Dr. Edward D. Fisher presented this patient, a young girl, who about two years ago had an attack of persistent vomiting. Following this, progressive wasting of both sides of the face was noticed. There seemed to be no atrophy of the bone, but absolute loss of subcutaneous tissue. There were no sensory disturbances; no electrical changes.

Dr. B. Sachs said the case was unique, so far as his experience and reading went. It differed from the ordinary facial hemiatrophy in the wide distribution of the lesion, and the absolute disappearance of the subcutaneous fat without involvement of any of the other tissues. It was certainly not a scleroderma. The girl's body was apparently well nourished.

The Nature of the Nerve Lesion in Brachial Birth Palsy (Erb's Type).—Dr. Thomas P. Prout read a paper on this subject. He stated that in order properly to appreciate the pathology underlying brachial birth palsy (Erb's type), the etiology of the over-stretching process in its production must be borne in mind, in sharp contradistinction to the oft-repeated statements in the text-books that it is produced by direct compression of the nerve trunks between the clavicle and the transverse processes of the vertebræ, or the clavicle and first rib. It is possible that the Erb syndrome may be produced in this manner, but when it occurs, the behavior of the case is very different from that observed in the cases he was here considering. Pressure lesions in nerve bundles, if uncomplicated, recover rapidly, whereas in these cases we have some condition of a permanent character in the nerve bundle which prevents complete recovery. The cases in which the only etiological factor is pressure recover within a year or eighteen months. The cases he was here considering reach a certain stage of recovery, and then present a permanent palsy of greater or lesser extent. What pathological lesion rendered these cases permanent?

The behavior of the perineural sheath (a dense, connective tissue structure surrounding and supporting the nerve strands) during the process of repair, is of great importance. Since this structure supports the nerve strands, its rupture occurs as a primary factor in the cases here considered. In fact, in any nerve lesion produced by an over-stretching process, this supporting sheath must first give way. In these cases it is torn asunder, and the arterioles belonging to it and supported by it are ruptured. A hemorrhage into the substance of the nerve and its sheath results. These facts have not heretofore been recognized in the literature of this subject. They are of the greatest importance, since they determine the ultimate extent and final character of the lesion. Were it not for the obstructive features of the repair process in the nerve sheath, we might expect a more or less complete recovery, in the vast majority of instances, without operative excision and suture.

Photomicrographs were shown of a case in point. (In all, four cases had been examined to date.) In this instance, only the fifth and sixth cervical roots were involved at the usual seat of the lesion, their junction to form the plexus. The perineural sheath presents many old dense pigment deposits, the site of old hemorrhages. In some portions, the perineural sheath is buckled inward upon the nerve fibres, strangulating them and preventing their regeneration. Evidences of strangulation are not only present at these points, but also in the nerve fibres underlying the pigment deposits. There is obliteration of the myelin sheath immediately beneath these areas, and fragmentation of the myelin sheath above and below. In the more severe cases, the strands of the plexus involved came to an abrupt termination in a mass representing an old organized hemorrhage. In these instances, there is a severing

of the nerve fibers, which are often thrown into folds for some distance from the site of the primary lesion.

The importance of these lesions cannot be over-estimated. Repair of the nerve sheath takes places before regeneration of the nerve fibre, and if this has buckled inward upon the nerve bundles following the relief of tension, the nerve fibres are inevitably going to be strangulated and their regeneration prevented. The same applies to the organization of an old hemorrhage impinging upon nerve strands. The nerve fibre may or may not be ruptured. However this may be, the pressure of the old hemorrhage and the cicatrix in the perineural sheath are sufficient not only to prevent regeneration in the severed nerve fibres, but to determine a neuritis in those not severed, and prevent their regeneration.

The sequence of events in the production of the obstetrical birth palsies may be summarized as follows: The lesions are (1) immediate and (2) remote. The immediate lesion consists in a tearing of the perineural sheath surrounding and supporting the nerve trunk, and the incidental rupture of the blood-vessels belonging to it. Hemorrhage occurs into and beneath the perineural sheath. There is, furthermore, a severance of the nerve strands more or less complete, depending on the severity of the case.

The remote lesion is brought about and its extent determined by (a) the healing of the perineural sheath; (b) the organization of the blood-clot; (c) the ultimate contraction of the cicatrix upon the nerve strands, which not only prevents their regeneration, but determines a pressure neuritis in those not severed upon which it may chance to impinge. This factor is of very great clinical importance. An infant in whom this accident has occurred, who remains more or less continuously peevish and fretful for some time afterwards, and in whom the handling of the extremity greatly increases its pain and irritability, is sufferng from a traumatic neuritis due to pressure upon certain nerve strands of the organizing blood-clot and the contraction of the cicatrix in the perineural sheath. Cases that do not present this symptom have been produced by simple trauma to the nerve, without rupture of the perineural sheath, and will recover spontaneously, while in those cases presenting this sign of a neuritis, a considerable palsy will follow, depending on the severity of the lesion. These facts have an important bearing on treatment.

Dr. Sachs said that a certain number of brachial birth palsies of the Erb type were due to pressure, and nothing else. A large proportion of the cases were absolutely painless; there was simply numbness, but no pain, and no symptoms such as we would associate with a laceration of the nerve. The speaker thought that Dr. Prout took an extreme position in claiming that some of these cases, at least, were not due to pressure, and that laceration of the nerve was necessarily the cause of this type of birth palsy. There was no doubt that in some of the violent cases the nerve strands were torn, but in the large proportion of cases he thought the symptoms were the direct result of pressure and hemorrhage.

Dr. L. Pierce Clark thought from the data which he and Dr. Prout had at their command, that in the vast majority of instances the palsy was the result of stretching and laceration, and not of pressure. This was clearly demonstrated in the operative cases. In these, the recovery of the patients was uneventful, and the progress very satisfactory. The pathological work was particularly interesting, in so far as nothing like it had ever been done in connection with this type of palsy.

Dr. William M. Leszynsky said he understood from the paper that in those cases that did not undergo spontaneous recovery, surgical interference was necessary. That being the case, he assumed that Dr. Prout concluded that in all cases that recovered without operation, spontaneous regeneration of the nerve had taken place, and that those cases, therefore, had no lesion of the kind he described. The question therefore arose, when should we operate on these cases, and how could we know whether spontaneous regeneration would take place or not?

Dr. Prout, in closing, said that if spontaneous regeneration occurred, it was not necessary to operate. This could be fairly definitely known within a year or eighteen months after the birth of the child. The cases that did not recover spontaneously presented exactly the lesions he had demonstrated, which represented a condition in the perineural sheath of the nerve which prevented spontaneous recovery. It was well known that many cases recovered spontaneously, but those that did not were due to stretching, and not to pressure. Those due to the latter cause would in all probability recover spontaneously. If they did not, however, we were not dealing with a pure pressure palsy.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

Stated Meeting, Held December 2, 1904.

Dr. Robert T. Morris in the Chair.

The Results of Four Plastic Operations.—Dr. Carl Beck presented a case of crushing injury of the thumb, a fracture of the first phalanx being shown by skiagraph. If he had treated the patient upon general principles he would have amputated the thumb and then disarticulated the finger in order to get sufficient skin to cover the stump. He tried transplantation of the toe, but on the fifth day following he found that it was to be a failure. Therefore he dissected the skin up from the thoracic region, grafted this in place and got an admirable result.

The second case was that of a man whose face and dorsum of both hands had been severely burned. He was treated at St. Mark's Hospital for several weeks, when it was found that the left hand would have to be covered by skin. Two oblong incisions were made a little anterior to the mammary region, the flaps were undermined and the hand thrust through and fastened there for nine days. This was successful and there was not much disturbance in the function of the hand.

The third case was that of a woman who had an extensive necrosis of the frontal bone. Dr. Beck formed a large osteoperiosteal flap from an area adjoining the defect, twisted it around, and fastened it in place with a perfect result. The defect on the top of the skull was covered over by hair, and the existence of bone was shown by skiagraph.

The fourth case was one of webbed fingers, in which he had tried to separate the fingers and cover with sufficient flap. His success was very good.

Dr. Sturmdorf asked, regarding the defect on the dorsum of the hand, why he did not do an ordinary Thiersch grafting.

Dr. Robert T. Morris said that plastic work during the past decade had undergone many changes, and that heterogeneous grafting was no longer done, because, if attempted, we were almost certain to have absorption of the flap. This was first noticed in attempts at implanting teeth.

Dr. Beck, in reply to Dr. Sturmdorf, said that the hand treated was burned to the third degree, and, under such circumstances the Thiersch method would not have sufficed to ensure functional ability of the hand.

Fracture of the Skull.—Dr. Alexis V. Moschowitz presented a child who had suffered a depressed fracture of the skull from a fall. The fracture was two or three inches in length and one-half an inch broad. The operation performed was according to the method of Heidenheim. Hemorrhage in these cases was usually very great, but by this method very little blood was lost.

Fracture of the Patella.—Dr. Moschowitz showed a young man who, six and a half weeks prior to admission to the Mt. Sinai Hospital, fell four stories. He came to the hospital because of inability to walk. There was a fracture of the patella, and the lower fragment was no larger than the finger tip. There was some separation. The speaker

sutured this small fragment to the patella. The result was almost perfect, as shown by the various movements of flexing the leg on the thigh, and the extended lower extremity on the abdomen.

Technique of Exposure of the Spinal Cord.—Dr. W. S. Bickham read this paper and illustrated the various points in the technique by pictures thrown on the screen. He first considered the relative values of osteoplastic resection of the spine and laminectomy. After laminectomy, patients had such a weak spine that in many instances they had not been able to sit up or even hold their heads up. The osteoplastic resection should be the operation of choice, this being a more surgical procedure. To-day there were many more laminectomies done than osteoplastic resections, and the reason for this he attributed to the fact that the latter operation was so little understood by surgeons. With regard to the features common to both operations, he considered the preparation of operation site, the preparation of patient, surgeon, and assistants, the anæsthetic, the instruments and accessories necessary, the landmarks for operation, the manner of incising the skin, muscles, and aponeurosis, the manner of clearing the soft parts from the spine and lamina, the manner of dividing the lamina, the instruments for making bone resection, the osteoplastic resection, the control of hemorrhage. He then considered the technique of osteoplastic reaction of the spine as follows: The incision, the exposure of the spinous process, the severing of the supraspinous and subspinous ligaments, the excision of the spinous process, the temporary packing of the preliminary wound, and the final suturing of the preliminary wound. Then the forming and turning back of the osteoplastic flap was considered as follows: Incision, division of muscles and aponeurosis, freeing the lamina preparatory to packing, division of lamina and sublaminous ligament, division of the supraspinous, intraspinous, and interlaminous ligaments, separation and turning back of the periosteal flap, freeing the spinal canal of vascular and fatty areolar tissue, opening the membranes of the cord, manner of dealing with membranes, the reposition of the composite flap with the finger of the left hand, the buried sutures in muscles and aponeurosis, the fascial and skin sutures, the provision for drainage when indicated, and the after-treatment. The technique of laminectomy was shown in this same way by means of lantern slides.

Dr. George Woolsey said he had had a number of cases of late in which he had performed laminectomy for tumors of the spinal cord, and in all cases the situation of the tumor was high up in the lower cervical region. From his own experience he said he could not say that the osteoplastic resection was to be preferred to laminectomy—indeed, the former did not seem to be as favorable a procedure as the reader of the paper had pointed out. There were certain objections. In looking up the subject, he found a number of German operators who performed the osteoplastic resection of the spine, and, in one instance, a fatal result was attributed to this method; and another man discarded this operation, saying it should not even be attempted. In every case the operation was for removal of tumors, and always three laminæ were exposed, and often more. He said that with the best localization we could get, the neurologists were liable to error, and often the operation must be extended in one direction or the other; after forming the osteoplastic flap such an extension must present embarrassment in execution and often endanger the vitality of the flap.

Dr. Algernon T. Bristow said that we should all welcome any improvement in technique in these operations, but we should remember that operations anatomically perfect often resulted in the death of patients; patients might die even when subjected to perfect technique. In operating for injuries, we should remember that we were dealing with an organism that had already received a severe injury, and the time of operating and the amount of traumatism inflicted were important factors in determining whether or not the patient would recover. The bodies of the vertebræ were the supports of the spine, and after laminectomy there should not be any great weakening of the spine. In one case he had removed six or seven laminæ, and the patient was shown at the Surgical Society of Brooklyn, the patient walking up several flights of stairs.

Dr. W. S. Bickham said no difficulty was encountered in extending the wound after osteoplastic resection.

Hæmaturia as a Symptom of Hydronephrosis.—Dr. L. Bolton Bangs said that with the exception of Israel authors made very little mention of hæmaturia as a symptom of hydronephrosis. In the past few years but thirteen cases had been reported. Hydronephrosis *per se* was a comparatively rare disease in this country, for nowhere in American literature were recorded any series of cases and individual experiences like those of Israel, who reported forty cases, among them being nine cases with hæmaturia as a symptom. It was inferred, therefore, that either the better conditions under which our people lived prevented this form of renal disease, or else American writers had not thought it worth while to publish their cases. Among the chief causes of hydronephrosis given by authors were: (1) Obstruction to the outflow from the kidney, due to something developed in the kidney itself, as, for example, calculus or new growths; (2) such changes in the position of the kidney as disturb the relation of the ureter to the kidney; (3) obstruction in the course of the ureter. Israel considered changes in the position of the kidney to be the most frequent cause of hydronephrosis, and that it could take place as the result of abnormal obesity, or of a congenitally low situation of the kidney. At the time of doing nephrotomy, Dr. Bangs had satisfied himself that there was no calculus either in the kidney or in its pelvis, and that there was no obstruction in the ureter. The report from the laboratory eliminated the question of neoplasm, but threw no light upon the etiology. Nor did analysis of the clinical history clear up the causation. The patient had been in unusually good health from his infancy up, and there was no history of traumatism; there was only a history of renal colic, or of pain located in the left side; and prior to the onset of nausea and general malaise there was no symptom indicating the beginning of his malady. The time when the blood first appeared in the urine was also vague and indefinite, for its presence seemed not to have been noticed until the fact was so stated by the first consultant. The obstinate constipation, of which he complained and which appeared to be the cause of more misery than any other symptom, was no doubt due to pressure of the renal tumor upon the descending colon; he did not suffer from this after the nephrotomy had reduced the size of the tumor. Therefore, how long the nephrosis had existed and what was its cause there was no means of knowing. The character of the hæmaturia was worthy of some study. The presence of blood in the urine was intermittent and variable in quantity, the latter being increased by light trauma, such as the jolting of a wagon, or by the manipulations of the kidney necessary to a diagnosis, but at no time had there been a serious amount of blood in the urine. After the nephrotomy, the only blood which appeared was found once in the urinous fluid coming through the drainage tube. He had examined the urine from the bladder for nine months, as well as the fluid from the sinus, and at no time was blood found, even microscopically. The degree of hemorrhage during the extirpation of the expanded and attenuated kidney seemed noteworthy. In the speaker's experience, even when deliberately and freely incising a fairly normal kidney for different operative purposes, and even when the manipulation of the incised kidney was prolonged, there had never been any loss of blood in such proportion as to jeopardize the patient. In this case there seemed to be very little kidney tissue left where the incision was made, and the blood appeared to come from the interior of the sac, and not from its cut edges. The patient made a good recovery, and about one year after the nephrectomy made an application for life insurance. In due time the Medical Department wrote for an opinion

as to the young man's longevity. He replied that he had no opinion as to the longevity of a person with one kidney, but that he knew of patients who were well and comfortable and apparently living out their time with one kidney doing all the work.

The Importance in Surgical Cases of Correcting Defective Unstriped Fibre, with Suggestion of Methods.—Dr. Alfred T. Livingston of Jamestown, N. Y., read this paper. He said that the perfect health of the entire organism depended upon normal activities of the circulation everywhere, but the equable distribution of blood in the human body was rare. The most important element in shock he considered to be a disturbance of the normal distribution of the blood; the blood in the peripheral vessels was crowded into the central circulation; there was not enough blood in the peripheral vessels for the heart to contract upon, and the central vessels were overstretched; this accounted for the lowering of the blood pressure. In such cases the use of saline solution was illogical, since a more vigorous action of the heart might be detrimental because of the then existing tendency to increase the abdominal engorgement. If one should try to cause the contraction of the central vessels, then shock would disappear. In operations there were three sources of shock, viz., traumatism, anæsthesia, and the operation. In ordinary operations there was always this double shock, and in cases of injury it was threefold. The patients should be prepared by toning the unstriped muscular fibres, especially those that are deficient in tone. Ergot was the drug of great value in the prevention of shock, toning up the unstriped muscular fibres of the blood-vessels in particular, but it should be given before, during, and after operation in the manner indicated by the speaker in his many papers upon this subject. The vomiting following operations when anæsthetics were given was chiefly due to an abnormal relaxation of the vessels at the base of the brain, and in such cases toning up the blood-vessels by ergot resulted in greatly lessening or entirely controlling this annoying feature. In the majority of cases pain was a sign of vascular plethora about the nerve, and the degree of pain was proportionate to the amount of pressure. The relief of this pain was best obtained by toning up the unstriped fibres, rather than by the giving of opiates. Most surgeons believed inflammation to be due to microorganisms, but the speaker believed it was due to a relaxed state of the blood-vessels, and if we controlled this relaxation inflammation would not occur. Inflammation could not develop or continue unless there was congestion, and this meant a relaxed condition of the unstriped muscular fibres; this could be readily corrected by the use of ergot. The process of healing and repair could be greatly aided by the use of ergot. The various methods of correcting relaxed muscular conditions was then considered under the following headings: (1) Massage, (2) dry cupping, (3) cold, (4) electricity, and (5) ergot. What he wished especially to emphasize was the action of ergot in producing a tonic effect upon the unstriped muscular fibre. Its hypodermic use was referred to only.

Dr. H. Grad said the profession owed Dr. Livingston thanks for bringing the matter so prominently forward. In the ordinary run of surgical cases, in the speaker's experience, the administration of the drug certainly brought about a state of nerve calmness and mitigated to a remarkable degree the nausea, retching, and vomiting following anæsthesia. This might be caused by the mucous that accumulated in the stomach, derived from the pharynx and from the respiratory tract, and also secreted in the stomach itself. It was also claimed that the mucous membrane of the stomach excreted the ether, causing the irritation. This irritation caused a congestion, and this in turn caused a hypersensitive condition of the nerve endings, and hence the vomiting. Irritation of the vomiting center in the medulla also might be the result of ether circulating in the blood. If these etiological factors were operative alone, then ergot would control the vomiting to a very great extent; but if the causes of the vomiting were different, then the administration of ergot would not be effective. Ergot also acted beneficially upon the shock as well, and whether this beneficial effect was an indirect one, by removing nausea and retching and relieving pain, or whether the therapeutic effect was due to bringing about a state of equilibrium in the circulation of the brain, and thereby exerting a calmative effect directly upon the cells of the central nervous system, he could not say, but he had reasons for believing that this latter was the case. When an anodyne was needed in operative cases, he found the administration of morphine together with ergot to be more effective than if morphine had been given alone, and the effect of the agent was more lasting.

Dr. Frederick Holme Wiggin spoke of his experience with ergot in preparing patients for operation, and in the prevention of shock, and also in the treatment of intestinal paresis. It had also been of great service to him in the treatment of epididymitis.

Dr. Bristow said that he had not used ergot as frequently as he felt that he should have. He had used it in peritonitis, but not in a sufficient number of cases to state positively that recoveries were due to its influence.

Dr. Osborne said that in surgical shock much might be done in the way of prevention, but in medical shock, so-called, nothing seemed to be of value. The cases described by Dr. Livingston were due to vasomotor disturbances, with the peripheral blood-vessels depleted and the abdominal vessels distended; in these cases it was apparent that the use of saline solutions was not indicated. The circulation should be equalized, and if ergot would do that a triumph would be attained in the treatment of shock.

Chicago Surgical Society.

At a meeting which was held December 5, 1904, Dr. Arthur Dean Bevan read a paper on "Actinomycosis," in which he referred to the early history of this disease, and stated that the disease manifested itself in four different forms, with four routes of infection, namely, head and neck actinomycosis, with infection from the mouth and pharynx; actinomycosis of the chest through the respiratory tract; abdominal actinomycosis, with infection probably always through the alimentary canal, though possibly in some instances the infection might come by way of the female genital organs; and actinomycosis of the skin. He reported several cases, in one of which there was invasion of the lymphatics. The different forms of the disease were illustrated by the citation of cases, and numerous microscopic slides were shown. Dr. John B. Murphy, in the discussion, stated that the lymphatic glands were not involved in any of the cases he had seen, nor was the infection transmitted through the lymphatic chain and arrested in the lymphatic glands. He mentioned the great infiltration that occurred around small foci of suppuration, and said that this was one of the first things that riveted his attention in the first case of actinomycosis he saw in 1883. This was a typical case of jaw actinomycosis, the infiltration having extended down to and involved the neck to the extent of an inch or more on each side. When the involved area was opened, a number of characteristic bodies escaped. As to treatment, Dr. Murphy's first, second, and third cases recovered, while a fourth one of peritoneal actinomycosis terminated fatally. He had seen two cases of actinomycosis of the appendix, one of his own, and the other in consultation with Dr. Lee. In the first the actinomycotic process was confined practically within the appendix. The appendix was removed, followed by recovery of the patient. The case of Dr. Lee took a different course. Dr. E. Wyllys Andrews stated that most of the patients he had observed had either died or, if they were alive, there was an increasing actinomycotic mass in some part of the body. He recalled the case of a man who had a mass in his chest and who, he thought, was going to die. These cases should be worked up with exceeding care. A comparatively small number of cases of actinomycosis were found to

involve the upper intestine. He thought in nearly one-half of the cases reported the actinomyces were found in the cæcum and in the appendix. Dr. M. L. Harris reported three cases of actinomycosis, regarding them as instances of hematogenous infection. The first patient, a boy, had a slowly developing swelling in the prevesical space, which presented the characteristic hardness. This mass was opened and a small amount of pus obtained. Inoculations from the pus gave a pure culture of the staphylococcus pyogenes albus. No granules were recognized in the pus which was first evacuated, but on the dressings a few days later the characteristic granules were seen, and when submitted to the microscope, proved to be actinomyces. The case progressed, the exudate spread, sinuses and fistulæ were formed about the abdominal wall, and into the lateral wall of the pelvis. The patient was subjected to several operations; the tracts were thoroughly cleared out, and during the operations the abdominal cavity was opened, because the speaker suspected the actinomycosis to be of primary intestinal origin. It was found that the abscess did not have its origin in the appendix, nor could he find any point in the intestinal tract which was involved, so he was unable to explain how the infection reached the prevesical space, except through the blood. The patient was subjected to all the recognized treatments for actinomycosis. Iodide of potassium was given internally—continually and interruptedly; he was given *x*-ray treatment thoroughly, but in spite of all treatment the patient progressed from bad to worse, and died after a period of several months. There was marked reduction in the hæmoglobin in this case before death. The two other cases were detailed at considerable length. Dr. A. J. Ochsner stated that he was almost never without a case of actinomycosis, and that the disease was more common in Chicago than was formerly supposed. He had one such case under treatment at the present time. He recalled half a dozen cases, in which there was involvement of the face and neck, one in which the larynx was implicated, in a number the abdomen was involved, in another the eighth rib, and in others the appendix. He had had two or three cases of actinomycosis of the lungs. As to treatment, he recommended giving large quantities of iodide of potassium for several days in succession, then interrupting its use for days, giving the spores time to develop, after which the dose could be repeated for a day or two, again withdrawn for a day or two, repeated again, etc. This was the method of treatment resorted to by veterinary surgeons when the actinomycotic process was localized in cattle, and was followed by excellent results. Actinomycosis in the human being should be treated on the same principles. Dr. L. L. McArthur narrated the case of a woman who was frequently chided by her husband for dragging at hay and chewing it while playing golf. She developed actinomycosis of the alveolar process, which required three or four months' treatment on the part of a dentist before healing took place. Ten months later she experienced pain in the right iliac region of a colicky character. Her family physician was summoned, and he, feeling a mass there, and noticing she had elevation of temperature, sent her to Dr. McArthur's service at St. Luke's Hospital. The attending physician considered it a probable appendical abscess, and in this Dr. McArthur concurred, and advised operative measures. After opening the abdomen, a tumor was found in the ileocecal region, which involved the appendix, ileum, and the cæcum for a distance of four or five inches. As the tumor appeared to him to be a hypertrophic tuberculosis, although there were no miliary bodies to be seen, with the consent of the attending physician he resected the entire ileocecal region, implanting in the side of the hepatic flexure of the colon the resected ileum. On lifting up the mass from the iliac fossa, a few drops of pus were visible on the fascia covering the iliac muscle. This was mopped up, drainage provided for, and the wound closed. The wound healed after a few weeks, the patient left the hospital, and for three months was quite well, when cough and high temperature set in, with chills and night sweats. The case was now thought to be one of acute tuberculosis. The patient was extremely ill, a tender area was found, with an enlargement in the neighborhood of the gall-bladder, and he considered the condition one of hepatic abscess with burrowing through the diaphragm. An incision over this area was made, and an abscess found which had perforated the posterior sheath of the rectus muscle, and in which were seen for the first time the typical granules, when the nature of the case was cleared up. The patient lingered along for two weeks, and then died. Post-mortem examination showed hypertrophic actinomycotic infection, from which the patient had recovered apparently, but later had developed hepatic abscesses, with perforation of the diaphragm. There were multiple stomach abscesses, which had burrowed into the diaphragm, as well as miliary abscesses along the bronchi.

The Nature of Eclampsia.—Hitschmann describes a case which is unusual in the history of eclampsia. The patient was taken with an eclamptic seizure in the fifth month, the urine containing much albumin. On emptying the uterus manually a large hydatid mole was brought to light, and the eclamptic attack was not repeated. The occurrence of eclampsia without the presence of a fœtus discredits the theory ascribing the disease to the entrance into the maternal circulation of products of fœtal metabolism, and strengthens the views of those who believe that changes in the placental cells can form a poison productive of eclampsia.—*Zentralblatt für Gynäkologie.*

Feeding and the Rest Cure in Typhoid Fever.—H. A. Hare believes that it is a mistake to confine typhoid patients to a purely milk diet. In passing through a siege of this illness himself he was continually conscious of the fact that he was underfed. Since that time, in treating cases of typhoid, he has given a varied diet of liquid and semi-solids, and is positive of the advantages of this method of feeding. The average adult requires at least 2,500 calories a day for normal existence. Each quart of milk represents from 500 to 600 calories. Thus it is evident that for a patient to receive the normal number of calories, he must drink not less than 4½ quarts of milk a day. The pure milk diet is inadequate in this disease. The writer's patients, after the first week of typhoid, receive from one to two soft-boiled eggs a day, in addition to the ordinary allowance of milk. Their diet is varied by the use of whey and curds, rice, which has been boiled to a pulp; wheat, barley, oatmeal gruel, and a cup of corn-starch, with vanilla or some other flavor. The marked ataxia so common in typhoid convalescence is rarely observed in his patients. The patients are hardly more emaciated than are many patients who have recovered from an attack of acute pneumonia. Boils and bed-sores are unknown. The patient's vital resistance is so strong that simultaneous collateral infections do not take place. On account of the deficient secretion of digestive juices, appropriate drugs are administered, such as pepsin and hydrochloric acid, when proteids are taken. The writer does not believe in the use of beef tea. He does not believe that the free use of cold water in itself is the chief factor for good in these cases, but that good feeding and thorough rubbing are most important. In other words, he advocates the employment of the rest cure in the treatment of typhoid fever. Sponging with friction, instead of the plunge, is attended by beneficial results. In cases in which there is profound toxæmia, but in which the temperature is considerably below 102½°, the point at which the cold plunge is considered wise, the writer advocates the use of tepid baths. By the use of hot or tepid baths, with friction, circulatory equilibrium can be reestablished, toxæmia diminished, and the temperature reduced to normal. As to the administration of alcohol, the writer uses it quite largely in these cases, but with good feeding he does not use nearly so much as he did formerly. The patient burns up food products in the body instead of burning up alcohol.—*The Therapeutic Gazette.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 17, 1904:

	Cases.	Deaths.
Measles	103	12
Diphtheria and Croup	329	40
Scarlet Fever	184	13
Smallpox	2	.....
Chickenpox	126	.....
Tuberculosis	310	134
Typhoid Fever	72	16
Cerebrospinal Meningitis	.....	26
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	1,126	241

The Mental Disorder of Neurasthenia.—Frank Parsons Norbury declares that there is a physical basis to all mental life, and neurasthenia, while not always within the borders of a true psychosis, nevertheless is properly studied as a mental disorder. The writer briefly considers some of the characteristic mental disorders of neurasthenia. In the introspection of neurasthenia there is the functional lowering of the excitability of the neuron, and of these agencies which depress activity, exhaustion or overfatigue (with attending malnutrition) is the chief. In neurasthenia the nervous system suffers unequally from the exhaustion. The higher psychical centers which are concerned in the mechanism of conscious attention are among the first to be affected, and introspection is among the first of these evidences. The sensory and motor centers become involved later, in about the following order: First, depression, marked by introspection; then asthenia, emotional disturbance intensified by the morbid introspection with possible melancholic state. Obsessions form a most interesting and striking group of mental symptoms in neurasthenia. They have their origin in the subconscious self, and suddenly spring into the realm of consciousness, and may become an irresistible impulse. The patient may at first overcome the influence of the thought, but at last it becomes irresistible. One well-known obsession is that of counting. The power of the will is slowly undermined, due to the normal association action of neuron groups being dissociated. Emotions also lose their normal inhibition. Another striking disturbance in neurasthenia is found in morbid fears. They are but the continued evidence of nervous exhaustion. These fears vary with the same degree and insistence as do obsessions. The writer here calls attention to the common fear of heart disease. He says that these morbid fears which are classed as phobias are truly representative pathognomonic mental disorders of neurasthenia. There are cases of neurasthenia in which the nutritive condition is good. Such patients are usually spare, inclined to be tall, and of nervous temperament. Again, there is the phlegmatic neurasthenic, who is overfat. He is anæmic, and usually has inherited the gouty diathesis. Not infrequently the neurasthenic state is but the forerunner to marked diathetic disease. Diagnosis of neurasthenia is made almost wholly by exclusion. Success in treatment demands the recognition of the mental phenomena as of first importance, and treatment must be instituted accordingly. Isolation is the greatest moral factor in treatment and should be enforced. Next, comes rigid, systematized rest, modified according to the individual case. Drugs have only a minor place in the treatment. The spirit of hope is the food upon which these patients thrive. The writer concludes by stating that neurasthenics should be considered from a psychopathological standpoint, and in dealing with them we are clinical workers in mental disease.—*Medicine.*

Coal Dust and Pulmonary Tuberculosis.—Some very surprising results which have attended a series of investigations made by a medical man in the mining districts of Upper Silesia are about to be made public. Among the many illnesses prevalent in his district lung diseases occupied proportionately a very low place, and consumptive persons on coming to reside near the coal mines recovered their health after some time without undergoing any special cure. These facts he is prepared to verify by statistics. The cures are attributed by him to the coal dust contained in the atmosphere, which, he alleges, has a drying and disinfecting influence on tubercle developments in the lungs. Creosote, he says, in explanation of this, is derived from coal tar, and it may possibly be present in a crude state in the coal dust in the atmosphere. It is now proposed to erect a sanitarium for consumptives in the dicerict referred to, in order practically to test the efficacy of the new cure.—*The London Standard.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 16, 1904:

ON WHAT LINES IS THE TREATMENT OF MALIGNANT DISEASE ADVANCING?*

By ROBERT ABBE, M.D.,
NEW YORK,
SURGEON TO ST. LUKE'S HOSPITAL.

The principles and methods of work, which expand from the study of individual patients, to general classes, have so far supplanted the display of special cases as a glorification of successful surgery, that we find to-day's interests do not deal with the stream of rare cases and extraordinary or monstrous pathological lesions, which once found its way to cosmopolitan hospitals by highways from every distant town and was the subject of exciting clinics. These are now detained and cared for in the innumerable small hospitals which have sprung up everywhere in the country. They are not missed by the student of to-day, who finds more profitable study of the problems associated with the causation and cure of disease. Resources of medicine and surgery are now on trial—and we must occasionally look over the field to see what to discard and what to hold to. Malignant disease continues to furnish a large share for surgical endeavor and research.

At first thought we would all say that during the past decade much progress has been made—but waves of doubt and depression come periodically to everyone—when after lengthening intervals of freedom and long respite from disease it still baffles his best endeavor when he most wishes to succeed.

Undoubtedly, however, gain has been made in three notable directions, viz., (1) in the recognition of the *principle* that carcinoma and sarcoma are primarily of local origin. This makes the cure almost certain when very early operation is done. (2) In recognizing the enormous value of increasingly extensive operation in advanced cases—widening the field of skin removal and lymphatic dissection. (3) In establishing the value of radio-therapy.

Apart from these we have to record attempts to utilize serum therapy—antitoxin—and tissue metabolism by oophorectomy (Beatson's method) and thyroid extract administration.

Regarding the first two (the principle of local origin, and value of wide removal), we cannot lay too much stress upon their importance, but, as their value has been so often emphasized by every writer, I will say but a word to deprecate the fact that there are still constantly presented to the surgeons to-day many cases operated upon by men who do but little surgery, and allow themselves to remove small mammary tumors without taking away the breast, or to amputate the breast without excising the lymphatics of the axilla, or pectoral muscles, or if these are done with a show of thoroughness, then to incise the skin near the tumor within the margin of safety, so as to make easy suture of the skin possible, paying more attention to the cosmetic effect than justified.

*Read before the meeting of the Practitioners' Society of New York, December 2, 1904.

It is in these cases which constitute such a vast majority of recurrences that the margins of the scars are the first and often the only site of return of disease, showing the undeniable fact of outlying invisible cells left in the cellular and cutaneous lymph channels, at operation.

This puts emphasis on the value of wide removal of skin and extensive skin grafting at the primary operation, and it is this, I believe, that has made the great advance in mammary operations. The dread of mutilation is to all patients paramount, and it should be the first duty of the surgeon and physician, if they expect to maintain the supremacy of surgery over "let alone treatment," that they should prepare the patient's mind for radical work regardless of defect.

Again, in deeper carcinomas, as of the rectum, it seems a wiser and safer operation to excise not only the lower part immediately near the growth which usually lies near the anal region, but to make a conjoint abdominal operation, establish an artificial anus and excise the sigmoid, as well as the sacral lymphatics which are always involved.

In cancers of the stomach it is not clear in my mind that it is wise to tax the resources of surgery to do these elaborated operations which are possible, but so often fatal, and so fruitless of permanent benefit—a triumph of surgical art which is not a triumph over disease, is not one to boast of—and this sentiment so far prevails that most operators are content with the simple, safe and admirable posterior gastroenterestomy in restoring digestive functions as far as the diseased conditions will ever permit.

The advanced cases of cancer of the tongue still tempt the surgeon to remove all apparent evidence of disease—but the almost inevitable early recurrence, coupled with the deplorable condition of the mouth, seems to emphasize the impotence of cutting operations, except in early interference.

I am inclined to think that in this class of epitheliomas we may look for help from radiotherapy. Of this I will speak later.

Three methods of treating malignant disease through systemic and what one might call alterative measures have commended much public attention, and may briefly be referred to as *serum-therapy, antitoxin treatment*, and *oophorectomy*.

The use of serum, so far as its latest advocacy by Doyen is concerned, is *sub judice*, and awaits the report of the French Surgical Commission, to establish any claim to consideration.

Of the more conspicuous use of the principles of bacteriotherapy as advocated by Fehleison in using the toxins of the erysipelas coccus, and by Coley in combining with it the *Bacillus prodigiosus*—to defeat the growth of malignant tumors—there have been enough well recorded cases to establish the fact that a few tumors, mostly of unusual types of sarcoma, have been seen to retrograde and in some cases disappear.

These constitute a very small proportion of the great number which have been subjected to the

treatment, and one may say, therefore, that there is no law of control that has been established.

It seems to me that we have to consider here the fact that the principle of bacteriotherapy on which this method is based presupposes an entirely unsettled problem of bacterial origin of cancer. The predominance of study, it seems to me, tends to the conclusion that cancer has not a parasitic origin. The last report of the Harvard Cancer Research laboratory is rather impressive.

On the other hand we must accept the pathological view that a tumor is a simple mass of cell tissues resembling those normally present, but arranged atypically, and growing at the expense of the organism. This may well be an erratic growth due either to stimulation or to loss of its normal inhibitory powers of growth. As an illustration, take the senile keratoses of the face which so easily degenerate into true epitheliomatous carcinoma, with lymphatic and metastatic invasion.

Here the overgrown cells may be considered as essentially weak and tired out tissue, and to such, an adequate stimulation may restore the equilibrium that is needed to continue the normal state of growth and repair. So with tumor tissue elsewhere.

In this way one may explain the effect of stimulation of antitoxins or serums, which, introduced into the circulation may well be conceived to have the power to correct the errors of tissue metabolism.

Little is really known of the intricate chemistry of growth and repair. We see also, extraordinary changes in the human body, resulting from removal of the ovaries in cases of mammary cancer. The tumor having been demonstrated to be malignant will often retrograde and sometimes disappear, though not usually permanently.

The method devised by Beatson of Glasgow, has commanded much attention, and been given a fair trial, enough to establish the fact mentioned, but not to place it among the list of surgical procedures for usual resort. I have myself removed the ovaries of eight women afflicted with hopeless mammary carcinoma, during five years past, and in all but one have seen retrograde changes with prolongation of life, but ultimate death from the disease; one alone surviving.

The most remarkable one, I showed at a meeting of this society, in the spring of 1901, one tumor the size of a hen's egg and eight small cutaneous nodules disappearing entirely within eight weeks of the oophorectomy. The round, bean-shaped nodules rapidly flattened, then became umbilicated, leaving a ring of tissue which finally melted away, leaving no trace.

Drawing showing the action of radium on a superficial carcinoma forty-eight hours after one hour exposure. The tube was applied to the skin over an area, part of which is occupied by a small, superficial bulla, the remainder by a slough which has involved the epithelial layers. Immediately below this the vessels of the corium show a marked round-celled infiltration. There are a number of large, flat, polyhedral cells near the vessels and in the connective-tissue spaces. About two millimeters below the surface of the area treated, the cells of the new growth have undergone complete destruction, as shown by the peculiar staining qualities of the débris and the pycnotic nuclear remnants. Just below this, on either side, are alveoli still containing unchanged nests of carcinoma.

Beatson's theory is that the ovarian influence stimulates active processes in the mammary epithelium, which takes on the characteristics of germinal epithelium, even to showing vacuolation. Yet, I cannot see that this sheds new light upon the subject in hand, except in the strongly suggestive view that cancer is a tissue metabolism, capable of partial or complete retrograde degeneration through the vital forces, stimulated by altered internal secretions.

It is extraordinary how other internal secretions,

such as the thyroid in myxœdema, adrenals in Addison's disease, and pituitary gland in acromegaly furnish stimulant to the correct conduct of cell-life in other parts of the body, and their withdrawal by atrophy or disease gives degenerate cell action.

We are prepared now to consider radiotherapy as an healing agent in superficial growths, whether ulcerated or not; and we shall conclude, I believe, that here also is furnished an external stimulus of a type heretofore unused, which adds a measure of strength and control to the vital spark left in the decadent cells of the morbid growths.

We may dismiss *phototherapy* from our consideration, because light as such and the various divisions of light rays, even the much-talked-of ultraviolet, are yet without claim of value in true malignant growths.

Lupus alone yields (after very long and patient effort) to the Finsen light. But the same disease subjected to radiotherapy is under prompt control without light rays.

It remains to consider the Röntgen rays, the ionized rays, discharged from the iron electrodes with spark, and the rays from radium.

The technic of using these three new agents is as yet not quite formulated, and I will not detail the many variations in advice given by observers, but express my own judgment as to the value to be placed upon them.

Many cases of tumor disappearance by these means lead us to ask whether microscopical evidence has been given as of the actual change in carcinoma tissue.

Of Röntgen ray effects there have been many demonstrations; of radium radiations, we now have clear proof of the same lethal effect on the nests of cells constituting the tumor. Of this I have had some very definite and beautiful records made by Dr. F. C. Wood.

I show an enlargement (p. 1042) of a section of skin over a carcinoma, recurrent beneath the skin, over which a tube of the strongest French radium (300,000) was laid for one hour only—excision following after two days. The nearest groups of cells, two millimeters below the surface, had undergone complete destruction, refusing the stain of living tissues and showing only débris and nuclear remnants. The cutaneous epithelium was destroyed, round-celled infiltration appears around all vessels of the corium. Similar effects were seen in the substance of the primary cancer mass in the breast, into which the tube of radium was thrust for one day.

The antibacterial action, which is at best very feeble, can play but a trifling part, and the feeble heat emitted by radium is insignificant.

We must look then to the rays, which are of negative electrons emitted by radium and the Röntgen ray, as the agent of power. These equally discharge the electroscope with great rapidity, and in this they are rivalled by the electric spark from the coil passing between iron electrodes. The latter device, in the form of a Piffard lamp, is richer in ultraviolet rays than any known instrument, but its power for good seems to reside in active rays other than the ultraviolet.

A quartz cover allows the latter to pass freely. Let them fall on an electroscope, and nothing results until the quartz is removed, and instantly the electroscope is discharged, showing a powerful emission of electrons. This latter agent we have used in connection with Röntgen rays, finding it to be apparently a strong ally.

What, then, has been the outcome of the application of the three forms of radiant energy just described?

Many tumors dissipated, some unaffected, occasional recurrences, a few cures.

One may summarize it by saying we have gained both knowledge and hope. Many epithelial cancers of the face have been cured abroad and in this country by either one or all the agents.

Typical ones of the lip and other parts that have been shown by me at several meetings of this society are convincing of the permanent value of radiotherapy.

The maxillary giant-celled sarcoma, cured by radium and several times shown by me to this society, remains cured to-day. In most cases where there are lymphatics of the axilla and groin adjacent to this disease, these decline also without special attention when the growth improves under treatment.

The cause must be conjectural, but it is easy to conceive that some by-product of the degenerating growth finds its way along the absorbents to the metastasis in the lymphatics.

Four weeks ago a man was referred to me by Dr. R. W. Taylor for amputation, owing to extensive cancer of the glans. A piece was removed which showed epithelial cancer; several lymphatics were enlarged in each groin. I gave five minutes' exposure to Röntgen ray, followed by five of rays from a Piffard lamp, twice weekly, and had the gratification of seeing rapid appearance of induration and growth, leaving a cicatrizing, granulating surface, which bids fair to be entirely healed in a few weeks, when I shall show the man to this society, I hope cured. Meanwhile, the swelling of the inguinal glands has disappeared.

The Röntgen ray, radium, and Piffard lamp emit somewhat the same influence and excite a grade of local reaction not at all like inflammation of usual type.

Radium notably sets up a brawny change when displaying its severest energy, resembling urticarial wheals, which is supplanted by a curative action.

It alone can be used in deep structural disease, bone and other tumors, where it may be buried for hours, or days, according to its strength.

From radium, therefore, we may expect the greatest future results. As yet few applications in deep growths have been made, owing somewhat to the reluctance of those who possess strong specimens, of which there are but few, to experiment on patients whose only hope has seemed heretofore to be in an operation.

There is promise of a large production of strong radium in Austria, and the next year will reveal further fruits of research and treatment.

13 West Fiftieth Street.

PROBLEMS RELATING TO SIMPLE ULCER OF THE STOMACH.*

By BEVERLEY ROBINSON, M.D.,
NEW YORK.
PHYSICIAN TO ST. LUKE'S HOSPITAL.

From the dual standpoint of medicine and surgery, I know of few diseases to-day which have more direct and positive interest to practitioners than simple or round ulcer of the stomach. This depends mainly upon the fact that the disease can be cured, as I believe, by timely, judicious, skilled intervention, and at a time and under conditions when delay and ignorance, on the one hand, or too great unbalanced zeal, on the other, do great harm.

Undoubtedly, in many intsances, by proper prophylactic treatment, simple ulcer may never develop, and if it be already present, it may not progress even for a short while, nor give rise to threatening symp-

*Read at a meeting of the N. Y. Clinical Society, October 28, 1904.

toms. If it has developed, and pain and dyspepsia are very marked, frequent, or continuous, and even if one or more hemorrhages have occurred, cure may result from purely medical control and assistance. If, on the other hand, these means have been faithfully and carefully tried for many weeks, and the symptoms still persist, with stationary or increased severity, surgical aid should be called, and in some cases surgery alone will bring about complete recovery, or in certain instances save life. The cases in which surgical operation (excision and sewing up of the ulcer, or gastroenterostomy) effects a cure are those of acute ulcer, in which the hemorrhage is sudden, profuse, repeated, and the menace to life too great to await the slower results of medicinal remedies, or hygiene and time; or those of chronic ulcer, in which the abundant, recurrent bleeding shows that the degenerated, gaping artery of the diseased surface may be obstructed for a while with a clot, but will soon, through its removal, bleed afresh. Here there is but one way to obtain a *cure*, and that is through an operation. Otherwise, whenever the stomach dilates, by reason of enlarging orifice of vessel, hemorrhage recurs, and the patient ultimately will surely die.

In cases of perforation of the stomach from any form or of any duration of ulcer, the formal indication is to operate, and the sooner the operation is performed, the greater the chances of saving life. Instances of cure without operation are known and recorded, but they are very infrequent, and unless special conditions prevail, such as empty stomach, very small opening from ulcer in stomach, chronic adhesions to adjacent organ, etc., even these instances would not have been possible.

With respect to the differential diagnosis, it is well to affirm at present that, while the chemical examinations after a test meal are of value in many instances, they may be misleading, unless we bear in mind other clinical features of the disease which point to the presence of peptic ulcer of stomach.

In the first place, the excess of free hydrochloric acid is not invariably present. On the contrary, there are not a few instances now recorded by competent and careful observers in which the free hydrochloric acid was either about normal in quantity, or decidedly below the average amount of the healthy stomach. The excessive fermentations of a dilated stomach where stenosis of the pylorus is present, due to a cicatrized ulcer, are of considerable value in some cases in fixing the diagnosis, but here again they must not be counted upon, and if they are persistently absent, the possible presence of an ulcer of the stomach cannot be eliminated altogether. Indeed, in a certain proportion of cases the evidences of flatulent dyspepsia preceding hemorrhage or collapse, indicative at first of a sudden perforation, may be almost or wholly lacking.

As regards treatment, I am of the opinion in this disease, as in others, that what results we obtain in hospitals is no proper index of those we obtain in private practice. It must be remembered that hospital patients are often badly cared for before they enter the hospital. In the first place, they do not seek medical advice soon enough; again, when they first get it, it is not always the most careful or the best. Again, the necessities of their existence, their mode of life, their poor, wretchedly prepared and ill-advised dietary is very often calculated to increase, rather than to diminish, the symptoms of the disease from which they are suffering. Admitted, then, that ulcer of the stomach becomes fully developed and chronic, as it frequently does in hospital patients, the dietary and medical treatment ordered at this stage are not as successful many times as we should desire. Hence many surgical operations are indicated or absolutely essential.

On the other hand, the patient in affluent circumstances, who seeks and gets the best medical advice in the beginning, is almost immediately put upon the most appropriate dietary, and gets regularly the most suitable and useful remedies. In my observation, such cases sooner or later get well, and without surgical interference. They may suffer, more or less, from obstinate dyspepsia for quite a prolonged period, but their hemorrhages are infrequent and relatively slight, and as for perforations, they very rarely occur. These patients are usually intelligent and instructed, and when they have before them the nature and threatening possibilities of their disease, they follow willingly and rigidly the rules laid down for them by their medical adviser as regards diet, medicine, and occupation, and the ultimate result is cure in many instances. Of course, there may be, and frequently is, recurrence of painful and unpleasant symptoms of stomachal intolerance for a short period, and after some neglect or unusual indulgence; but these are short-lived if properly met—as they usually are—and disappear as they appeared, very rapidly.

It is a fact of observation that the man who works with his hands may do better, so far as symptoms of ulcer are concerned, if he persists in his work, than the man of brains, who uses his head and has many anxieties for himself and others in a business or professional way. The former may often go on and do his work regularly, without interruption and apparently without interfering with his ultimate recovery. The latter, on the contrary, must at least have a temporary rest from mental toil and worry, if he may hope ultimately to recover. What the accurate explanation is I do not know, nor do I know that it has been absolutely affirmed. I believe, however, from what I do know, that mental effort is often connected apparently with an excessive production of acid secretions of the stomach, and this fact, if true, would explain, when continuous in action, the development and progress of chronic peptic ulcer.

One statement is no doubt absolutely correct, viz., that women with gastric ulcer must go to bed if they wish and expect recovery. Now, this observation is only in accord with what I have just stated, since women, by reason of their sensitive, impressionable natures, would be, rationally, the first ones to succumb to the conditions favored or produced by the action of the nervous system upon the gastric secretions.

It is clear, therefore, to my mind that the neuropathic condition is, in many instances, an underlying factor of great or even primary importance in the production and continuance of chronic ulcer of the stomach. No doubt persistent hyperacidity, which is present in so many instances, not only where anæmia exists, but also quite independent of this state, has much to do with the development of the ulcer, and when the ulcer is present, unless properly and continuously neutralized, prevents its healing. No doubt also that the blocking up or obstruction of the circulation in limited areas of the stomachal mucous membrane renders it far more susceptible to corrosive action than it would be if the blood current had in these places a normal flow.

On the other hand, we have cases of chronic ulcer in which there is no hyperacidity during life, and no occluded or diseased vessels in limited areas, and if we seek for a plausible or convincing explanation of facts observed, either during life or at the autopsy, we are obliged to concede the important action of diminished or impaired nerve force. This

explanation, it seems to me, is satisfactory, when we note how many exceptions there are if we estimate the influence of mere dietary regimen. It has been affirmed, for example, that meat eaters are more likely to suffer from chronic ulcer of the stomach, and vegetarians are relatively exempt from it. Later observations prove that numerous exceptions may be found, and when nervous energy is reestablished, any moderate or rational dietary may be acceptable and perfectly tolerated. The symptom, continuous pain, with tenderness over a limited area, is more characteristic than any other of the presence of ulcer. And yet even this symptom may be counterfeited in some examples of neurasthenia, probably, and where chronic ulcer does not really exist. Despite observations from prominent clinicians, who affirm that, with pain and prolonged dyspeptic symptoms, and although the amount of hæmatemesis or melæna is slight and infrequently repeated, we shall always find ulcer present if the patient is operated upon, I continue to believe that this is an extreme view, and will not be justified by future experience. Indeed, I am still of the opinion that a pronounced anæmic condition, with marked depression of nerve tone, and particularly where free hydrochloric acid is absent during prolonged periods, will account satisfactorily for quite a number of them.

The clear indication, however, in such cases is to insist upon rational and somewhat prolonged medical treatment by experienced clinicians before surgical interference is advised or attempted.

The question of hemorrhage is often doubtful, even with good clinicians, and in order to recognize it special tests must be used (Campbell Howard), and I am quite skeptical as to the use of orthoform to allay pain, and if it does, to regard this fact as corroborating strongly the diagnosis of gastric ulcer. In those instances in which the "circumscribed spot of tenderness in the epigastrium is accompanied with a similar tender spot to the left of one of the lower dorsal vertebræ," I agree that this symptom has great importance in determining our diagnosis of gastric ulcer.

With regard to the tenderness, however, we must bear in mind that it proceeds largely from the locality of the ulcer, and if this be situated under the costal cartilages or upon the posterior wall, pain on pressure may not be felt. Moreover, it should be remembered that ulcer, and even perforation from it, may occur without previous stomachal symptoms. The most important symptom in determining the existence of perforation is abdominal rigidity. There may be no abdominal distention, and the pain may be badly localized. Although the abdomen may be tympanitic everywhere, the liver dullness may not be distinctly obliterated. Even the abdominal rigidity, although well marked, may not be as limited as is usually believed. Fever may or may not be present, depending somewhat upon the degree of peritonitis. Usually after the first period of collapse the temperature is apt to rise. This rise of temperature may be somewhat due to the application of warmth and use of stimulants on the part of physician or nurse. Of course, the localization of the peritonitis may sometimes explain the absence of increase of temperature. Occasionally the pain accused is situated in the lower abdomen, and in this case may be due to a complicating appendicitis. More frequently the pain is most marked towards the upper part of the abdomen on the right side. There are instances in which all symptoms point to perforation of the stomach, including abdominal rigidity, and yet the subsequent histories go to prove that the perforation did not occur. In one analogous case I have seen, in which the perforation was supposed to be in the bowel, the rigidity lasted a brief period and then disappeared. It was mainly because of this fact that the consulting surgeon decided against the existence of perforation, and although subsequently the patient died, as there was no autopsy, the correct diagnosis could not, in my judgment, be absolutely affirmed. No doubt many cases of gastric ulcer should be to-day studied by the internist and by the surgeon.

Theoretically, with past experience to guide, treatment of ulcer belonged essentially to the physician. With lately acquired knowledge, it is wisdom and duty to find out which cases belong to the surgeons, and at what stage of the pathological process. It is probable in many instances laparotomies have been too long delayed, owing to more than one good reason. Of these I should mention particularly lack of operative experience, faulty surgical technique, and a decided opposition on the part of medical men to permit operations upon their patients, which they considered unjustifiable, when the fatal or injurious outcome of very many of them was fairly estimated. Physicians are at the present time in a different medical attitude, and yet they still wish to prevent hasty and unfortunate operatory procedure. It is true that the surgeon has one great advantage over the physician, namely, that he can better study living sections, and is not given over so much to the study of dead lesions, as shown at the autopsies.

On the other hand, the family physician has opportunities to study to more advantage and with greater care the previous clinical history of a given case, and hence his final judgment appears to me, in general, more reliable. I am obliged to confess, however, that the too advanced value placed upon mere laboratory researches jeopardizes sadly even good medical judgment, and renders the physician liable, at times, to form or support opinions which formerly he would not have held. In so far I believe he is to be sympathized with, while retaining the hope that in the future chemic and microscopic research will cease to retain their actual exaggerated valuation.

My own belief is that in many instances in which pain in the epigastrium and obstinate stomachal indigestion, with or without periodic vomiting, exist, it is wisdom to treat the patient as though gastric ulcer might develop, even though it be not yet present. This is especially true of anæmic young women, who have been overworked and victims of wrong dietary, and of many cares and anxieties. In many of these cases it is, of course, proper to give a test meal, and later have a microscopical and chemical examination of the stomachal contents. If there has been an excess of free hydrochloric acid, with evidences of inordinate products of gastric fermentation, my judgment as to the importance of preventive treatment would only be confirmed.

On the other hand, even if the microscopical and chemical examination of the gastric contents after a test meal is doubtful or negative as to the presence of ulcer, I do not believe, with the acquired knowledge which has come to us from well-observed cases, medically and surgically, that we should be justified in following a very different plan of treatment. We must admit, also, that there are numerous instances in which the patients or friends object very strongly to the idea of introducing a stomach tube, either for preliminary washing before giving the test meal, or later to withdraw the contents of the stomach which are present.

In these patients we may be able, as we know, to

obtain sufficient gastric contents by forced regurgitation on the part of the patient himself, to satisfy in a measure our requirements. In instances, of course, where there has been a late attack of hæmatemesis, or blood in notable quantity has been found in the stools, without other rational, assignable cause for these signs, our diagnosis of the beginning or advanced presence of gastric ulcer is even surer, and our course of conduct as to treatment more imperative. Besides, we should not make any attempt to introduce the stomach tube. The cardinal principles governing medical treatment of declared gastric ulcer are (1) absolute or relative rest, mental and bodily, if possible. Frequently bed is the place for such patients, although at times, as stated, and especially with those who labor essentially with their hands, cure may be obtained without this rule being absolutely enforced. (2) The use of rectal feeding in a measure or altogether, and the partial or complete relief of stomachal digestion, at least for a time. Gradual return to feeding with much care and many limitations may later be counseled and enforced, and wherever anæmia is notably a factor in the make-up of the disease, its special treatment should not be ignored.

I place great emphasis on the latter part of the treatment, when pain has disappeared and the ulcer is almost or entirely cicatrized, because I believe the nervous system is often affected as to its function, and it cannot be fully restored unless the healthy formation of healthy blood is effected, whether the anæmia be a primary or merely a complicating factor. The nervous system, after all, receives its sustenance in the main from the blood, and unless this be normal, both in quantity and quality, the derangements of the former are more than likely to continue and become worse.

There is a great difference between the medicinal treatment of acute and chronic ulcer of the stomach. This was pointed out specially by Fenwick, who emphasized the truth of it, and showed how closely it was based upon anatomical and pathological conditions essentially distinctive. In very many cases acute ulcer will be greatly improved and perhaps cured by a relatively short treatment, with diet, rest, and the use of a few medicinal agents. No such happy outcome should be looked for in chronic ulcer of the stomach. Here months, and indeed years, may elapse, as we know, before the patients have become completely rehabilitated. In the vast majority of such cases, if food be given by the mouth, it should be in the form of milk, just as in the days of Cruveilhier, who first insisted upon its crowning efficacy. As a rule, it is wise to give it peptonized and warmed, rather than raw or cold. In case it is thus allowed, on account of some personal peculiarity, a liberal addition of lime water may be added. Kumyss is not advisable by reason of its acidity. Matzoon or zoolack is less objectionable. Milk, after being heated almost to the boiling point, may be diluted and cooled with the addition of rice or barley water. It may also be made more digestible and soothing with gelatine or isinglass. The former is indicated whenever there is any evidence of bleeding from the ulcer. A small quantity of arrowroot with milk, a little cream and gelatin, as in Meig's well-known formula, are not undesirable at times. It seems objectionable to permit milk in any form, according to Murdock, whenever the gastric contents show little or no hydrochloric acid present. In these cases we should allow albuminized water, beef juice or light broths, diluted or not with barley water, rice water, or oatmeal gruel.

I am opposed in the beginning of treatment to anything further in the way of food. Even the addition of light soups with cereals or vegetables is objectionable, because of possible local irritations or fermentations produced. Indeed, I have little doubt that if all food be interdicted by the mouth for many days, and the patient be nourished solely with properly formulated enemata, he will progress more favorably than if we attempt to give him at first the mildest nourishment in liquid form by the stomach. We know the old-time formulæ of some at least of these enemas with egg, milk, beef extract, whiskey, etc. All of them are objectionable after a time, and produce rectal intolerance. Besides, once every twenty-four hours the rectum must be flushed thoroughly with warm water, to get rid of any remaining and infecting detritus. A bad taste is often complained of by these patients after several days of treatment, and this may cause nausea and even vomiting. Most of the objectionable features of enemata may be gotten rid of simply by giving them under the form of warm water, heated to about the temperature of 100° Fah., and repeated four or more times in twenty-four hours. The amount given each time should be from six to ten ounces, and should be introduced slowly and with very moderate pressure. These enemata may be continued occasionally two weeks or more, without producing any untoward consequences. There is no bad taste in the mouth, the strength of the patient is kept up fairly well, and there is little or no complaint of suffering from excessive thirst.

There is one food which I have omitted above, and which, it is claimed, is especially valuable when hydrochloric acid is deficient in the stomachal secretions, and that is buttermilk, freshly made and freely taken. In several cases it really appears to have been followed by a permanent cure. Is it possible, in view of the late discovery of a great French scientist, Metchnikoff, that buttermilk in ulcer of the stomach is a true elixir of life?

Of the different medicinal agents, none has received as many encomiums as the salts of bismuth. Of these, the most widely used is the subnitrate. To be of any service it must be given appropriately before food, or on the fasting stomach in the early morning. In any case small, insufficient doses are of very little value. Probably the best way to give bismuth is to suspend it with water, to which is added a little milk sugar. Cane sugar should not be used on account of its proneness to acid fermentation. A fair proportion of prepared chalk and lime water may be added, and thus we have, as I believe, an admirable and efficient formula, which is likewise not unpalatable—a decided advantage. I have rarely, if ever, been disposed to prescribe the silver salts in suspected ulcer of the stomach. The nitrate of silver, we are told by some writers, is useful, and possibly covers over certain sensitive areas, by reason of its decomposition, with the coating of an albuminate film. And in certain hyperæsthetic conditions in which there is intolerance for all kinds of food—even in liquid form and most bland—it may be of service. In case the bowels become at all constipated, some natural salt like sulphate of soda may be given, or the liquid form of magnesia, which is preferable because of its well-known alkalinity, as well as its aperitive qualities.

In the treatment of anæmia I would prefer to make use of the vegetable forms of iron, rather than the perchloride, protochloride, or carbonate, which may be more or less irritating locally by their acidity and perhaps slightly corrosive action; this is without doubt true of the tincture of the perchloride unless given with pure neutral glycerin.

The pain of ulcer, when excessive, may perhaps be allayed with orthoform. A question of moment

is the time during which liquid diet by the stomach should be continued. Of course, this is variable according to the patients, and may be enforced from several weeks to as many months. Certainly, so long as there is marked tenderness on pressure, it would be hazardous to deviate from a stringent rule in this regard, and would render the patient liable to a sudden relapse of all painful and distressing symptoms. Despite the fact that much has been written on this topic, nothing better or more accurate has been stated, and provisionally we should abide by the indication which proceeds from local tenderness. When, however, this symptom has completely disappeared we may gradually and with continued watchfulness return to a moderate and somewhat varied diet, always selecting meats and a few vegetables very easy of digestion. Among the latter, when properly prepared, rice is especially good. Potato, on the other hand, in any form is bad, and will often occasion distress and renewed symptoms of grave import. The white meats are, I believe, preferable. Roast beef and beefsteak should be withheld for a long while. As far as possible meat should be roasted or broiled, and very few prepared dishes with gravy or sauces permitted.

While it is claimed that it is desirable to make a further chemical and microscopical examination of the gastric contents before solid food is allowed, I do not assign much practical importance to the results obtained. They differ so frequently, and particularly with the first findings and before any kind of regular treatment was followed. There are cases, for example, in which no free acid was originally found, and later on it may be found again in even more than normal quantity. What is true of free acid is likewise true of rennet. It may not be discovered at first and later appear, or vice versa—present at first and later be absent.

In certain cases in which there is marked hyperacidity without gastric symptoms, revealed by chemical analysis of the stomachal contents, and the general condition is below par, forced nutrition will occasionally benefit both conditions. Even in those instances in which acid gastric catarrh or an ulcer of the stomach is present, it is desirable, according to C. v. Noorden, "to give large amounts of food after the first eight or ten days of moderation."[1] Personally, in these cases, I should be very skeptical about the advisability so soon of such a liberal dietary, although recommended by this eminent authority.

The two complications most to be dreaded are: (1) hemorrhage; (2) perforation. The former may be very profuse and alarming, and yet rarely does a fatal result immediately follow. Absolute rest and quiet in bed should, of course, be insisted upon, and no nutriment be permitted except by the bowel. Cold applications to the epigastrium are indicated. I have but little faith in the use of gelatin hypodermically. On the other hand, we have to-day in the repeated use of a solution of adrenalin after this manner a most potent remedy upon which we shall rely later, more and more. When not given subcutaneously it may, of course, be given by the mouth several times a day in doses of ten to twenty drops of the 1 to 1,000 solution. Ewald's suggestion of washing out the stomach with iced water makes no appeal to me. If hemorrhage is not arrested by these means we must consider the propriety of a surgical operation.

The indication to operate may also be present if the hemorrhage is frequently repeated, although at no time very profuse. Even though hemorrhage may be slight and rarely repeated, if stomachal distress is great and continuous despite well ordered and judicious treatment continued for several weeks or months, we may think that an operation is required. The two operations hitherto upheld are resection of gastric ulcer with sewing up gastric wall, and gastroenterostomy. The former has had a very great fatality, and surgeons are generally to-day in favor of making an artificial anastomosis between the stomach and the intestine by posterior gastro-enterostomy, or by Finney's method of pyloroplasty.[2] In many instances one of the latter operations will give complete relief to symptoms; and the explanation of this fact seems to be that the stomachal digestion is more rapid, and food being held in the stomach a shorter time is less exposed to the prolonged action of the hydrochloric acid secreted oftentimes in excess.

Unfortunately in many instances there is a return of the characteristic symptoms of ulcer. There may be again hæmatemesis, gastric distress, and even perforation. These symptoms are due to the formation or progress of fresh or other ulcers. In point of fact, where one ulcer is present, others also often occur. Indeed, unless the underlying cause or causes of ulcer of the stomach be neutralized continuously, or overcome, it is improbable that a permanent cure will follow. The lower segment of the stomach after an anastomosis with the duodenum or ileum has been effected, takes on a similar rôle to the pylorus, and hence ulceration at this site is in an equal degree likely to occur if other conditions remain about the same. It is true that since the surgeons have abandoned anterior gastroenterostomy, renewed and grave symptoms of ulcer after operation have not occurred as frequently as previously, still the mortality in these cases is very high in the aggregate. Even the latest report of operation for gastric hemorrhage, at the Boston City Hospital and Massachusetts General Hospital, 1898 to 1903 inclusive, reads: "Ten cases; ten deaths." The physicians should not be blamed, therefore, at their lack of enthusiasm for operation in such cases, even the most threatening, at least for the present. It is to be hoped and expected that with larger experience and improved technique surgical results will improve.

On the other hand, when the surgeons ask us urgently to turn over our cases to them sooner for operation, claiming that their success would in that case be greatly and speedily increased, we fail in a measure to recognize the validity of their reasoning. Their strong ground of argument is that to be successful they must operate while the patient is still in fairly good shape, and not unduly weakened from repeated hemorrhages and insufficient nutrition. On our side we claim if the patients who have gastric hemorrhages have most careful and judicious medical treatment they will rarely reach the stage where an operation is imperatively needed, and we should not prejudice, as it were, the curative effects of hygiene and medicines in any particular case, until it is proved beyond peradventure to be useless. Alas! for the uncontrolled tendency of the day which would seek to cure all human ailments with the knife, and allow less and less to the sanest, most instructed, broadest way of regarding departures from health and well being. It should be borne in mind, also, even with a very profuse initial hemorrhage, that it may not occur again, and even if it does recur, it may be in far less amount. Moreover, such cases are susceptible of cure by mild medicinal and hygienic treatment. Again, such ulcers, although sometimes existing singly in a given case, may exist with one or more other ulcers at different sites. If this be true, it is

too dangerous to excise and ligate all of them. Finally, even if search be made for numerous bleeding points, they cannot invariably be found—at all events soon enough to offer chances of a thorough and successful operation. And in such cases when the stomach is, as it were, "weeping blood," nothing further can be done except a gastroenterostomy, and this operation, as we know, in such a condition is of uncertain value.

The claim that old ulcers of the stomach, which have been allowed to remain unrelieved or uncured too long under mere medical treatment, should be operated upon for fear lest carcinomatous changes take place at their site, is, in my judgment, not sufficiently, by reason of the extreme infreqency of this occurrence, to justify a formidable and too often almost immediately fatal operation. If acute or sub-acute perforation occurs, and as soon as the initial collapse has been at least partially recovered from, it seems advisable to operate as speedily as possible. In similar instances, although it is possible that recovery may occasionally take place under wise medical care, the chances are so very few that it seems only right to turn over the patients to the surgeon almost immediately for operative interference. To delay uselessly for a more exact diagnosis of the precise nature of the perforation is not justified by the latest reports which have come to us. In these cases, where morphine has been given to relieve pain, the condition when seen by the surgeon is often obscured, but with a reliable history of the previous symptoms and the presence of persistent abdominal muscular rigidity during a few hours it is indicated to operate.

In chronic perforations, where adhesions with adjacent organs have already been formed, and which limit the extent to which the extruded gastric contents are carried, and consequently localize the subsequent peritonitis, operation may be deferred a little while, or until the signs of an abscess cavity are undoubted by reason of physical signs, or the results of exploratory puncture.

A most interesting question in connection with operations for simple ulcer of the stomach is to determine what the ultimate results of such operations are. We know to-day that the immediate results are frequently very good, and that the various painful or threatening symptoms of the disease are often entirely relieved for a while. The inquiry about after results has rarely hitherto been made, at least in a systematic manner, and so as to include numerous cases. When it has occasionally been made, the outcome is at times unsatisfactory, partly because some of the patients could not be followed up, or when found they would not answer questions addressed to them.

In regard to hemorrhage from erosive or recurrent ulcers, Maunsell Moullin[3] writes: "There is no difficulty in arresting the bleeding, but it must always be borne in mind that the operation deals merely with one of the consequences of the ulceration, not with the cause, and that it cannot in any way prevent other ulcers forming subsequently, or bleeding taking place from them if they do form. I have known recurrent ulceration to follow gastroenterostomy, in spite of the fact that the artificial communication was acting in a perfectly satisfactory manner. In two of my cases no further trouble has followed, but in several others after an interval the hæmatemesis occurred again. If adhesions are present and are left after operation, the patient will always be liable to suffer pain after taking food. Simple division of adhesions is of little use. The only really useful method is to excise a smaller or larger portion of the gastric wall, and bring the cut edges together by sutures. It is evident that where adhesions are extensive the condition is practically incurable." Hence, surgeons would now urge an earlier exploratory operation than physicians hitherto have considered advisable. Another reason why physicians are opposed to early operations is because, despite repeated attacks of hæmatemesis with melæna in a given case, no cause subsequently may be found that is sufficient to account for the symptoms. It is true that occasionally, even under these circumstances, benefit to the patient has followed operation. Such "singularly happy coincidences" do not justify, in my judgment, hazardous operations at an early period of a *possible* ulcer of the stomach. In an able article by John Lindsay Steven,[4] "On the Surgical Treatment of Diseases of the Stomach from a Physician's Point of View," I find some interesting and telling thoughts. Steven wisely remarks that in the very nature of things the physician sees more of the natural history of ulcer of the stomach than the surgeon does. He sees the cases earlier, and he sees them later, when the surgeon has done his best. The surgeon's interest, perhaps, tends to slacken when the wound is healed up and the patient is so far restored to the status quo ante. It then falls to the lot of the physician to watch the ulterior and, in a way, natural progress of the malady, and to compare the course of the comparatively few cases which should be and have been operated upon with the much greater number of nearly similar cases of the disease in which no operation was justified. From this it follows that the physician's outlook on operations for gastric ulcer, excepting those for perforation, is scarcely likely to be so hopeful as that of his surgical brother. Much of the foregoing is copied textually; some of it is changed to suit my own appreciations.

Later, Steven writes, in speaking of dilatation of the stomach, and this it seems to me may be applied as well to simple ulcer of the stomach: "A cure by medical means must always be preferable, for, however successful the operation, there must ever be the risk of a cicatrix yielding and giving rise to hernia, or of obstructive complications arising from the dislocation of normal relationships which is necessarily involved in any surgical procedure. There is also, I think, some danger of the artificial opening contracting somewhat in the course of time."

Finally, Steven writes, and with this I cordially agree: "When medicine has entirely failed surgery must be resorted to." But, fortunately, medicine does not fail so frequently as some late surgical authorities would have us believe. Thus Murdock writes: [5]"So far as I have been able to learn in only two out of thirty-two cases which I have reported have the patients suffered from a recurrence of the ulcer."

"Under medical treatment Lenthe found the mortality in fifty-five cases to be only 2.4 per cent., and Fenwick observes that when the disease is taken in hand at an early stage and properly treated the mortality does not exceed 4 per cent."

Contrast this with reports from surgeons of operations for chronic gastric ulcer, and we must conclude that the mortality "from gastroenterostomy is higher than the mortality from chronic gastric ulcer when the patients have the benefit of proper medical treatment."

For example, in fifty-two cases of gastric ulcer at Mount Sinai Hospital from 1898 to 1904, there were ten cases of hemorrhage. In only one case

was surgical interference required, and this was the only one of the ten which was fatal. (Manges.[6]).

NOTE.—Dr. F. H. Murdock's latest report[7] regarding "orthoform in the diagnosis of gastric ulcer" is interesting and important. He writes: "As this remedy will not anæsthetize nerve endings when they are protected by skin or mucous membrane, it is certain that if it relieves pain in the stomach it can do so only by coming in contact with a surface from which the mucous membrane has been removed." My own experience, as reported in my paper, has not confirmed such an absolute judgment, nor does it wholly coincide with the experience of others. Orthoform does not invariably relieve ulcer of the stomach, where the diagnosis seems reasonably sure; in some instances of stomachal disturbance, where probably there is no ulcer, orthoform occasionally gives temporary relief, and this it accomplishes as a local analgesic by contact "with nerve terminals through highly inflamed tissue."

Addendum: The following report of laboratory work from a most reliable observer gives additional value to my paper:

DEAR DR. ROBINSON:—

In answer to your esteemed favor asking for my laboratory experience with specimens from cases of simple gastric ulcer, I beg leave to submit the following:

Stomach Contents.—The belief that the examination of stomach contents obtained after a proper test meal, showing marked increase of HCl is a *certain* indication of simple gastric ulcer, is faulty. My laboratory records show a decided HCl hyperacidity in a large percentage of cases of reported simple gastric ulcer, but we cannot overlook the few instances of normal and even diminished HCl where the clinical diagnosis of simple gastric ulcer seemed justified—and on this account a *positive* diagnosis of this lesion must not be made by laboratory methods alone.

These exceptional and usually complicated cases do not detract from the usefulness of the knowledge that gastric analysis gives us.

The usual, but by no means invariable rule, that increased HCl is suggestive of simple ulcer and diminished or absent HCl suggestive of carcinoma is still a good one, and these points are often of much corroborative value in the clinical picture.

The presence or absence of lactic acid may be somewhat suggestive, but does, I believe, not merit the importance which has been attached to it as a factor in the diagnosis of carcinoma. The few complicated cases where, for example, a carcinoma develops in a chronic ulcer, may give confusing results on analysis of stomach contents, but this does not outweigh its value in the majority of cases.

The mere appearance of the contents or vomit may teach much.

The analysis of gastric contents is as yet of no use in differentiating between gastric and duodenal ulcer. In gastric neurosis, increased, normal, diminished, absent, and even continuous secretion of HCl may be found, thus simulating all other pictures from the purely analytical point of view.

Urine.—When attention was first directed to evidences in the urine of faulty body chemistry in cases of gastric hyperacidity, my conclusions were as follows: A lowered urea-uric acid ratio constant in all. In cases of hyperacidity due to gastric ulcer—a normal ratio or a high ratio of mineral and ethereal sulphates and no excess of indican. In cases of hyperacidity in gastric neuroses—a lowered ratio of mineral and ethereal sulphate and a decided excess of indican. Further observation has, however, shown cases which do not follow these lines.

Fæces.—In the chemical and microscopical examinations of fæces I have made in cases of supposed gastric ulcer, no specific changes were found which would be of value in diagnosis. The latest medical litreature (Boas, *Deutsche medizinische Wochenschrift,* and Roessel, *Deutsches Archiv für klinische Medizin*) recommends a careful *chemical* search for blood in the fæces as an aid in the diagnosis of gastric ulcer.

Blood.—All the evidences of a secondary anæmia are usually very pronounced. The reduction in coloring matter and number of red corpuscles—some change in the character of the latter, with a normal leucocyte count, and the usual slight changes in the differential count.

Hoping the above is the information you desire, I am

Yours very faithfully,

FREDERIC E. SONDERN.

THE "YOLK CURE" IN THE TREATMENT OF THE UNDERFED.*

BY HEINRICH STERN, M.D.,

NEW YORK.

WHO is underfed?—Some time ago I attempted to answer this question.† I concluded that underweight and underfed are *not* synonymous conceptions, that an individual of underweight but in metabolic equilibrium is not underfed, and that in the real underfed there is always a traceable disease or disorder which, directly or mediately, prevents normal ingestion or complete utilization of foodstuffs, giving rise thereby to bodily decline.

Does overfeeding alone avert the further deterioration or does it tend to restore lost body-substance in these instances? No,—overfeeding, on the contary, may even call forth aggravation of the patient's condition on account of overloading, overburdening the digestive organs and overproduction of alimentary poisons.

As overfeeding *per se* is not a rational therapeutic procedure, what ought we to do to prevent further waste and to cause reparation of lost body-substance? We must attempt to prepare the organism that the nutrient material is received properly, and that it is elaborated and assimilated.

It is absolutely useless to try to check bodily decline by forced feeding, without paying attention to the condition of the digestive organs and the general assimilatory qualities. As soon as the organism is able physiologically to dispose of the ingesta the tide of body-decay is stemmed in all those instances in which some digestive-assimilative disturbance, directly or remotely, stood at the foundation of the malnutrition. In advanced cachectic states, of course, when reparation of the digestive and assimilative functions cannot be any longer accomplished, body-decline will continue, uninterruptedly, as a rule.

We are wont to consider a number of chronic affections as "wasting diseases." Such pathological states, however, occasion little or no body-waste so long as the digestive and assimilative properties are maintained at or near the physiological standards. In chronic ulcerative phthisis, for instance, it is often astonishing how little loss of body-substance has occurred, even in cases which have very far progressed. In such cases, the inroads made by the disease itself are in a measure counteracted by the good digestion and assimilation.

The treatment of the so-called wasting diseases resolves itself in the prevention of waste. The secret of success in the treatment of consumptive affections lies in the proper management of the organs

*Read at the meeting of the Manhattan Clinical Society, November 4, 1904.

†Who is underfed? MEDICAL RECORD, May 21, 1904.

of digestion and assimilation. The most potent factor in maintaining physiological digestion and assimilation is an adequate food-supply, that is, a nourishment not only sufficient as regards the quantity, but one which the declining organism with the weakened or impaired organs is able to anabolize, one, in other words, which furnishes the needs of the specifically affected and altered organism. If the food is not adapted to the digestive and assimilative capacity of the patient, he will slowly starve, although his food-receiving organs may be filled with it to the point of bursting.

As a matter of course, measures other than dietary fulfil a certain, more or less important, purpose in the management of the condition of subalimentation; their specific value, however, is mostly of a negative, of a defensive character so to speak, as their application does not tend to actually overcome body-decline and much less to increase body-weight, but to a retardation of metabolic and catabolic processes.

The most rational therapy for the digestive and assimilatory apparatus of the underfed as well as for the condition of underfed, is the one in which the diet plays the most prominent rôle, that is that diet which is not selected for the disease but for the individual, that diet which is altered as the patient's condition alters, that diet, in short, which does not call forth anorexia, sitophobia, cardiac irritability, dyspnœa, or other untoward phenomena, but that diet which is the least bulky, the least burdensome to the alimentary organs, the richest in heat-units, and the most potent protector of body substance.

In the "yolk cure" we have a dietary regimen exhibiting all the advantages of a nutriment of the first order without its usual drawbacks.

Under "yolk cure" I understand a dietary regimen in which the greater portion of calories is yielded by the yolk of the hen's egg, and in which the latter forms the only fatty substance. Besides this *rigid* "yolk cure" we may speak of *modified* forms of the same. A modified "yolk cure" is a dietary regimen which is either (*a*) not a succession of "yolk days" (that is when days on which yolks do not preponderate in the diet are inserted), or (*b*) when the yolks although contained in the diet in a certain amount, do not furnish the bulk of the calories and are not the sole representatives therein of the fatty ingesta. In a majority of instances a modified "yolk cure" will be found to offer certain advantages over the strict regimen when the patient's alimentary tract is in good condition and after subsidence of the acute decline, or after the patient has started to gain in body-weight. Moreover, the "yolk cure," modified according to the individual needs and desires and remodified from time to time in accordance with the changed conditions in the organism is the only means by which a yolk diet may be continued for many months and even for years.

The yolk of the hen's egg in the raw or half-raw state is very readily digested. Experiments conducted by me in the healthy human stomach show that two raw yolks (slightly seasoned) leave the stomach in 70 to 90 minutes; three in 70 to 100 minutes; four, in 80 to 100 minutes. One yolk taken in hot water and whiskey leaves the stomach in 50 to 70 minutes; two leave the stomach in 50 to 75 minutes. One yolk taken in a cup of hot coffee (some sugar, or milk) leaves the stomach in 60 minutes; two leave the stomach in 60 to 70 minutes.

The "idiosyncrasy" for eggs which undoubtedly exists in a number of even healthy individuals, in my opinion is solely due to the white of the egg. I have never found it when the yolks only were partaken of. The white of the egg, containing the bulk of the latter's proteid substances, in the face of retarded digestion, in gastric motor insufficiency or in any other condition detaining the ingesta in the gastrointestinal canal, is liable to yield hydrogen sulphide and ammonia; the yolk which is at no time lodged in the stomach as long as the egg white, does not exhibit the elements for the production of hydrogen sulphide to the degree that the latter could call forth any untoward consequences.

Yolks are very well assimilated. This is proved by the comparatively small amount of fat in the fæces when yolks had formed the exclusive fatty substance in the diet. It is a known fact that the higher the melting point of a fat the slower and more incomplete will be its assimilation. The raw yolk, beaten up, being liquid, is quickly and almost totally absorbed. According to my own findings from 1.5 per cent. to 3.5 per cent. of the yolk-fat reappears in the fæces. The great absorbability of yolk fat will be appreciated when we understand that milk-fat reappears in the fæces of the adult to the amount of 4.4 per cent. to 6.6 per cent., and in those of the nursling to that of 5.1 per cent. to 7 per cent. The residue left by yolk-fat in the fæces is smaller than that of any other animal fat.

Yolks are well-borne and well-liked in almost any amount by almost every individual. This cannot be said of any of the other fatty ingesta. Suet, lard, and tallow are not well tolerated by the ordinary stomach in large amounts and certainly not in quantities that yield the bulk of the necessary heat-units. A great proportion of these fats, 10, 12, and more per cent., usually reappears in the fæces. Olive oil, like all vegetable fats, is not well-borne in larger than the ordinary amounts. Besides, the individual of our zone does not easily develop a taste for large quantities of vegetable oil; the acquisition of an aversion for it is much more frequently the case. Cream and butter are agreeable to the patient as a rule, but when taken in amounts to furnish the mass of body-fuel they are liable to decompose in the stomach, setting free thereby fatty acids of low molecular weight. These low fatty acids tend to derange the digestive functions and the systemic equilibrium. Moreover, they are the forerunners of the so-called acetone-bodies which, with more or less justification, have been brought into casual relationship to the coma of the diabetic and various other, apparently autotoxic, conditions.

Furthermore, the yolk of the hen's egg contains a diastatic ferment assisting in the conversion of amyloid substances. It does not exhibit the fermenting qualities of either the pancreatic or salivary starch-converting enzyme; its ferment-properties, however, are important nevertheless and should not be underestimated. Again, yolks are efficient stimulators of gastric secretion and may be looked upon in certain respects as digestants. They may be partaken of in hydrochlorhydria and in all conditions characterized by deficient flow of the gastric juice.

That lecithin is contained in the yolks is a fact too well known again to receive attention on this occasion. The ingestion of yolks hence may tend to the restoration of nerve force and the amelioration of the state of subalimentation.

An average yolk of the hen's egg contains between five and six grams of fat, representing about fifty calories. These, as we have seen, are almost totally assimilable calories. It takes, therefore, about twenty yolks to furnish one thousand and about thirty yolks to make up fifteen hundred calories. From eight to twenty calories, yielded by yolks, per day and kilogram of body-weight will be found necessary in overcoming the condition of underfed.

Yolks supply but very small amounts of nitrogen. However, it is body-albumin-saving in a much higher degree than any other article of food with which I have experimented. Of course, the excreted nitrogen while under the rigid, unmodified "yolk cure" exceeds that which had been ingested; the deficit, however, is so trifling that, practically, it does not need to be taken into account. The modified "yolk cure," on the other hand, may be so devised that the patient remains in nitrogen balance.

In a paper read before the New York State Medical Association on October 18, 1904 and published in *American Medicine,* December 3, 1904, entitled "Concerning the Suppression of the Acetone Bodies in Diabetics," I have already referred to the "yolk cure" as it should be pursued in diabetes complicated by acetonuria. I have reported some cases in which after adherence to the specific regimen the excretion of acetone substances had completely ceased and in which the glycosuria, at the same time, had diminished or vanished altogether. In all these cases, the "yolk cure" had called forth systemic and nutritive improvement, and increase of body-weight, vigor, and resistance. In one of the reported instances, that of a diabetic boy, 15½ years old, whom I presented to the association, excreting very large amounts of sugar and acetone substances, the body-weight increased, while under the "yolk cure" from 98½ pounds to 122½ pounds.* Not wishing to repeat myself I refer those interested in the treatment of diabetic cachexia by the "yolk cure" to my original article in which they will find an outline of specific technique and a number of cooking recipes for diabetic yolk dishes.

While in the strict antidiabetic regimen carbohydrates have no place at all and proteids are limited to a minimum, and while the antidiabetic, antiacidotic "yolk cure" has to conform to these restrictions, the "yolk cure" for the non-diabetic underfed does not take the question of carbohydrates and proteids into consideration. On the other hand, quantity and quality of each food-stuff have to be determined when treatment of the non-diabetic underfed is undertaken. We should ascertain whether, when, and in what amounts a certain type of food is tolerated by the stomach, to what extent the nutritive substances are elaborated during the process of digestion, and what proportion of the nutritive and calorific principles is utilized for the general processes of anabolism. This is by no means an easy task in the majority of cases of under-alimentation; a minute study of the individual digestive, elaborative, and assimilative conditions, however, is imperative if we wish to augment absolute and specific weight of the underfed individual. Simple clinical methods at the disposal of every practitioner enable him to study his patient's alimentary qualities to the extent that he can prescribe the indicated dietary regimen in many of the common forms of malnutrition. In other, rarer, cases in which clinical observation and simple diagnostic methods alone do not afford sufficient insight into the alimentary conditions, resort must be taken to more complicated methods of examination and determination. The latter, not easy of execution in many instances, are but rarely performed by the general practitioner.

One fact we may be assured of, namely, that the yolks are well-tolerated by almost every underfed individual. Yolks hence are to be the basis of the nourishment of the underfed. It is for the clinician to determine in what kind and in how much of a menstruum the yolks are to be ingested. Here it is where the difficulty arises. In some cases it will be found the yolks are best administered in milk, coffee, or tea. In others in the form of a modified eggnog. Their beneficial effect in many instances are only noticeable when they are taken together with certain carbohydrates in suitable amounts. Taken in soup or broth, together with beef, lamb, or chicken, they often give rise to bodily improvement which does not ensue in the same degree when other types of ingesta serve as vehicles. Again, in other cases, especially in those of phthisis pulmonum, an ordinary mixed diet in which the fat substances are merely replaced by the yolks, is frequently all that is necessary to stimulate the assimilative properties and to cause increase of weight, vigor, and resistance.

If a patient who is not in the last stages of a consumptive affection, does not gain in body-weight while he is under the "yolk cure," the latter as a rule is not properly executed, that is, the food which is partaken of together with the yolks is either not the right kind or is ingested in amounts not suited to the alimentary condition. While the proper kind of nutriment favors the specific yolk action, food wrong in character or amount, or in both, retards or suppresses the absorption of the yolk constituents.

On the other hand, the yolks facilitate the digestion of certain amounts of carbohydrates (diastatic ferment) and that of comparatively large quantities of proteids (stimulation of gastric secretion). They do not seem to possess properties which render other fats added to the food easy of absorption. Again, impaired fat absorption appears to be directly responsible for the underfed state in a rather large percentage of cases. As experience (fecal examinations) has shown me that yolks are almost as completely absorbed in most instances of disease followed by loss of body-weight (in not too-far advanced stages) as they are in the normal individual, all fatty substances in the food should be replaced as completely as possible by yolks. When improvement has ensued, it might not be necessary to insist upon yolks as the sole fatty nutrients in all instances; some other fats, in limited amounts may be added to the diet or what seems more rational, one or more days on which the yolks do not form an important part in the diet but on which the common fat substances are ingested in limited amounts, may be intercalated every week. On the other days, however, the yolks should continue to furnish the bulk of the heat-units or at least they should form the sole fatty matter entering the organism with the diet.

A sample of a yolk menu destined for a consumptive weighing 110 pounds (50 kilograms) whose normal weight ought to be 140 pounds (63.63 kilograms) but whose alimentary system admits the ingestion of some carbohydrates and of almost normal amounts of proteids, is given in the following. This patient should obtain food to the value of 35 calories per day and kilogram of body-weight, that is 1,750 calories in the twenty-four hours.

	No. of yolks.	Calories yielded by yolks, approximately.	Total calories approximately.
Breakfast:			
250 c.c. skim milk with 4 yolks	4	200	290
30 grams wheaten toast			75
Early lunch:			
Cup of coffee, 2 yolks	2	100	100
Dinner:			
One plate of soup, 4 yolks	4	200	225
Beef, very lean, 150 grams			125
30 grams wheaten toast			75
4 o'clock:			
25c c.c. skim milk, 30 c.c. whisky, 3 yolks	3	150	370

*The weight in the meantime has increased to 126½ pounds.

	No. of yolks.	Calories yielded by yolks, approximately.	Total calories approximately.
Supper:			
Porridge of farina or rice, 100 grams, 1 yolk, skim milk.....	1	50	350
Apple sauce, 75 grams.....			30
At bedtime:			
Night cap (90 c.c. hot water, 10 c.c. whisky, 1 yolk, teaspoonful granulated sugar)	1	50	110
Total	15	750	1,750

In a prolonged yolk diet, the proportion of the various types of nutritives may and must be altered according to the prevailing alimentary circumstances; a dietary as outlined in the foregoing, however, may be looked upon as a standard in the suitable cases. The whole eggs may be well tolerated in certain cases; when whole eggs are employed extra yolks may be added to them. In order to avoid monotony and aversion, the latter being invariably the consequence of the long-continued use of the same kind of meat or of the same kind of farinaceous material, a variety of dishes in which yolks may be incorporated should be devised.

All yolk dishes must contain salt in sufficient amounts. Flavoring and seasoning substances may be added to the various articles of food as long as there is no contraindication to their employment; it should always be borne in mind that spices are not inert substances and that their use may as well retard as increase digestive activity, as the case may be. As a general rule, patients under the "yolk cure" are not subject to obstipation. Mild laxatives may be employed in cases tending to this condition.

The "yolk cure" in its various modifications has nothing in common with the legion of unnatural and irrational feeding-systems extolled here, there, and everywhere. It is not a fad with me and I hope it will not become one with others. It has its limitations, to be sure, but if conscientiously employed in certain forms of malnutrition, it will increase the body-weight and restore bodily resistance when other dietary régimes have proved decided failures.

56 East Seventy-sixth Street.

TRACHOMA.

By ALBERT C. BARDES, M.D.,
NEW YORK.
ATTENDING SURGEON NEW AMSTERDAM EYE AND EAR HOSPITAL.

Although a great deal has been written upon the subject of trachoma in recent years, it continues to present a fruitful field for further interesting investigations.

Trachoma is known to have existed from time immemorial. The ancient Egyptians suffered from it as long as four thousand years ago, and the eyes of well-preserved mummies of that period offer unmistakable evidence of its baleful activity. Celsus, an ancient Roman writer, has left an excellent description of the scourge as it existed some twenty centuries ago, and in no way did the malady at that time differ from that of to-day. Curious to relate, the treatment of the disease at that remote period was, in principle, precisely like that employed by many of our modern surgeons, and from the fact that the ancients endeavored to arrest the progress of the malady by surgical intervention, which in those pre-anæsthetic days must have been extremely painful, we are permitted to infer that they were prompted to have recourse to these heroic measures by a full knowledge of the disastrous consequences that are apt to follow an uncured trachoma.

It appears that the disease had its origin in the sandy plains of Egypt, and from the fact that it is more prevalent in that country than in any other part of the globe, it has been termed "Egyptian Ophthalmia." With the improved facilities for traveling, the disease has found its way throughout the world, but nowhere is it as troublesome as in the land of its origin. So contagious is the affliction in Egypt that but few of the natives escape an attack, and trachoma alone is responsible for the extreme prevalence of blindness which forces itself upon the attention of travelers in the Holy Land. During the hot and dry months of July and August, when the intense heat of the day and the blinding rays of a scourging sun unite with the heavy night-dews in their relentless action upon the tender organism of the eye, the most violent outbreaks will occur, and, to make the distress complete, the desert liberally furnishes that irritating, fine sand, which, by the agency of a hot wind, is as rapidly as surely adding to the tortures of the already overtaxed eye.

Like most contagious diseases, trachoma flourishes where the rules of sanitation are neglected. The unhealthy state of the dwellings in Egypt, together with the sparing use of water for cleansing purposes, are the principal factors that favor its continued activity in that country. That cleanliness is the keynote to its prevention has been amply proved by the fact that, in those parts of Egypt where Europeans have taken up their abode and taught the natives the habits of that virtue which is next to godliness, this dreaded eye disease does not assume the dangerous form that it does elsewhere in the same country.

When we consider the highly contagious nature of granular lids and the rapidity with which the contagion spreads, we can readily understand that it assumes the proportions of a veritable scourge in countries where it is endemic. The transmissibility of trachoma is of such alarming portent that the United States Immigration authorities have classed it under the head of "dangerously contagious diseases," since the ocular defects which it is apt to produce are liable to render the sufferer a public charge.

A characteristic feature of trachoma is the epidemic form which it assumes from time to time, particularly when the summer is unusually dry and warm. The earliest epidemic of which we have an authentic account occurred in Europe in the twelfth century, when it was introduced from the Holy Land by crusaders, who had contracted it while warring with the Saracens. Ever since that time Europe has been the scene of periodical epidemics of varying severity, which have swept over the densely populated portions of that continent like huge tidal waves, leaving suffering and blindness in their wake.

Perhaps the most disastrous epidemic that ever invaded Europe raged in the beginning of the last century, when the malady was brought from Egypt by the soldiers of Napoleon. In 1798, when Napoleon opened his Egyptian campaign, no fewer than 20,000 of his troops contracted the dreaded Egyptian scourge. The men suffered so intensely that for a long time they were unable to use their eyes, many of them becoming blind. This incapacity of the men has indeed been held largely responsible for the failure of Napoleon's Egyptian ventures. These soldiers, when recalled to Europe a few years later to take part in the extensive Napoleonic wars then raging, disseminated the disease in every country they invaded. This particular epidemic was so violent and destructive in character that it did not begin to subside until the lapse of thirty years, and it is estimated that fully a million people contracted the disease.

The recent epidemic in New York City has been

ascribed to the extensive immigration of Russians and Roumanians to the lower East Side. The habits and surroundings of these people are decidedly unhygienic and furnish all the elements favorable to the propagation of a contagious disease. The apartments of these people are crowded and ill-ventilated, the bath-tub is unknown, one wash-basin and towel serves for the whole family, and the food is anything but wholesome.

The principal sufferers of the New York epidemic have been children. In some of the public schools as many as twenty per cent. of the children had some form of ocular defect that was traceable to granular lids. Notwithstanding the energetic measures taken by the health authorities to eradicate the disease, there are still many cases that have escaped detection.

Trachoma is an inflammatory and slowly progressing disease, in which the inner surface of the eyelids is studded with small elevations or granules. Like all true hypertrophies, trachoma runs a definite course. It progresses up to a certain point, then the inflammatory action subsides and retrogressive changes occur, during which the granules atrophy and finally disappear entirely. Unfortunately, this absorption of the granules does not cure the disease, for the conjunctiva, instead of resuming its normal state, is replaced by dense scar tissue, which shortens and contracts the lids, leading to consequences decidedly more troublesome than the original granules. Usually there is a direct relation between the severity of the primary, morbid process and that of its sequelæ, and from three to ten years elapse before all the changes that take place in a trachomatous eye have made their appearance.

The course and character of the malady are greatly influenced by racial conditions, climate, and environment. In New York City, the principal sufferers are children of Jewish and of Irish extraction. Very few negroes contract the disease. It is noteworthy that the right eye usually fares worse than the left, probably because, being nearer the right hand, it is rubbed and irritated more frequently than its fellow.

Most of the patients are boys, and those between the ages of ten and fourteen experience the greatest inconvenience, because at that period the eyes are first used in hard and earnest study. When a girl contracts the trouble, the attack is usually a mild one and devoid of serious consequences. One reason why boys are the principal sufferers is doubtlessly because they are less cleanly in their habits than girls. Many boys do not possess a handkerchief and acquire the habit of wiping their watery eyes with hands not overclean. During warm weather the rapid spread of granular lids is readily accounted for by the frequency with which boys patronize that potent disseminator of contagion—the public bath. Although the disease is more contagious during the summer than the winter months, it is decidedly more troublesome during the latter, the symptoms being aggravated by the cold and damp winter weather.

The infecting element in trachoma is the secretion which, evidently, contains a specific microorganism that sets up the disease by being transferred from one eye to another. This implies that trachoma is contagious from the time the eye begins to discharge up to the time the secretion dries up—a matter of a year or more in most cases. The infection, the sources of which are numerous, may take place through the medium of the finger, a towel, a handkerchief, or any other article brought in contact with the eyes. Experimentation has shown that the secretion from a trachomatous eye, like gonorrheal pus, has no effect whatever when introduced into a healthy eye, and that there must be an abrasion or inflammation of the conjunctiva in order that the infection may find a fertile field. As long ago as 1816 Mackenzie, a Scotch oculist, by way of experiment, applied to his own eyes compresses soaked in trachoma secretion, but, being in good health, proved immune against the disease. A few years later, in 1820, a French oculist experimented on five boys who were hopelessly blind from amaurosis, but who had healthy lids. He introduced the trachoma secretion into their eyes, but in every case the result was negative. When, however, the secretion is applied to a lid that is congested, or in which there is an abrasion, it seldom fails to produce the disease.

When trachoma attacks an eye, it sets up a low grade of inflammation. Autoinfection quickly follows, and one part of the conjuctiva after another becomes inoculated until the activity of the disease has reached its climax. As the inflammation advances, it extends down to the lymph glands, and these glands, which in health are invisible, now become hypertrophied and project through the conjunctiva like balls of fine shot.

That the granules in trachoma have nothing in common with the granulations of wounds excepting appearance, is proved by the construction of the conjunctiva and the nature of the disease. No mucous membrane throws out granulations unless its susface has previously ulcerated, and in trachoma there is no true ulceration. If these trachoma granules were true granulations, adhesions between the lids and the globe would be of frequent occurrence, whereas they are not.

We often see cases of so-called mild trachoma, in which the symptoms are slight, showing fine, velvety granules and scant secretion. These are really cases of follicular conjunctivitis, a harmless, catarrhal disorder of the lids, in which no part deeper than the conjunctiva is involved. These elevations, which are extremely vascular, readily bleed upon manipulation. They give the conjunctiva a red, velvety appearance, instead of the grayish frog-spawn appearance of a trachomatous lid. With proper treatment there is everything in favor of a satisfactory cure within a few weeks, and when recovery takes place, there are no cicatricial or other destructive changes.

Of true trachoma there are two varieties, the acute and the chronic. Most of the cases that apply for treatment are of the chronic variety and evidently have existed for months and even years before they come to us. Usually the disease advances so slowly, and the symptoms at first are so slight, that no attention is paid to them; and it is not until the granules become at all numerous and troublesome, or until the eyes are accidentally inspected, that the true condition is brought to light.

The extent of the trachomatous involvement is not always commensurate with the severity of the symptoms, for frequently the lids are found densely covered with granules, and yet no uneasiness is experienced. On the other hand, a few scattered granules may cause considerable distress. This may happen either in the case of the lids sitting too closely upon the eyeball, enhancing the irritation of the granules, or by poor health of the patient, which magnifies the distress.

There appears to be a direct connection between granular lids and adenoid growths. It is a clinical fact that most children suffering from trachoma also have adenoid vegetations in the nasopharynx. Since both conditions are dependent upon a strumous or lymphoid diathesis, it is quite likely that the same cause is operative in the production of both conditions.

In the early, or inflammatory, stage of trachoma, the granules are accountable for the symptoms, while in the late, or cicatricial, stage, the scar tissue is the offending agent. In both instances the free movement of the globe is interfered with either by the granules or by scar tissue which act as foreign bodies and set up a mechanical irritation.

Patients with trachoma frequently complain of having sand in the eyes; the lids feel stiff and heavy, and the eyes burn and itch. The sensation produced by the granules is by no means painful: it is an uneasiness that irritates and tires the eyes and makes them sensitive to light. When the irritation is severe, an active mucopurulent discharge is thrown out, the lids are swollen and tender, the eyeball is inflamed and the patient holds down the head to avoid the light. The lids are drooping, partly to shut out the light and partly owing to the congestion and weight of the lids.

When the lid of a trachomatous eye is turned over, the conjunctiva is found thickened and thrown into folds that resemble a cock's comb. The color is deep red in recent cases and grayish in advanced cases, and the surface is covered with masses of granules that appear like warts or frog-spawn. It is particularly in the depressions, or culs-de-sac, of the lids, that the granules are large and numerous. The fact that trachoma usually begins in the lower lids explains why, as a rule, more granules are found there than in the upper lids, but sometimes the latter are in a worse condition. This shows the necessity of thoroughly everting the upper lid when inspecting an eye for signs of trachoma.

Frequently trachoma is accompanied by an ulcer of the cornea, a decidedly troublesome complication. The action of the roughened lid upon the eyeball is purely mechanical, but the irritation it sets up is sometimes so severe that the cornea is completely destroyed and blindness follows. When the cornea is attacked in trachoma, its epithelial layer is first detached by the friction of the lids, and the cornea loses its polish. The process of destruction is then hastened by the corroding action of the discharge, and the cornea becomes ulcerated. Whenever, in the course of trachoma the cornea becomes involved, the case is a serious one, for rarely does an ulcer heal without leaving an opacity behind that impairs the sight. The danger is the greater if the ulcer is deep or is situated near the center of the pupil. Corneal involvement is mostly found in individuals with prominent eyes or closely fitting lids, or else in persons in poor health or with a faulty diathesis.

Another morbid and highly undesirable process that is apt to occur in trachoma, either alone or in conjunction with a corneal ulcer, is pannus, an affliction in which a highly vascular membrane creeps down from the upper lid and usually stops abruptly when it has covered the upper half of the eye. The membrane is situated beneath the conjunctiva, giving the eye an inflamed and clouded appearance and obscuring the sight in the upper half of the pupil. Pannus frequently occurs without any apparent or known cause, even during treatment, and in this way it can in a short time destroy the result of months of treatment. With appropriate attention a pannus of recent origin may undergo complete retrogression, and the cornea may acquire its normal transparency, which is more than can be expected after the healing of a corneal ulcer.

It is particularly in the late, or cicatricial, stage that we encounter the many troublesome sequelæ for which trachoma is noted. The prominent cicatricial changes that follow the absorption of the granules never fail to tell of the previous existence of the trachomatous process. Through the contraction of the scar tissue the lids become shortened and inverted, frequently destroying the integrity of the cornea and interfering with the free movement of the eye.

The treatment of trachoma consists in removing the granules, which is accomplished either by surgical means or by the use of astringents. The astringents commonly employed are copper sulphate, silver nitrate, and mercuric chloride. Silver has the feeblest action and therefore is borne best. Copper, being applied in bulk, has a strong cauterant action, but its application is painful. Bichloride stands between the two and, in many respects, is the most satisfactory agent. In acute cases in which the granules are vascular and the secretion abundant, a 2 per cent. solution of silver nitrate or a solution of one of the organic silver salts, or a 1-1000 solution of bichloride will often remove the granules. For home use, citrate of copper ointment, 15 grains to the ounce, can be prescribed. The complications that result from trachoma, such as corneal ulcer, pannus, etc., are best treated by eradicating the source of the trouble—the granules.

When the trachomatous process is well established, the non-surgical method of treatment is tedious and unsatisfactory. The main objections to the use of astringents are the great length of time necessary to effect a cure and the pain attendant upon this course. When caustics are used, sufferers soon lose their patience and discontinue treatment as soon as the urgent symptoms have abated. This lack of completeness in the treatment of trachoma is accountable for many relapses.

Only those cases of trachoma that undergo early treatment before the cicatrices are formed, can be completely cured. The most that can be done for advanced cases is to arrest the progress of the disease and so prevent the troublesome sequelæ.

The only satisfactory way to treat trachoma is by surgical procedure. The operation most in vogue is that of expression, which is accomplished with Knapp's roller forceps or with Noyes' angular forceps. If the conjunctiva is dense and firm, it is necessary to scarify it before the granules can be readily expressed. The operation of expression is extremely painful and is usually done under ether, a procedure to which many parents object. For this reason many prefer to have their children treated with the tedious and uncertain astringents. It was to overcome this popular prejudice against operating that I substituted cocaine anæsthesia for general narcosis. The treatment of more than a hundred cases by this method justifies my belief in its efficacy. Cocaine expressions are attended with no pain, and but few sittings are required in order to effect a cure.

Complete local anæsthesia is obtained by rubbing into the conjunctiva a 20 per cent. solution of cocaine and applying to the lacrymal opening some vaselin to prevent the escape of the cocaine into the nose. As soon as the lid is insensible to pain, it is grasped with an expressing forceps and, with a stripping motion, repeatedly executed, the granules are crushed. The operation should be sufficiently energetic to obliterate the granules, without causing an undue reaction, otherwise adhesive bands may unite various parts of the bruised conjunctiva, and the contraction of the lids that follows acts precisely like the shortening produced in the cicatricial stage of trachoma. This is one of the things to be prepared for, when removing all the granules at one sitting. It is preferable not to attempt too much at one time.

After the squeezing a 1 per cent. solution of silver nitrate or a solution of an organic salt of silver can be rubbed into the conjunctiva, and the patient in-

structed to call again as soon as the soreness has left the lids.

Inasmuch as trachoma is usually found in children in poor health, it behooves us not only to apply local treatment, but to attend to the general health as well. Plenty of outdoor exercise is necessary, together with a liberal supply of milk and eggs and other wholesome food, and possibly cod-liver oil or syrup of the ioxide of iron internally.

The personal hygiene of the sufferer should be improved wherever feasible, and in order to prevent the spread of the disease, all the conditions that syrup of the iodide of iron internally.

Institutions for children should be frequently inspected, special attention being directed to the eyes, to the sanitation and to the food; and the inmates should be cautioned against using the towel, washbasin, or other individual article of another child. Children that have granular lids should be kept apart from the others, until the lids are entirely well.

THE PRESENT ATTITUDE REGARDING THE TREATMENT OF PROSTATIC HYPERTROPHY.*

By MARTIN W. WARE, M.D.,

ADJUNCT SURGEON, GENITO-URINARY DEPARTMENT, MT. SINAI HOSPITAL; SURGEON TO GOOD SAMARITAN DISPENSARY; INSTRUCTOR SURGERY, POST-GRADUATE MEDICAL SCHOOL.

As late as fifteen years ago, no other relief of the symptoms caused by enlarged prostate was taught to be justifiable than the use of some form of catheter in the hands of the invalid or his attendant, and our teachers then pointed with pride to that triumph of the methods of a surgical antisepsis then in vogue, which made it possible for an occasional victim to eke out a catheter life of one or more decades. Up to this time and thereafter an occasional departure marked the evolution of the surgery of the prostate, but all failed, in that *sine quâ non,* that they were wanting in anatomical foundation. When this was supplied it lay in the nature of things to see a rapid development of a well-planned operation, such as a shelling out of the prostate, by either the perineal or the suprapubic route. Success has marked the removal by either or both combined, and the strife is on, as to which is the best method. We can cite an analogous contention waged between the adherents of perineal or suprapubic lithotomy, and in a like manner between those who contend that the fibroid or cancerous uterus may be removed by laparotomy or per vaginam. These analogies ought to suffice to show that the prostate may be removed either way, but modern surgery demands respect for anatomy, and every stroke of the knife must reveal anatomy, nor must the laws of physics be neglected in an operation. Mindful of these two ends, the perineal route, with the various mechanical aids for bringing the prostate into view, deserves the lead, and all the more so since the integrity of the sexual function can be maintained by sparing the seminal vesicles and the ducts opening into the prostatic urethra, which are often sacrificed in the suprapubic operation. These factors tend to establish the perineal route as the operation of choice, but there are findings at times, which must needs make the suprapubic operation one of necessity. The presence of a calculus, however its presence may be recognized, certainly calls for the suprapubic incision, as does the presence of a large diverticulum or vesical hemorrhage.

On the other hand, the perineal route is one of absolute necessity, when there is suppurative inflammation of the prostate or diseased conditions of the urethra, such as stricture or perineal extravasation. A cystoscopic examination should be part of the routine in studying every case of prostatic enlargement. The size and consistence of the prostatic enlargement may determine the method of choice. Thus if the growth is largely vesical and moderately perceptible to rectal palpation the suprapubic incision is better. If the prostate is beyond reach, by rectal examination, owing to the narrow pelvic outlet, *sectio alta* is better, and the same holds good for some exceedingly stout patients when access to the prostate from the perineum is difficult, owing to the great development of fat. If the residual urine be not great and other factors demand intervention the perineal route should be preferred because of the small capacity of the bladder, which would limit the manipulations of the hand. The presence of a bilateral hernia and of enlarged abdominal veins would oblige us to attack the prostate from the perineum.

From total abstinence in the surgical treatment of the prostate, the pendulum has swung at the present hour to the extreme of operating in every case. It behooves us, therefore, to try to formulate exact indications for operative intervention. When absolute retention can not be relieved by catheter, or there are intravesical hemorrhages, certainly the patients are benefited more by a radical operation than by temporary suprapubic puncture. Nor can there any longer be a question of operation when a stone coexists. An individual septic from the foul condition of the urine, infected by long badly performed catheterization, is eminently in need of an operation. This then narrows us down to the individual afflicted with the first signs of prostatic enlargement. Shall he be condemned to a long siege of catheter life and its pitfalls, or forthwith be subjected to the chances of an operation. I should in such class of patients draw the line as to social conditions, and when these are of the highest order advise a carefully conducted catheterism by the physician, and upon the slightest evidence of deterioration in the status of the patient advise operative intervention. In the lowest walks of life an operation at all times is to be endorsed for economic reasons, and because of the deplorable lack of sanitary conditions. The wish to dispense with catheterization may come from the patient. We can then hold out to him the chances of an operation, provided his physical condition warrants. When such complications weigh against the performance of an operation of the magnitude of prostatectomy we may still offer the patient the benefits of Bottini's operation. Very rarely shall we be called upon to establish permanent suprapubic drainage with a watertight fistula. The catheter *à demeure* also has a very useful mission to fulfil, to be used both in lieu of very frequent catheterization, when the introduction is attended each time with great difficulty and pain, and also in the treatment of the cystitis, prior to one or other of the operative measures. In view of the bad showing made by vasectomy and the very great risk incident to ligation of the internal iliacs, no cognizance should be taken of either of these any longer. Such patients, with infected bladders, who submit themselves for any of the operative procedures, who have not received the direct personal attention of a physician in the matter of catheterization and disinfection of the bladder, must needs undergo preliminary treatment supplemented by cystoscopy, unless it be that one or more of the accidents peculiar to prostatic hypertrophy show themselves to such an extent that the operation grows forthwith to be an emergency procedure. In the performance of the operation the choice of the

*Read before the Eastern Medical Society, November 1, 1904.

method of anæsthesia must be wholly in accord with the physical condition of the patient. In skilful hands a rapid removal of the gland will be possible under the influence of the nitrous oxide gas in the vast majority of instances. Spinal anæsthesia may be effectually used at times, and chloroform will be necessary when either of those mentioned is contra-indicated.

We do not purpose going into the details of the treatment after prostatectomy, but the impression should not prevail that even the most thorough removal of the gland relieves the patient at once of any further needs of the catheter. The brilliancy of a prostatectomy performed within a few minutes is eclipsed in the eyes of the patient by a somewhat protracted after-treatment. As a rule, the patient derives the full benefits of the operation within two or three months of its performance. The maintenance of the sexual function is more likely, when the prostate is exposed by the perineum, as the seminal vesicals can certainly be spared. The uninterrupted flow of urine rendered possible by the removal of the prostate will cure the cystitis and reduce the frequency of micturition, particularly the nocturnal. On the other hand, when there are complications of atony of the bladder, large diverticula, and infections of the kidney, good end results will be difficult to attain.

The Treatment of Dysentery.—Joseph Herbert Ford distinguishes two sharply defined varieties of dysentery—the one caused by the Bacillus dysenteriæ, the other supposed to be caused by the Amœba dysenteriæ. Clinically, each of these is divided into the two sub-varieties—acute and chronic. Besides these, must be considered mixed infections by both of these organisms. These last varieties are of great importance but are seldom recognized. The frequent occurrence of the mixed infections is noted especially in cases following a chronic course, for then the bacillus is found in the stools only when the disease is undergoing an exacerbation, and thus examinations made for it at other times—the results being almost invariably negative—have led to erroneous conclusions. Doubtless the bacillus, like the amœba, remains quiescent in the intestinal walls till it is aroused to activity by some unfavorable circumstance. The prophylactic treatment of dysentery consists in the use of pure water, the avoidance of any polluted food, and of unripe fruit which might cause catarrh of the stomach or intestines and so temporarily lower the vitality of these organs. The best general hygienic precautions should be observed in regard to the dwelling house. When a patient is suffering from the disease, the most careful attention should be given to everything connected with the sick room, especially to the bed and bedding and to the dejecta of the patient. In the case of acute bacillary dysentery, the specific treatment consists in the hypodermic injection of the appropriate antitoxin. The dose is 10 c.c. and should be repeated daily, or even oftener if required. Infection by one type of the B. dysenteriæ does not yield to treatment by the antitoxin developed from the other. To avoid this difficulty, a serum is now developed from both these types of balicci—acid and alkaline. The writer has had the most gratifying results from the use of anti-dysenteric serum in acute cases. Of medicines given by mouth, the saline laxatives give better results in the United States and in the Philippines than do any other drugs. The oil of turpentine is very serviceable, especially in cases in which there is pronounced tympanites and great prostration. As an injection per rectum, olive oil gives the best results in acute bacillary cases. It acts as a sedative to the inflamed surface and removes mucus better than does any other agent. Milk is excellent in these cases when olive oil is not at hand, and may be mixed with egg albumen and a faintly acid antiseptic. Potassium permanganate is probably the best of this class. In acute amœbic dysentery, the only beneficial treatment per os is eliminative. The use of salines is here indicated. Eucalyptus gum in solutions of from 0.1 to 0.4 per cent, injected 3 or 4 times daily, is the most valuable drug for use per rectum in cases of acute amœbic dysentery. It is an astringent as well as possessing antiseptic and amœbicidal properties. Its solution is acid in reaction which is prejudicial to the amœba. This drug is much superior to quinine, but if it cannot be obtained quinine should be used in solutions of 1 per cent. twice or three times daily. The quinine solutions usually employed are entirely too weak to be efficient. In the acute mixed infections, treatment per rectum is most important. Eucalyptus gum in solution of milk and olive oil give the best results. Olive oil gives better results in bacillary cases and in mixed infections than in those of purely amœbic origin, and in acute rather than in chronic infections. The best prophylaxis of chronic dysentery consists in the exercise of great care during the course of convalescence from the acute form. The physician's observation is necessary for several months after all symptoms have subsided. Chills must be carefully avoided. An abdominal binder should be worn. In cases of chronic bacillary dysentery, the most valuable drug for use in enemata for routine employment is oil of gualtheria in solutions of from 0.05 to 0.2 per cent. Antitoxin is of some value in these cases, but it never gives the satisfactory results following its use in acute cases. In cases of chronic amœbic dysentery, no drug can equal eucalyptol for use in enemata. It is intensely toxic to bacteria and protozoa and is a stimulant to chronic ulcers, and controls any catarrhal process in the large intestines. It has a general tonic influence on the small intestines and promotes digestion. Surgical treatment of the chronic ulcers has in a few cases been successful. A line of treatment which meets with success in one locality does not necessarily have the same results in another, as has been proved. The writer has given the results of his observations in the treatment of cases in the United States and in the Philippines.—*The Journal of Tropical Medicine.*

Fractures Treated by Electricity.—Francesco Blasi has made interesting experimental and clinical researches on the treatment of cases of fractures, in rabbits and in man, by different forms of electricity, in conjunction with immobilization. Rabbits were placed under the same conditions, and then a fracture of both bones of the forearm produced. This was immobilized, and the electric current was applied to the limb daily. Galvanism, faradism, and static electricity were all tried, and in another series of cases no electrical treatment was given. In the rabbits the galvanic current reduced œdema very rapidly, there were no signs of suffering, and after the apparatus was removed the animal walked and ran well at once. The other forms of electricity seemed beneficial to a less degree, and there was some limping after removal of the bandages. The formation of callus was more rapid and greater under galvanism. Four cases in man were treated, one of over a month standing without any tendency to union. In this case the patient was cured in about three weeks from the beginning of electrical treatment. The other cases all did well. His conclusions are: 1. Galvanic electricity is beneficial to fractures. 2. It favors all the conditions necessary to the formation of a callus. 3. It reduces to a minimum the period of functional incapacity. 4. No strong apparatus for immobilization is necessary, simply a temporary splint and bandage. The most noticeable thing was the absence of atrophy and disability after removal of the bandage.—*Annali di Elettricità Medica e Terapia Fisica,* October, 1904.

Untaxed Wood Alcohol.—Because wood alcohol is untaxed, and is sufficiently like grain alcohol to be substituted for it without easy detection by the inexpert, an enormous fraud is perpetrated all the time on the users and consumers of alcoholic preparations.—*Philadelphia Press.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 31, 1904.

THE HOSPITAL PROBLEM IN NEW YORK.

HOSPITAL Saturday and Sunday fell this year on December 24 and 25, and collections for the support of the hospitals were taken up at the services on those days in most of the synagogues and churches in New York. In addition to this, employers of labor and the various trades, through their unions, have been asked to contribute to the fund, in return for which the hospitals will provide for treatment, if necessary, for any member of a contributing union or for any one recommended by a contributing employer. Last year the amount contributed by the churches was $15,672, and by the collections made in the trades and professions and upon the various Exchanges through auxiliary committees and by means of subscription lists, enough was realized to bring the grand total up to $75,670—less than $3,000 more than is needed to make up the deficit in one hospital alone of the fifty in this borough.

A year ago Mr. Frank Tucker, vice-president of the Provident Loan Association, called attention to the fact that twenty of the private hospitals in this borough were running at an aggregate annual deficit of nearly half a million dollars—a condition which clearly cannot continue indefinitely. Assuming that this deficit is unavoidable and cannot be reduced by any economies consistent with the proper conduct of the hospitals, either the charitably disposed must respond with much greater liberality than in the past to the appeals of the hospital managers, or the hospitals must close their doors. To meet the difficulty Mr. Tucker has suggested that an endowment fund of $10,000,000 be raised, the income of which should go to supplement the incomes of the hospitals in this borough. This suggestion he renews in an article in *Charities* of December 17, in which he reviews the report of the Presbyterian Hospital, which shows a deficit for the year past of $72,936, in spite of the fact that the institution received and applied toward maintenance $45,603 in legacies. Mr. Tucker shows that the hospital has been meeting about the same deficit for some years past by drawing on its endowment fund, with the result that out of a total of $651,600 received in endowments, $370,000 has been spent, leaving only $281,600 to meet deficits in the future. With an average annual deficit of $70,000, it is pointed out, a radical change in the hospital's policy must take place within four years unless it receives some unusual gift or legacy.

This condition, he says, is not peculiar to the Presbyterian Hospital, but is common to the greater number of private and quasi-private hospitals in the city. He asks where the remedy is to be found, and concludes that relief must come from some hitherto untried measure entirely distinct from the present methods of raising money. Taking the Presbyterian Hospital as a type of all the others, it is shown that the management is economical, every effort is made to collect a fair charge from patients who are able to pay, the managers give liberally themselves, and use every legitimate influence to induce others to contribute, and yet there is an annual deficit of over $70,000. Where is the remedy to be found? Mr. Tucker again answers the question by urging "the raising of a large endowment fund, the income to be used in supplementing the present incomes of the group of New York hospitals which find themselves in the same financial condition as the Presbyterian, the fund to be administered by an independent board of men and women selected for their knowledge of social conditions."

We would not say or do anything to discourage the raising of a ten-million-dollar fund for the support of the hospitals, and we wish Mr. Tucker a full measure of success in his endeavor to secure it, but any relief which such a measure would afford could only be temporary. Unless hospital managers have less of human nature in their composition than other men, the existence of this large sum earning interest for their benefit would not stimulate them to the practice of greater economy, and the probability is that the income from the fund would soon be found inadequate to meet the growing financial wants of the beneficiary hospitals.

The problem will never be solved in this or any other way which takes no account of medical public opinion. What the hospitals need more than endowments, and more than annual subscriptions, and without which they will always be in financial straits, is the sympathetic approval and moral support of the medical profession. These they unfortunately have not. The great majority of practising physicians in this city to-day are, if not actively antagonistic, at least coldly indifferent to the welfare of the hospitals under private management, and would view with complacency the closing of their doors in consequence of lack of funds. These medical men do not deny the good done by a hospital such as the Presbyterian to the sick poor, or the educational advantages it offers to the young graduate on the house staff, but they regard it (we speak of the Presbyterian Hospital only as a type, and because Mr. Tucker made its financial needs the text of his appeal for a guarantee fund), whether rightly or wrongly, as a close corporation run in the interests of the select few comprising its visiting staff, and working injury to the great mass of practitioners whose patients it takes away. It must be admitted that there is some foundation for this general antagonism to the non-municipal hospitals among the profession, and there is no doubt that the hospitals are themselves in great measure to blame for the existence of this feeling. A more liberal policy toward the general practitioner, who would often gladly secure for his patient the benefit of hospital care if it were not that he must thereby of necessity lose the "case," and a stricter compliance on the part of the hospital authorities with the ethical rule which governs the transfer of a patient from

the care of one practitioner to that of another in private life, would go far to modify medical public opinion which is now by no means friendly to the hospitals under private management in this city.

A PERMANENT TUBERCULOSIS EXHIBIT.

The great success of the tuberculosis exhibit in connection with the meeting last year at Baltimore has naturally suggested the advisability of making a permanent exhibit of this kind. New York should naturally take the lead in this, for it was the pioneer city in many directions in starting the present crusade against tuberculosis. It has been surpassed, however, by other municipalities in certain departments of the propaganda, notably by Berlin, which has established within the last two years such a permanent exhibit. It is designed especially for the laity, but it finds its most appreciative visitors among physicians and those engaged in the work of social betterment. In a health talk before a lay society recently, Dr. James E. Newcomb, of this city, gave a general description of this exhibit, from which we learn the following details:

In the western part of the city (Charlottenburg), easily accessible by many lines of urban transit, a large building has been erected which is officially known as the "Permanent Exhibition for the Welfare of the Working Classes." It contains all sorts of safety machinery and apparatus for the preservation of life and limb among the artisans. The tuberculosis exhibit is placed in a commodious hall in the front wing of the building, and is in charge of Dr. Arthur Kayserling, who is the Secretary of the International Tuberculosis Society and editor of its journal.

The museum contains various graphic and statistical charts illustrating the ravages of the disease, models of the respiratory system, and of other organs most commonly affected, collections of sputa receptacles gathered from various countries, models of disinfection apparatus for rooms, dishes, furniture, clothing, etc., portraits of men who have been or still are actively identified with the crusade, culture tubes showing the methods of studying the bacillus, charts showing the effect of good housing in reducing the amount of the disease, and the nucleus of a good library. Over the main entrance to the hall is a large map giving the names of the countries belonging to the International Society, each with its national seal and date of admission. At the time of Dr. Newcomb's visit the list was as follows: Belgium, Denmark, Germany, England, France, Italy, Norway, Austria, Portugal, Russia, Sweden, Spain, Hungary, Uruguay, Argentine Confederation, and Switzerland. It was a matter of both surprise and regret, the lecturer said, not to see the name of the United States, but Dr. Kayserling informed him that the organization of our new national society, effected last summer at Atlantic City, would doubtless be soon followed by formal application for admission to the international organization. The museum also contains models of various sanatoria, and of their detailed construction, of shelters, beds, sleeping bags, improved tenements, devices for illustrating proper ventilation, and related matters. Scattered around are various cards, charts, etc., each containing some aphorism impressing on the visitor the fact that tuberculosis is a communicable, preventable, and curable malady.

The museum is opened on certain days at certain hours, on one or two evenings, and for several hours on Sunday, so that all persons interested can visit it at a personally convenient time. Up to date the installation of exhibits has cost only about fifteen hundred dollars, and such care has been taken in the purchases that good value has been secured for the monies expended.

The general impression made on the visitor is most satisfactory. Upon him is most strongly impressed the fact that the doing for the patient of the right thing at the right time yields most satisfactory results. No attempt is made to exploit any of the disputed questions relative to the pathology of tuberculosis. It is useless to bring before the laity any of the various scientific problems of the crusade, so long as the conditions governing them are but imperfectly understood by physicians themselves. To mystify the question in the minds of the public by continual references to peculiarities in the life history of bacteria is to stray on ground where we are not sure of our own footing. The lay mind becomes confused from inability to follow the lines of argument advanced and suspects that the whole matter of germ life is thereby discredited. The Berlin exhibit wisely keeps to the main proposition that tuberculosis is a communicable, preventable, and curable disease.

We would recommend the establishment of such an exhibit to the serious attention of our local authorities. The expense involved in assembling it would be trifling in comparison with the benefits to be secured. It might be housed in some one of our public buildings connected with the Health Department, and it would be most advisable to secure the cooperation of the Committee on Tuberculosis of the Charity Organization Society, which has amply justified its formation. We can think of no other method by which the expenditure of so small a sum as that named above would accomplish so much good.

Wounds of the Ureter.

In the *Journal of the Association of Military Surgeons* for December, Dr. G. T. Vaughan discusses this subject in connection with the report of two cases of gunshot wound. The rarity of gunshot wound of the ureter is indicated by the author's inability to find more than one authenticated case on record. Previous to 1877 division of the ureter was usually treated by removal of the corresponding kidney, and even as late as 1893 Hermann Thompson states that in ureteral lesions, a complete cure is obtainable only by such removal. Yet as far back as 1877 Tauffer had done a successful ureterovesical anastomosis, and in the year Thompson wrote the second successful operation was done by Novaro. The enormous increase of intra-abdominal surgery of late years has resulted in a collection by Bovee of 111 cases of ureterovesical anastomoses, with but 7 deaths. To these Vaughan now adds two cases, both successful. The author concludes that this operation is indicated whenever the lower part of the ureter has been divided or resected, and the proximal end is long enough to reach the bladder. He believes it is to be preferred to any of the methods of uretero-ureteral union which have so far been suggested or practised, for the reasons given by Baldy, which are that, first, it is much easier of performance; secondly, it is less likely to be followed by stricture; and, thirdly, in case a stricture does form, it is more accessible and more easy to treat.

The Addition of Bicarbonate of Sodium to an Infant's Food.

The adulteration and preservation of food by chemical means are matters which are being widely agitated at the present time. The general consensus of opinion with regard to adulteration is that the practice should be prohibited. With respect to the addition of chemicals to preserve food, opinions are somewhat divided, but it would seem that a stand is to be made against the indiscriminate use of so-called food preservatives.

Dr. Godfrey R. Pisek writes in the *Archives of Pediatrics* for November upon a phase of the food preservative question of which little notice has been taken. Many of the textbooks state that, in order to overcome the difference between breast milk and cow's milk, one to two grains of bicarbonate of sodium should be added to each ounce of the infant's food. "A young infant taking twenty ounces of food would receive forty grains of bicarbonate of sodium or two ounces of lime water, which contain not far from one and a half grains of calcium hydrate. The forty grains of bicarbonate of sodium will neutralize about eighteen grains of absolute hydrochloric acid and the two ounces of lime water about one and a half grains, or about one-twelfth as much. . . . The food for an infant taking only twenty ounces would probably not contain more than 0.75 to 0.8 per cent. proteids; about one-fifth of it would be milk. In other words, there would not be more than four ounces of milk in the mixture. If the diluent was water, it would not be acid, and therefore only the acidity of the milk would have to be overcome. This leaves forty grains of bicarbonate of sodium to four ounces of milk. In short, there is added to fresh cow's milk two and one-half times as much bicarbonate of sodium as would be needed to neutralize it if it was sour."

The writer holds that the gastric juice of an infant's stomach is not nearly sufficient to neutralize the amount of bicarbonate of sodium added to the food, and that in other respects the addition must tend to prevent gastric digestion.

The Catholic Physician.

A paper bearing this title was read by the Rev. Charles Coppens, S. J., before the Medical Section of the Second Australian Catholic Congress, held recently, and is reprinted in the St. Louis *Review* of November 3. The author lays stress upon the fact that a great responsibility weighs upon the conscience of the physician for the proper performance of his professional duties, but he also argues that a medical man has no right, in certain cases, to act as master of life and death. In the case of pregnancy, in which the physician concludes that in order to save the life of the mother, the child must be sacrificed, the author contends that such a procedure is unjustifiable, and that consequences must be left confidently to God. Under no circumstances, thinks the author, should abortion be performed. It is asserted that the medical profession has not only failed to exert its influence as it could and should have done to check this evil, but it must bear the blame for having encouraged and promoted the abuse. The paper goes on to say that in many families in the United States there are few or no children, partly because physicians pronounce themselves as opposed to large families.

The paper offers the opinion that the only hope of saving modern society is the practice of such morality as the Catholic Church proclaims and enforces on her children in the face of the world's opposition, and that this is emphatically true in respect to the propagation of the human species. Therefore, Catholic physicians and surgeons are strongly urged to obey closely the precepts of the Church, and never to advise the practice of abortion.

Catholic medical men are also bidden to take care that no patient, whether a new-born child or a dying adult, is permitted to pass away without receiving the last rites of the Church, and to be especially heedful not to let the use of anæsthetics cloud the mind of the dying man or woman, at the moment on which a happy eternity may depend.

News of the Week.

New Charter of the Red Cross.—A new charter of the American National Red Cross has been passed by both houses of Congress. This charter, which puts the organization practically under the control of the Government, was drawn by two former Secretaries of State—Mr. Richard Olney and Mr. John W. Foster. Under it the governing body of the general society is to consist of a central committee of eighteen members. Six of these are to be chosen by the incorporators of the parent organization; when six or more State and Territorial societies are formed these will be entitled to elect six members, and the President of the United States will also have the appointment of six central committeemen, one of whom he must designate as chairman. This control committee will select from among its members seven to constitute an executive committee. The accounts of the organization must be audited by the War Department.

Opposition to a Public Pool Bath,—It has been proposed to construct a public plunge bath on East Twenty-third street, in this city, at a cost of $250,000, but the project has met such decided opposition on the part of the Advisory Board of the Health Department and others, that it will probably be abandoned. Dr. Simon Baruch sent a protest to Comptroller Grout against the undertaking, pointing out the unhygienic conditions inseparable from a pool bath and the impossibility of preventing such a bath from being the means of the spread of various diseases of the skin and eyes. He showed also that the sum of a quarter million dollars, which such a pool would cost, would suffice to hold two or three adequate "rain baths" which would afford cleansing facilities to a far greater number of persons without exposing them to the danger of contracting loathsome diseases. It is believed this timely protest will kill the project, for it is inconceivable that the Health Department, to which the question has been referred, will report in its favor.

Degrees in Pharmacy at Columbia.—The Columbia University Council has authorized the degree of Graduate in Pharmacy to be conferred, as in the past, by the New York College of Pharmacy, but has provided for the establishment of a course of higher grade leading to the degree of Pharmaceutical Chemist. Candidates for the degree of Pharmaceutical Chemist will be required to pursue a course of study extending over two full academic years. After 1907 the advanced degree of Doctor of Pharmacy, which is now conferred by the College of Pharmacy upon those who hold the degree of Graduate in Pharmacy, and who take an advanced course in addition, will be conferred only upon graduates of the advanced course who already hold the degree of Pharmaceutical Chemist.

Hospital News.—A new wing is to be added to the Jewish Hospital on Classon avenue, Brooklyn, at a cost of $125,000. The hospital association has

$80,000 on hand, and it is proposed to hold a bazaar to raise the $45,000 still needed for the annex.

New Pavilions at Bellevue.—The construction of four new portable wards to be built on the Bellevue Hospital lawn to relieve the overflow of patients during the winter has been begun. These wards are to be built of wood sheathed with corrugated iron and builders' felt. They will be fitted up with all the conveniences of an inside ward. Each will accommodate thirty patients. They will be finished before the end of January.

New York Post-Graduate Hospital.—The directors of the New York Post-Graduate Medical School and Hospital have appealed to the citizens of New York for $100,000, the raising of which will make effective a gift of an equal amount conditionally pledged.

A Trolley-Car Sanatorium.—A committee of the New Jersey State Charities Aid Association has devised a plan for the establishment of a trolley-car settlement for pauper consumption patients at Snake Hill on the Hackensack Meadows. It is believed that the Board of Chosen Freeholders, which has charge of the county institutions at Secacus, will provide for the tuberculosis colony on the highest point on the hill. The president of the Public Service Corporation, a trolley company operating in northern New Jersey, has promised to place at the disposal of the committee several trolley cars whose days of usefulness are over. The cars will be taken to Snake Hill and placed on stone foundations at a considerable distance from the penitentiary, almshouse and lunatic asylums. The first patients to be admitted to the trolley-car settlement will be consumptive men and women inmates of the almshouse. There are about twenty of each. The town of Scotsdale, Ariz., has a tuberculosis colony inhabiting about 1,500 abandoned trolley cars.

New Children's Hospital in Chicago.—Approximately $100,000 already has been subscribed for the construction of the Children's Memorial Hospital, Chicago, which will cost $300,000. The nucleus of the new institution will be the Maurice Porter Memorial Hospital for Children. Mrs. Porter will give $75,000 towards the erection of the new institution, and another gift of $20,000 is in hand, with many smaller subscriptions.

Chicago Detention Hospital.—The annual report of the Detention Hospital, Chicago, shows that the total number of patients admitted during the year was 1,604. The average daily number in the insane department has been 1,780, and at the poorhouse 1,160. The total cost of maintenance has been $376,422.

Cook County Hospital.—There were treated in this institution during the year 22,301 patients. The total cost of maintenance was $329,268.96.

Michael Reese Hospital.—A new hospital by this name will soon be constructed in Chicago at a cost of $400,000. It will be a six-story, fire-proof structure.

Dedication of Elgin (Ill.) Hospital.—Archbishop Quigley, of Chicago, took part in the dedication and consecration of St. Joseph's Hospital, just completed at a cost of $45,000. The building was erected through the efforts of the Sisters of St. Francis. It is said to be one of the finest structures for hospital purposes in Northern Illinois.

Cook County (Ill.) Hospital Commission.—President Brundage has appointed a Nominating Commission, consisting of twenty-five well-known physicians, to select the attending staff for the Cook County Hospital. This commission will announce in a short time their choice of candidates.

The Presbyterian Hospital of Cincinnati, owing to lack of funds, will be closed in January. For many years Mr. Alexander McDonald has given it a yearly donation of $7,500, and in addition has made gifts in all amounting to $250,000. But recently he informed the trustees of the hospital that, inasmuch as the Presbyterian Church, as an organization, had failed to support it as liberally as he felt it should, he would withdraw future contributions, notifying the trustees that they would have to look elsewhere in future for financial assistance. His announcement was followed a few days later by the resignation of the Board of Lady Managers.

Berlin's New Hospital.—Apparently the new hospital under construction in Vienna, to replace the now somewhat antiquated *Allgemeines Krankenhaus,* will be eclipsed by an institution shortly to be established in Berlin. A description in the *Globe* states that is to be called, after the famous pathologist, the Rudolf Virchow Hospital, and will be fitted with accommodation for 2,000 patients. When fully equipped it will have a staff of 650 physicians, nurses, attendants, and servants. In connection with the hospital there will be a pathological and anatomical laboratory, bathhouse with medico-mechanical institute, section for Roentgen appliances, and a separate building also for apothecaries. Hitherto the largest German hospital was that at Eppendorf, near Hamburg, with accommodation for 1,600 patients.

Graduates of Washington University, St. Louis.—The authorities of the medical department of this university complain of unfair treatment at the hands of the editor of the *Journal of the American Medical Association* in a "Table of State Board Examination Results in 1903," published some time ago in that journal. It was there stated that three out of thirteen graduates failed in the license examinations during the year, a record of 23 per cent. failures. The *Bulletin* of the University for December says that the Illinois State Board of Health certified that seventy-seven Washington University graduates were examined in that State during 1903, and all passed successfully. This would reduce the percentage of failures to 7½. Furthermore, the three men who were reported by the Association *Journal* as having failed were old graduates before the organization of the Medical Department of the University in 1891.

A Physician's Gifts to His Patients.—Dr. George W. Little, of Glens Falls, N. Y., has reversed the usual current of Christmas gifts by presenting to each of his patients a souvenir silver spoon. The spoon is ornamented with a medallion relief of the donor, and bears the inscription: "Dedicated to the patients who have survived my practice."

Fight for Pure Drugs.—The members of the Retail Druggists' Association of Chicago, at a recent meeting, passed resolutions expressing regret that certain pharmacists have been inexcusably careless (*sic*) in selling spurious drugs. They also pledged themselves to cooperate in prosecuting druggists who in the future dispense chemicals of an inferior quality.

Dr. A. J. Loomis has resigned from the visiting staff of the Jersey City Hospital after a service of eighteen years.

Dr. Thomas G. Ashton has been elected Adjunct Professor of Medicine in the University of Pennsylvania.

Expectoration in the Subway.—Dr. Darlington, of the Board of Health, is carrying on a vigorous campaign against the spitters everywhere, and especially in the subway. Detectives are posted at many of the stations to arrest unwary offenders.

Society of the Rutland Railroad Surgeons.—A meeting of the surgeons of the Rutland Railroad Company was held at Burlington, Vt., on December 15, 1904. The object of the meeting was to effect a permanent organization of the staff, which was done with the election of the following officers: *President,* Dr. W. N. Bryant, Ludlow; *Vice-President,* C. A. Pease, Burlington; *Secretary and Treasurer,* S. S. Eddy, Middlebury. A discussion of the work of the Surgical Department and its relations to the road was opened by Hon. H. H. Powers, General Counsel, Rutland Railroad. This was followed by the reading and discussion of the following papers: (1) Spinal Injuries, by Dr. D. A. Shirres, McGill University, Montreal, P. Q.; (2) Abdominal Injuries, by Dr. S. E. Maynard, Burlington, Vt.; (3) General Consideration of Fractures, by Dr. C. H. Herrick, Troy, N. Y.

Cincinnati Anti-Spitting Ordinance.—Complaints to the Health Board have been so frequent of late of violations of the anti-spitting ordinance the board has concluded to bring the matter to an issue at an early date. One of the sanitary officers has been instructed to commence his trips on street cars and arrest the first prosperous and well-to-do looking man who is caught violating the ordinance. A man who is able to carry the case up is desired, as the ordinance has never been tested in the upper courts.

Medical Director Hosea J. Babin, U. S. Navy, in charge of the naval hospital in this city, was retired for age recently. He is a native of Canada, and was appointed an acting assistant surgeon from Massachusetts in February, 1865. He was commissioned assistant surgeon in May of that year, passed assistant surgeon in 1869, surgeon in 1876, medical inspector in 1894, and medical director in 1898.

The Late Dr. Pryor.—The Medical Board of St. Vincent's Hospital, at the regular quarterly meeting held December 13, 1904, caused the following minute to be entered on its records, sending copies to the bereaved family and to the medical journals: "The members of the Medical Board of St. Vincent's Hospital have learned with profound regret of the death of their colleague, Dr. William R. Pryor. Of undaunted courage and indomitable perseverance, Dr. Pryor followed truth unflinchingly and the highest ideals without faltering. These qualities, coupled with technical skill of the first order, and unusually acute power and wide range of observation, had won for him an enviable reputation and a commanding eminence in his special field. His fine enthusiasm, his frankness and directness of purpose, his readiness to lend a helping hand, were enduring qualities which gained for him the highest prizes of ambition, the gratitude of his patients, the love and respect of his associates. Dr. Frederick S. Dennis, President; Dr. George D. Stewart, Secretary."

At a meeting of the New York Obstetrical Society, held October 11, 1904, the following resolutions were adopted: "That in the death of Dr. Pryor we have lost a prominent member of the society, distinguished alike as an original thinker, an earnest advocate of the truth, and an honorable gentleman. That we extend the family of our deceased Fellow our heartfelt sympathy. That a copy of these resolutions be sent to them and published in the medical journals. Henry C. Coe, Edwin B. Cragin, Clement Cleveland, Committee."

The Late Dr. Gilfillan.—The Medical and Surgical Staff of St. John's Hospital, feeling deeply the loss sustained by themselves personally, and by the institution whose interests they guard, in the death of Dr. William Gilfillan, have passed a resolution "That the Staff tender to his family the expression of their earnest and affectionate sympathy. His long and faithful service in the profession, and in St. John's Hospital, brought him into very close personal communion with his medical brethren. He was a loyal gentleman, never deviating from the best traditions of the profession of medicine. He was a man of courtesy and gentleness, courage, skill, and great patience. These qualities brought to him well deserved respect and regard. Association with him was a privilege, and we look upon his departure with profound sorrow." Committee: Alexander Hutchins, M. D., Henry A. Fairbairn, M.D.

Obituary Notes.—Dr. Henry McLean, of Brooklyn, died at his home, in that city, on December 23. He was born in Newburgh, N. Y., in 1850, and was a graduate of the Medical Department of the New York University in the class of 1873. He was a member of the Medical Society of the County of Kings, and of the Medical Society of the State of New York. He was visiting physician to the Kings County, St. Mary's Maternity, and Infants' Hospitals, and to the Brooklyn Central Dispensary. He served on the Board of Education from 1886 to 1896, and was a member of several social organizations.

Dr. Clarence Willard Butler died at his home in Montclair, N. J., on December 20, of malignant disease. He was born in Ohio in 1848, was graduated from Oberlin College, and received the degree of M.D. from the New York Homœopathic College in 1872. He had lived in Montclair for the last ten years, and was a prominent member of various State and national homœopathic medical societies.

Dr. William M. L. Fiske, of Brooklyn, died at his home in that borough, on December 21, of disease of the heart. He was born in New York in 1841. In 1859 he entered Bellevue Hospital Medical School, but left at the beginning of the Civil War to enlist in the Forty-seventh Regiment N.Y.V. He returned to the school later, and was graduated in 1863, afterward graduating from the New York Homœopathic College in 1864. He was then appointed assistant surgeon in the United States Army, and served in that capacity till the end of the Civil War. He then began practice in Brooklyn, and became prominent in homœopathic circles. He was one of the Board of Health Examiners of New York State.

Dr. Henry Mallory, president of the Board of Health of Hamilton, Ohio, and one of the oldest practising physicians of the State, died December 22, of pneumonia, aged 82 years. During the Civil war he served as a member of the Thirty-fifth Ohio Volunteer infantry, being elected captain, and after the battle of Mill Springs was elected surgeon of the Fourth Kentucky. He was made a division surgeon before the close of the war.

Dr. Samuel Hemingway died suddenly of disease of the heart on December 19, at his home in Newark, N. J. He was born in 1854, and practised for a number of years in this city and Newark, retiring some ten years ago.

Dr. Joseph D. Tantum, of Trenton, N. J., died at the German Hospital, Philadelphia, on December 18, at the age of forty-eight years. He was graduated from the Medical Department of the University of Pennsylvania in 1878.

Dr. Horatio Gates Mirick died at his home in Brooklyn, on December 22, at the age of seventy-four years. He began practice in 1856, and retired in 1892.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent).

WM. CADGE MEMORIAL—DUODENAL ULCER AND ITS TREATMENT —MENINGITIS—LUMBAR PUNCTURE—ACUTE LOCAL TUBERCULOSIS AFTER OPERATIONS.

LONDON, December 9, 1904.

On Tuesday the President of the Royal College of Surgeons went to Norwich and unveiled the memorial window to the late William Cadge in the beautiful cathedral. Many of your readers have probably visited that city and admired the church of which all artists are proud. The Cadge memorial will be an additional object of interest. Subscriptions were received from America and many other lands, for the fame of the great and good Norwich surgeon had penetrated to all countries where surgery is honored. The ceremony was performed in the presence of the profession of Norwich and of representatives of the provinces as well as a considerable contingent from London. The President (Mr. Tweedy) gave a sympathetic address in which he spoke from personal knowledge of the simplicity, sincerity, and strength of Wm. Cadge, who unceasingly cultivated all the charities of life as citizen, friend, philanthropist, and physician, "and gained the good opinion and confidence of his companions and his peers while he lived and their affectionate remembrance in death." He has "finished 'the work given him to do.' He rests from his labors and, leaving behind him an example of high purpose and worthy endeavor, has joined the glorious company of whom it is written 'Opera illorum sequantur illos.'"

Mr. D'Arcy Power brought the subject of Duodenal Ulcer before the Medical Society of London last week. He gave particulars of 7 cases on which he had operated and noticed others he had seen. He considers the disease deserves further attention. He divided the cases into those which perforated and those which did not. In the former the patient was generally a man in the prime of life seized suddenly with intense pain and collapse. Pulse small, regular, quick, but not nearly so accelerated as respiration. Sometimes a point of maximum tenderness in right hypochondrium. Vomiting might occur but no passage of fæces or flatus. If no operation was done, death from peritonitis followed. In the non-perforating cases the patient was usually older, say 50 to 60, and a martyr to indigestion and fits of vomiting, with constipation. Emaciation marked. Gastric dilatation might be more marked than in cancer. Sometimes the history suggested a former ulcer which had healed and the cicatrix, with inflammatory thickening, might cause a lump to be perceptible and so suggest cancer of the gall-bladder or pylorus. Often diagnosis could not be made until perforation took place. Direct suture was less favorable than in perforation of the stomach. Gastrojejunostomy was the treatment advised.

The discussion which followed showed a practical agreement as to the great value of gastroenterostomy. That the diagnosis is surrounded with difficulties is obvious enough and some useful suggestions were made. One or two speakers had collected statistics from the post-mortem room. Jaundice was sometimes present. Melæna without hæmatemesis was said to point to duodenal ulcer. Pain was very variable; it mostly came on an hour or so before a meal and was relieved by eating, or it would come on in the small hours of the night; sometimes it shot up towards the scapula. Tenderness about the region of the gall-bladder was more significant, and also rigidity of the rectus. Hæmatemesis and melæna may be altogether absent or small quantities of black blood passed almost constantly. In gastric ulcer a solid meal at once induces pain, relieved by a draught of hot water; in duodenal ulcer solids and fluids alike cause pain, but later on. Mr. Mayo Robson, who has operated on 30 cases, did not think diagnosis so difficult as other speakers. He said most of his cases were in the professional classes who lived too freely and took insufficient exercise, thus giving rise to hyperchlorhydria.

The "Crises of Posterior Basic Meningitis" was the title given to a paper at the Clinical Society by Dr. C. R. Box. He related 5 cases characterized by sudden rises of temperature, sometimes as much as 7° F., coming on with chills or even rigor, followed by headache, and often vomiting; the neck becoming stiff or retracted and the mental state dull, the pulse not falling, but rather rising. The symptoms subside as rapidly as they come on, the whole "crisis" lasting, say 12 hours. Dr. Box suggested temporary increase of the intraventricular pressure as the cause and thought lumbar puncture might relieve it.

Objection was taken to the term "crisis" by two or three speakers, chiefly on the ground that it suggested a turning point in the disease, a sort of critical period. The President (Dr. F. Taylor) on this point agreed that the term was scarcely justifiable, though the meaning has been extended of late, *e.g.* in ataxy. Objection was also taken to the explanation proposed by Dr. Box, on the ground that such variations of temperature and the other symptoms were met with in various conditions and could not be considered as diagnostic of posterior basic meningitis. Dr. Batten declared the fall was as characteristic as the rise and that he had seen a fall of 10° F. in 12 hours. Dr. Pasteur observed that drowsiness being present between the attacks but not during them was against the idea of increased pressure. The President thought the evidence of post-basic meningitis inconclusive, similar attacks occurring in various septic conditions. Dr. Box in his reply referred to the use of the term crisis in other diseases, *e.g.* floating kidney.

A case of unilateral tuberculous meningitis was related by Drs. Rolleston and Tebbs, in which a bullous eruption followed lumbar puncture. I notice this on account of the operation which does not seem to have been widely resorted to in this country. At any rate most of our records of it are from abroad and in conversation I do not often hear of its frequent adoption. A correspondent traveling in Egypt gives an almost enthusiastic account of its use as an anæsthetic—particularly for pelvic operations. Our surgeons are more cautious and slow to record their experience until it is more extensive. The operation, too, though spoken of as so easy and simple, does not seem to me very inviting and perhaps the "open mind" is for the present more appropriate.

The case which has led to these remarks was that of a boy of 5, who after a day's malaise was seized with general convulsions, more marked on the right side, with conjugate deviation of the head and eyes to the right. Puncture was performed between the spines of the 3rd and 4th lumbar vertebræ, subsequently a cannula introduced and cerebrospinal fluid, at first stained with blood, was allowed to run away. Next day 2 bullæ appeared on the right little toe. The child died that afternoon, the whole illness having lasted 5 days. At the autopsy tuberculous meningitis limited to the left sylvian fissure was thought to be due to an embolus from a caseous gland invading the apex of the left lung. There was a clot 3 inches long under the arachnoid in contact with the posterior nerve roots of the cauda equina on the right side, probably due to the lumbar puncture. This clot probably irritated the nerve roots and ganglia and produced the bullæ. Dr. Box remarked that lumbar puncture, though of great value, was by no means always harmless; he had twice seen thecal hemorrhage follow it. Dr. Batten remarked that the puncture was some distance from the first sacral root ganglion and asked if this root was examined, to which Dr. Rolleston replied in the negative. Injury of the roots above the ganglia, Dr. Batten thought, would not produce the bullæ. Dr. A. E. Russell said that Bayliss had shown that stimulation of the peripheral end of a cut posterior nerve set up great vasomotor changes in the limb supplied.

Drs. Corner and Dudgeon then described a case of post-operative acute local tuberculosis, affecting all the tissues around after removal of a gland from the neck. Local swelling after the wound was healed was the chief sign and this shed some light on swellings seen after operations for some other tuberculous cases, which were referred to as occurring after healing of the wound by first intention. Local infection seemed less likely if the wound was left open, or drainage employed. It was suggested that when the chance of infection seemed obvious, as when glands burst while being excised, it is best to drain if the situation permitted.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

THE CHEMISTRY OF CONSTIPATION—X-RAY TREATMENT OF TUBERCULOUS DACTYLITIS AND EPITHELIOMA.

VIENNA, December 10, 1904.

Most observers have sought to explain the nature and consequences of constipation on a chemical basis, although we are still ignorant as to the exact metabolic changes accompanying the condition and the nature of the toxins absorbed by the body from the stagnating intestinal contents. K. Glaesser has reported to the Medical Association the results obtained on analysis of the feces and urine of animals suffering from constipation artificially induced. The experiments were conducted by resecting a segment of intestine of sufficient length, turning it end for end, and restoring the interrupted canal by suture with the segment in this reversed position. As the intestinal current could not pass this portion of the gut, local stagnation was set up which increased by degrees and finally caused marked dilatation, partly in the reversed portion and partly above it, so that a considerable obstruction was formed. Thus a well-marked impediment to the passage of intestinal contents was produced without stenosis, and if the

resected portion was sufficiently large and was situated close enough to the colon extreme constipation resulted. The animals recovered from the operation promptly and showed an interesting state of affairs. They were constipated so that they defecated only once every ten to twelve days, and, although the appetite was good, and plenty of food was taken, they slowly lost weight, and finally died of cachexia. An autopsy dilatation of the reversed portion of the intestine and extreme emaciation were revealed. The animals were given a uniform diet and were placed in nitrogen equilibrium before the operation was performed, atfer which the investigation was continued by studying the nitrogen in the feces and urine. A prominent feature was that the dried bulk of the stools was much less than before the operation. It appeared as if constipation had the effect of favoring the absorption of the solid portions of the food and causing more complete extraction of the nourishment. Another advantage was that the nitrogen of the feces was greatly decreased after the operation, apparently indicating a more thorough absorption of the albuminous food constituents. The nature of the fecal nitrogen was changed, however, and whereas normally it consists principally of coagulable albumin, in these cases there was an almost equal amount of coagulable and non-coagulable albumin. More decomposition products were present and, though these ordinarily can be precipitated and fractionated into albumoses, pepton, non- and diamino-acids, in these constipation stools they were principally basic albuminous bodies precipitable by phosphotungstic acid. The disordered state of the metabolism was shown still more clearly in the urine. The animals lost their nitrogen equilibrium and from the day of operation the nitrogen contents of the urine rose steadily, till, as death approached, the quantity excreted had increased to almost the double amount. In spite of the richly albuminous diet, nitrogen excretion was in excess and progressive cachexia resulted. The ammonia of the urine also was affected in a peculiar manner. After a defecation the ammonia content was normal, but as the constipation progressed it rose until it had reached and even exceeded double the physiological limits. This condition persisted until the next stool, after which the ammonia at once dropped back to the normal amount. This phenomenon occurred with great regularity and accidental variations could be excluded.

Dr. Freund presented before the Medical Association four cases from Prof. Finger's clinic. The first patient was a girl of eleven, who, for a number of years, had suffered from tuberculous caries of the proximal phalanx of the right index finger. The lesion had been curetted twice, the last time a year and a half ago, and before treatment the first joint of the finger was the seat of a spindle shaped enlargement, with the skin reddened and a lateral sinus which discharged a thin pus containing cheesy, bony débris. Bare bone could be felt with a probe, which readily penetrated the spongy tissues. The sinus could be seen on an *x*-ray plate and had a length of 1½ cm. and a breadth of 6 mm. The favorable results obtained by the use of the *x*-ray in a previous case led to its application in this instance. Two series of treatments were given, each consisting of six sessions, in which the finger was placed 5 cm. away from a fairly hard tube. Each series gave rise to a slight reaction, consisting of redness, swelling, and an increased secretion of thin pus, but after the subsidence of the second reaction the discharge stopped and the sinus closed. At present the finger is normal in appearance and the site of the sinus is indicated by an inconspicuous scar. An *x*-ray picture shows that the former fistulous tract has been almost entirely filled with solid bone and the rest of the bone also is firmer in structure. The patient will not receive further treatment, as the bone will be completely consolidated in a few weeks. The fact that in immediate connection with the *x*-ray treatment the nature of the disease process was completely changed and that the suppuration which had persisted for eight years, without modification by several operations, suddenly ceased, warrants the assumption that the cure was the direct result of the treatment. Apparently the rays penetrated through the atrophic non-calcareous bone tissue to the disease focus and occasioned a local hyperæmia. This was probably the chief feature of the cure, in accordance with the generally accepted dictum of Bier that congestion represents an important factor in the treatment of tubercular processes. The other three were cases of epithelioma treated with the *x*-ray. One patient with a growth the size of a fice-cent piece in the naso-libial angle was treated eight times; another with a similar condition at the inner canthus, six times, and a patient with epithelioma of the upper lip the same number of times. In each instance the ulcer was completely cicatrized with excellent cosmetic effect and only in the second case did infiltration of the scar persist. In treating larger, deeply seated neoplasms it seems advisable to remove the tumor by extirpation and then to treat the granulating wound surface with the *x*-ray in order to destroy any foci that may by chance have been left behind. Freund has frequently made the observation that women at the time of menstruation react more promptly and intensely to the rays and that in the normal skin repeated treatments may, if pregnancy should intervene, give rise to telangiectases. At the menstrual epoch the circulatory as a whole is in a modified state which manifests itself by greater sensitiveness to stimuli of various sorts. Accordingly, *x*-rays of slight intensity may, under these circumstances, give rise to severe reactions in the more vascular regions, and Freund has always observed this before menstruation. Of course, the same thing holds good for all conditions associated with increased sensitiveness of the vessels, such as pregnancy. If a pathological change has been caused in the vessel walls by the *x*-rays such an increase in the reaction may plainly be preceived. Freund observed the formation of telangiectases of the breast in a woman on the occurrence of pregnancy a long time after a protracted series of *x*-ray treatments. It is not unlikely that in this instance the lesion was caused by the augmented quantity and pressure of the blood entering vessels which had already suffered changes in their walls through the action of the rays. The same observer recommends for the protection of the physician that the patient and apparatus be surrounded by a screen covered with lead sheeting and provided with windows of lead glass, through which the patient and tube may be kept under constant observation.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent).

AMŒBIC CYSTITIS—BACTERIAL VIRULENCE AND IMMUNITY—SARCOMA OF THE EYE—NEW GOVERNMENT LABORATORY BUILDING—SMALLPOX—CONTINUED HIGH DEATH RATE.

MANILA, November 14, 1904.

At the November meeting of the Manila Medical Society a case of amœbic cystitis was reported by Dr. J. R. McDill. If the cases of amœbic cystitis due to rectovesical fistula are excluded, a perusal of the literature on this subject shows that this is a very rare condition and that few cases have been made a matter of record. The case in question came under observation on account of some abdominal symptoms which were afterwards attributed to a floating kidney. The infection is supposed to have been contracted from an unclean catheter which was used on the patient by a careless attendant. The treatment consisted of bladder irrigations of a 1-1000 quinine solution, soon after which all traces of amœbæ in the urine disappeared. At the same meeting a paper was read by Dr. R. P. Strong, Director of the Government Biological Laboratory, entitled "Some Questions Relating to the Virulence of Microorganisms, with Particular Reference to their Immunizing Powers." The conclusion reached was that the virulence, as shown by experiments on animals, was not in direct proportion to the dose injected. The experiments were all made with the cholera organism and the writer expressed the hope that others would take up this work with other bacteria with the view of ascertaining whether the same results would be reached. Another paper was read by Dr. Paul G. Woolley, entitled, "A Case of Sarcoma of the Eye Involving Chiefly the Ciliary Body." This was a primary sarcoma of the eye due to an injury. The condition is rather rare according to the author of the paper. A number of excellent photomicrographs were exhibited to illustrate the case.

The construction of the new government laboratory building, of which mention has been made in these columns from time to time, has advanced sufficiently far to permit of its being occupied by a number of branches of the Bureau of Government Laboratories. The lighting and power plant has not yet been installed and the numerous carpenters and other workmen who are engaged around the building make its inspection rather unsatisfactory at present. There is little doubt, however, that when completed this will be one of the foremost institutions of its kind in the world. It will offer opportunities for research work which can scarcely be equalled by any American institution, and when the opportunities for obtaining virgin material are added to this it will be seen what a splendid promise the future holds forth. The Bureau is composed at present of the following divisions: (1) A serum laboratory at which are manufactured vaccine virus, rinderpest serum, etc. (2) A library in which are to be stored and catalogued all the scientific books in possession of the government. (3) A well-appointed chemical laboratory. (4) An entomological division, which has already done good work in the study of the insects which were destroying the cacao plants of the islands. (5) A biological laboratory, which gives much promise for the future. (6) A botanical division. The large number of plants which remain unidentified gives this division a large field in which to work. There are a number

of other branches of this bureau, but they can scarcely be dignified by the name of division, as for instance the branch which takes the photographs for all departments of the government. It has also been proposed to incorporate a division of weights and measures, the necessity for which has already been felt. The superintendent of government laboratories, Paul C. Freer, formerly professor of chemistry at the University of Michigan, is at present in the United States on a leave of absence. Dr. R. P. Strong, the director of the biological laboratory, is acting in his place.

The outbreak of smallpox at various points of the islands still continues. The situation, as nearly as can be ascertained, remains about stationary. No other quarantinable diseases are reported in the islands at the present time. A particularly discouraging factor with which the Board of Health has to deal is the continued high death rate in Manila. The last report issued shows this to be 55.28 per 1,000. It was confidently expected that, when the large number of deaths due to cholera could be eliminated, the mortality would show a decided improvement, but that such was not the case is shown by the fact that there has been no cholera reported in the city of Manila for more than six months and yet the percentage of deaths is as high and some months even higher than during the cholera epidemic. It was also thought that the population as given by the official census of 1903 (219,941) was entirely too low and therefore the death rate calculation as rendered was erroneous, but a police census which was recently completed shows that the present population does not exceed the figures given by the official census. Smallpox was another disease the deaths from which caused the mortality statistics to remain high, but no deaths from this disease have been reported for a number of weeks and still the percentage refuses to drop. The greatest number of deaths is of course among infants under one year of age. When the utter lack of knowledge of how to take care of children and the poor physiques of the Filipinos as a class are considered, it is difficult to see how any great improvement is to be expected in the near future.

THE DANGERS OF HYPNOTISM.

To the Editor of the Medical Record:

Sir: So much is being said about hypnotism and its possible uses, that it is advisable to point out some of the dangers and unfortunate experiences that may occur. In the present state of our knowledge it may be a two-edged sword capable of doing harm as well as good. Ernest Hart, late editor of the *British Medical Journal*, met with experiences that led him to take this position most emphatically. For several years the writer has been interested in studying rudimentary forms of sense perception and the various methods of their development. In the course of this study it has been found that the exact opposite of hypnotism, namely, full control of the faculties by the individual himself, is the best method of bringing out latent powers of the mind, if such there are. The results have been so instructive and satisfying that it has not been thought necessary or advisable to resort to hypnotization in any form whatever in bringing them about. Nevertheless, occasionally an experiment has been made with hypnotism in order to see what would happen, and by way of contrast. In this way it has been brought out that there may be exceedingly unpleasant forms of automatism developed, and much intensified by hypnotism. A lady of most gentle breeding, writing with planchette for amusement, finds that it begins to swear and use the foulest language imaginable. Another subject who has the power of automatic mirror writing, finds this same thing happening in a most disagreeable way and is compelled to refrain from anything of the sort. Reinforced by hypnotization, this sort of thing may be done with no consciousness whatever. At times there comes out in greater or less degree what has been termed veritable double personality, as described by Binet in his book on the subject. Persons in this state are for the time entirely lost to their own personality and do all sorts of strange things, disappearing it may be from among their friends and coming to themselves suddenly among entire strangers, and engaged in some other occupation than that to which they have been accustomed. This is really a form of automatism of highly complex character, and anything that sets it in operation in any degree or to any extent whatever is a most powerful and it may be a most dangerous agent. The irresponsibility of drug habits appears to be an automatism of this same general nature. The writer has had a most disagreeable personal experience in attempting to investigate the subject of automatic writing, by experiments of a hypnotic nature. So long as the thing is not taken seriously at all, and is for purposes of mere amusement, the results may be trivial. But if a determined effort is made and the subject becomes decidedly in earnest, it may be like letting loose a piece of machinery to run without a balance wheel, automatism of this sort being specially liable to recur or perpetuate itself to a greater or less degree. When it is supposed that the subject has returned to his normal condition, and in the absence it may be of the hypnotizer who originated it all. The hand that has been started writing automatically goes right on, it may be putting down things entirely foreign to the person's real nature and that will cause chagrin and keenest regret when the subject returns to his normal condition, especially if they fall into the hands of persons who do not understand the nature of the experiments or know that it is mere experiment. In this and other ways the inception of automatism in any earnest and positive way by hypnotization is not to be regarded as a trivial matter. Even with the best understanding of the subject now possible, there is danger in originating anything that puts a hypnotized person under his own control—in other words, that originates automatism. So long as the subject is under the control of the hypnotizer absolutely, there is not so much danger, but let him go out under his own control and he runs without a balance wheel. In this way autosuggestion, which fortunately is more difficult and exceptional, may originate exceedingly unpleasant experiences. The writer has even come to the conclusion that there may be causes of insanity confined to institutions that, if the truth were known, are really of this type. So the study of the subject may be imperative for the sake of those thus afflicted. But until it is very much better understood than at present, it needs to be undertaken, if at all, with such precautions as will insure avoidance of the origination of automatisms that may become for the time being, if not permanently, the source of irresponsibility, if not of insanity. Slight abnormality in this regard may rectify itself, but there is a point at which it becomes like the therapeutic use of deadly poisons, justifiable, no doubt, but to be used only with full understanding and utmost care.

M. A. Veeder, M.D.

Lyons N. Y.

Progress of Medical Science.

The Boston Medical and Surgical Journal, December 22, 1904.

Pulmonary Congestion as a Cause of Sudden Death.—W. W. Miner reports three cases in which he has lately met with severe and extensive congestion of the lungs in post-mortem examinations. These persons all died suddenly. Their friends had not considered them to be in any danger of the approach of death. One of them was a strong man with a severe cold, but who was walking about as usual. Three hours later his body was found at the foot of a stairway where he had fallen. One was a young man in vigorous health, and the third an elderly man in fair condition. In two of these cases there were no ante-mortem symptoms which attracted any attention. The second patient, however, complained of not feeling well after felling some small oak trees, and he dropped dead while leading his horse homeward with the fuel he had cut down and loaded on his wagon. In each of these cases, autopsy showed ample cause of death in the remarkably congested condition of the lungs which had been of very short duration. The writer then quotes from various authorities concerning this condition. Two of these cases reported were addicted to the use of alcohol. The third man had overexerted himself by chopping fuel with a poor axe, and pulmonary congestion developed, followed by death. A veterinary surgeon whom the writer consulted, stated that this condition was not infrequently found in horses at post-mortem; and it was found not only in animals which had been overdriven, but also in those which were quartered in damp, dark, or unhealthy stables, which might cause debility and inability to resist attacks of disease.

New York Medical Journal, December 24, 1904.

A Contribution to the Serum Therapy of Syphilis.—J. De Listo says that antisyphilitic serum is in no sense an antitoxin but a toxin for the bacillus of syphilis. Up to date, about one hundred cases have been treated by him, with the remedy and the clinical histories of several are given. The average dose is about 20 c.c., at intervals of one week. The author realizes that some of the cases claimed as cured by the serum might not be accepted as such by other observers, but in one instance it is stated that a man assumed to be cured, tore the skin covering his old chancre at the time of initial coitus with his wife some three or four months after he had been dismissed from treatment. Both man and wife were kept under close observation for nine months, during which time the former had no recurrence of symptoms, while the latter failed to develop the slightest sign of the disease. Not all the cases have done well. In one case of ataxia the results were surprisingly good while other similar cases were not at all benefited.

The Plasmœba of Dengue; a Brief Description of the Earlier Phases of Its Plasmic Characteristics.—H. A.

Eberle, of the U. S. Army medical corps, gives his experiences in the Philippines with this organism, illustrating his paper with some excellent photographs of the parasite and temperature charts from certain cases of illness. He regarded the malady as a serious one for marked cachexias and impairment of nutrition often follow in its train. Histologically, the parasite belongs to the sporozoa, and since it is first found in the blood plasma, the author has named it the plasmœba. It impregnates the cells producing a pale, violet tinted growth assuming various shapes as it increases in size, and in which can be noticed, after two to four hours, faintly darker bodies, the earliest spore formations which occupy usually from two-thirds of to the entire corpuscle. On many occasions, when the spores form in the pseudopodia, they give the corpuscles the appearance of being crenated, but in fact they are merely projections beyond the border of the corpuscle pushing out the elastic limiting membrane of the cell. These spores mature in the course of a few hours and are characterized by a definite outline inclosing a pale protoplasm without nucleus or nucleolus. These matured spores are highly refractive and finally burst through the limiting membrane of the corpuscle and are poured out into the plasma (the greater number, however, being passive) and ready to enter on a new cycle. The fever runs a general course of slow insiduous invasion, a stage of vacillation from 102° to 104° attaining its maximum in about forty-eight hours and then shows a gradual decline. There is seldom any distinct crisis. Quinine has no effect in cutting short its course and does not lower the temperature. Only in complicated cases is it to be given, and then only in combination with some other antipyretic.

Medical News, December 24, 1904.

Hysterectomy and the General Health.—Eugene Coleman Savidge declares that when the choice is hysterectomy or death, hysterectomy is the only path to general health. But there are cases in which the wisdom of a hysterectomy is debatable. He defines "debatable hysterectomy" as the removal of Fallopian tubes and ovaries, as well as the uterus, in patients whose health might be restored more or less completely by other methods. Cases of hysterectomy in which a part of the ovary is retained are excluded. The writer, believes, that a bit, at least, of ovarian tissue, is essential to a woman's well being, notwithstanding the undeniable good wrought by these operations. The entire removal of ovarian tissue is followed by definite modifications in the nutritive, renal, hepatic, arterial and cardiac functions. The changes wrought are both psychical and material. There will develop a mixed condition of arterial tension, venous engorgement and muscular relaxation, followed by renal insufficiency, and life is materially shortened. The ordinary physical changes which take place after hysterectomy are well known—the roughened voice, the increased hair growth, the increase of fat. There is a wiping out of zest, and spirit, and pride of bearing. The writer calls attention to the fact that there is a necessity for making a marked difference in the treatment of American women in comparison with that of the women of other nationalities. The American woman has a more highly developed nervous system, with the corresponding nervous vitality. The difference between the American and English woman has developed chiefly from an inherited perception of the chance to rise. Boundless opportunity is open to the American woman. Knowledge of this fact has stimulated search for advancement, and has resulted in the restless, aspiring, nervous system which is the inheritance of the women of our land. It is in these cases that "debatable" hysterectomy works most harm. The American woman is different from the clinic woman. She has latent capacities and a promise of effective longevity that is jeopardized by the "debatable" hysterectomy which robs the spirit, abases the pride, exhausts the energy, and devitalizes the whole woman. The writer adds that this is his "American idea" in modern gynecology.

The Significance of Pus in the Nose, with Special Reference to the Affections of the Accessory Sinuses and Their Proper Treatment.—George L. Richards believes that when more attention is paid by the average practitioner to the real pathological conditions present in the nose, and when they are not all dismissed under the heading of catarrh or neuralgia, progress will have been made. He sums up his paper as follows: The patient presents himself to the physician with pus coming from one or both sides of the nose. What is the plan of procedure? Clear the nose of all visible sources of obstruction, especially polypi, which easily grow or are maintained wherever and whenever surfaces are bathed in pus. Examine the teeth to see whether there is anything in the way of probable dental origin of sinus trouble. Ascertain, if possible, by inspection whether the pus seems to come from the antrum or from the frontal sinus or from various points in the ethmoid cells. Try transillumination, not only for the antrum but also for the frontal sinus as well. Make an exploratory puncture of the antrum. If the antrum is free, explore the frontal sinus for pus; try to wash out with the canula, or to pass a probe, if possible. If not, remove the middle turbinate. If the antrum contains pus, endeavor to cure it by washing out for a reasonable length of time. If this is not successful, a radical operation should be performed. The better the drainage, the faster the cure. Where there are several empyemata it is better to clear out the nose as thoroughly as possible and then, under ether, do the operation on all the cavities at once. Each case should receive careful individual study. A skilled operator should not the surgical work.

American Medicine, December 24, 1904.

The Military Importance of Mild Typhoid Infections Such as Mountain Fever.—Major Charles E. Woodruff calls attention to the fact that mild and atypical forms of typhoid infection are found in every part of the United States, and that when troops are organized for war there are sure to be numerous cases arising to infect every camp. Disinfection in a camp is practically impossible, so that it is now an axiom of warfare to remove every infective case from the camp rather than to try the impossible task at disinfecting. It is shown that in civil practice a very large number of cases of typhoid fever are not recognized by the physician sufficiently early, or perhaps are wholly mistaken, and when such physicians are called into the service of the nation, they will be dangerous unless they follow the invariable rule to treat as typhoid every simple continued fever of a few days' duration, resisting quinine. The fever of the West—called mountain fever—has been proved to be typhoid, and the retention of the dangerous term "mountain fever" is very reprehensible, as it tends to obscure the real state of the patient and will interfere with camp sanitation. The treatment requires an equipment which cannot possibly be carried along with a mobile army, so that it must be recognized that the patient's welfare, as well as that of the camp, demands his immediate removal to a base hospital. Modern armies are never far from railroads, and the transportation of the patient is a minor difficulty compared with the transportation of a field hospital, which must, therefore, be a mere collecting station for the sick. The medical department of the army is entirely too small for these modern duties of sanitation, and there is an urgent necessity for its enlargement on new lines which have proved so efficient in the Japanese army. At present the medical department is organized to treat the sick, and sanitation is a secondary matter, but the birth of sanitary science makes it necessary to reverse the matter. The medical officer must act for the commanding officer, and not merely recommend measures which may or may not be carried out, depending entirely upon a layman's opinion as to their necessity.

Prevention of Measles and Whooping Cough.—Chas. S. Caverly states that the profession and the public are too prone to view these diseases as harmless. Although preventable, the means adopted to check them, measured by their prevalence and fatalities, are largely ineffectual. While death rates from scarlet fever have quite uniformly been cut down, those from measles and whooping cough remain unchanged, causing more deaths than scarlet fever. Their prevention presents peculiar difficulties. For instance, the indifference of the public, shared by the profession, the failure of many patients to see a physician, their contagiousness at a time when they cannot be recognized, and the variable length of time that they remain virulent. They are officially classed as "dangerous to the public health," but are dealt with more leniently than some of the communicable diseases, because of the prevalent apathy toward their spread. There is not sufficient unanimity among doctors as to the necessity of preventing these diseases. They are difficult of early and certain diagnosis because their early symptoms are common to these and less severe and less contagious diseases. The schools offer the best opportunity for their spread. There should be a change of sentiment among parents and teachers in regard to "colds." In catarrhal diseases of all kinds affecting the upper air tracts the child should be excluded from the school. The early communicability of measles and whooping cough must never be overlooked. Health officers and physicians must work together to isolate these diseases until the symptoms of the sequels and complications, as well as of the primary disease, are well passed.

Unusual Case of Addison's Disease.—Herbert B. Whitney reports the case of a healthy laboring man of 33 who was taken with sudden weakness two months before death; he did not give up work until about a month later. His only symptoms throughout the disease were progressive muscular weakness and toward the last, one or two attacks of apparent collapse. There was no discoloration of the skin and no noticeable loss of weight. Inability of the patient to speak English and the peculiar combination of a very acute course without bronzing, made the diagnosis

peculiarly difficult. The case was considered inexplicable until autopsy disclosed tuberculous adrenals. Recognition of this form of Addison's disease would seem to depend chiefly upon remembrance of the fact that there may be no bronzing and that the course may be as rapid as that of an acute infection.

Journal of the American Medical Association, December 24, 1904.

Treatment of Aphasia by Training.—This system of training is described by C. K. Mills, it having been suggested by a patient he had under observation. The author summarizes the various pedagogic methods of training described in the books and gives his detailed experience with several patients. He prints two tables illustrative of the method he prefers and these may be placed in the patient's hands. The first table has reference to the proper pronunciation of vowel sounds and in the second, these sounds are incorporated into short, easy sentences. Mills notes the fact that experience with aphasics impresses on the observer the difference in time and completeness of recovery in cases apparently equal in the original loss of speech. The patient's previous business, mode of life, strength of character, etc., all bear directly on this point. Cases of pure sensory aphasia make rather rapid partial recoveries, at least this is true of cases with word deafness. When sensorimotor aphasia is present, the recovery from the aphasia is usually but partial. It seems probable that in many instances destruction of the cerebral areas of speech is incomplete; in these cases language is partially reacquired by the calling into activity of the uninvolved portions of these areas. The centers in the right hemisphere have a potentiality for speech, but this potentiality differs greatly in different persons.

The Control of Internal Hemorrhage by Drugs.—T. L. Coley summarizes our knowledge concerning the various agents which have the reputation of being able to control internal bleeding. It is necessary to bear in mind, says the author, that the direct indications for treatment vary with the individual case. These indications include the source of the blood, the condition of the circulation and the amount of blood lost. In cases of total collapse alcohol and strychnine would probably be of value. Fainting from loss of blood may not be in itself an indication for medical treatment, for we know the value of this condition in inducing thrombosis. The use of the vegetable and mineral astringents in those cases in which the bleeding point cannot be reached directly, is highly illogical. The same is true of the use of the mineral acids. Aconite approaches the action of this group on the circulation, without the untoward local effects. Ergot seems distinctively harmful in pulmonary hemorrhage, and from its action can scarcely prove of any value in other than uterine bleeding. Hydrastis has some value in similar conditions. The susceptibility of the splanchnic area to vasomotor influence might be utilized by administering hydrastis and strychnine in bleeding of this region. The author never saw noteworthy or conclusive results follow the employment of gelatin or calcium chloride. Normal salt solution is undoubtedly a valuable agent, and immediate response often follows its use. He has had poor success with suprarenal extract administered for its internal hemostatic effect and believes that the indications for its employment are distinctly local.

Diaphoresis and Diaphoretics in Ophthalmic Therapeutics.—Two papers are published under this title. The first is by Hiram Woods who does not find this class of agents of much use in atrophy of the optic nerve, optic neuritis, choroidal atrophy, cicatricial changes in the vitreous or uvea, chronic iritis, retinal detachment from cicatricial contraction, or primary glaucoma, but excluding these there are left many lesions in which diaphoresis is useful. These are especially acute trouble in the uvea, retina, orbital tissues and toxic blindness. Some cases of acute retinal detachment have been reported cured. His general conclusions are as follows: (1) The greatest utility of diaphoretics is in the acute congestive and exudative lesions of the uveal tract. (2) Diaphoretics are useful in retinal detachment produced by exudate from choroidal vessels during the course of acute choroidoretinitis. Judging from reported cases, they are also useful in the retinal detachment of high myopia. It is doubtful if restoration of function in the detached retina is usual or permanent. (3) Diaphoretics are useful in alcohol-tobacco amblyopia and probably in other forms of toxic blindness. (4) Diaphoretics influence to a slight extent only, if at all, lesions of the cornea and sclera. (5) Diaphoretics are useless in atrophic and cicatricial lesions.

The second paper is by T. A. Woodruff, who agrees in the main with Woods and thus describes his method of employing this form of therapeutic agency; baths should be given when the stomach is empty, as being less liable to produce any untoward effects, this being especially the case when pilocarpin is to assist in the production of the sweat. The patient should be in bed and wrapped up to the neck in a blanket and again covered with at least four blankets. Under the latter half a dozen quart bottles containing boiling hot water should be placed. If used at all, pilocarpin should now be given hypodermically, beginning with one-tenth to one-eighth of a grain, the dose of which can be increased if considered necessary to produce a more profuse perspiration, but usually a larger amount of the drug is unnecessary and not at all essential to the success of the treatment. The patient is now given to drink at least a pint of hot water, weak, sour lemonade or tea. In a few minutes he should begin to break out into a profuse perspiration, which should continue for at least two hours, only stopping short of that time if he shows any bad symptoms. At the end of the sweat he should be thoroughly dried and the skin rubbed with alcohol and then allowed to rest the remainder of the day. This treatment should be continued at least every other day until twelve baths are taken. At an interval of two or three weeks a similar course of treatment should be repeated, and then continued at various intervals so long as necessary. It is important that the treatment be carried out systematically and at regular intervals if we desire to get results.

The Lancet, December 10, 1904.

Mercurial Injections in Nervous Diseases of Syphilitic Origin.—M. Faure gives injections slowly into the muscles following them with gentle massage. He prefers the buttocks and passes the needle in four centimeters. The average daily dose is the equivalent of one centigram of mercury. His series of injections varies from six to twenty administrations. The series is repeated after a pause of equal duration to make up a total of from forty to eighty, extended over from one to two years. He notes that an intensive treatment is not necessarily a heroic treatment, for intensity may be obtained insidiously by very prolonged administration and the use of average doses frequently repeated. It is necessary to give the patient all the mercury that is required for the cure of the disease without giving him enough to produce toxic symptoms. He also declares (1) that patients who have not derived any benefit from a given preparation or from small doses, have improved under the use of another preparation or of larger doses; and (2) that patients who have become worse when treated with a certain salt or with large doses have improved when a different salt or small doses were substituted. The great advantage of the injections is that the amount of the drug given can be more accurately determined than by any other mode of administration. We know just how much is absorbed, which is not the ease with either pills or inunctions. In general, the familiar preparations of benzoate, biniodide, and perchloride of mercury agree well when given in ordinary doses, while cacodylate, hermophenyl, and other organic compounds agree even better but seem to be less active in equivalent doses, and may be reserved for delicate patients.

Some Unusual Effects of Movable Kidney.—C. Manseli Moullin gives the clinical histories of several cases in which a movable kidney gave the symptoms of respectively chronic gastric ulcer, evidences of obstruction of the gall-bladder and common bileduct and appendicitis. He believes that this particular kidney condition is far more common than is generally believed. All kidneys are in fact movable. In many people the up and down range of movement is from one to two inches. Such cases are not necessarily pathological. The name should be reserved for those cases in which the kidney not only descends but fails to ascend spontaneously when the diaphragm relaxes and which do not resume their natural position unless either the patient lies down or some external pressure is brought to bear on the abdomen. Moullin notes that whatever the nature of the symptoms to which a movable kidney gives rise, there is one test which enables the true cause to be distinguished at once and almost without fail. Symptoms that are due to a misplaced kidney are relieved and in most instances disappear entirely as soon as the patient is placed in the recumbent position. When they are due to organic disease of other organs, change of position has little or no effect.

Diseases of the Nervous System Sometimes Regarded as Functorial, with Particular Reference to Diabetes.—W. H. Dickinson says that while we have not yet discovered the initial nervous lesion of diabetes, we find on post mortem sufficient changes in the cerebrospinal centers to indicate that they play a part in the disease. The extravasations which have there been found, are not large enough to account for the diabetic process, but they suggest an attitude of the vessels which may have something to do with it. The occasional presence of sugar in the urine of the insane is beyond question, but we do not know in what percentage or what special variety of case. The loss of the patellar reflex is common in diabetes and seems to be an early symptom. A less common failure and a later manifestation is superficial impairment of sensation, affecting

especially the lower limbs. The vascular lesions found in the brain and cord are for the most part hemorrhagic or exudatory, allowing of escape of vessel contents, enlargement of the perivascular spaces and impart an appearance similar to that found in syringomyelia. All these changes indicate, however, but hypercoma, and the exciting factor in diabetes is still unknown. Taking together the results of experiment, of accident and disease, of mental impressions, and, though not frequent yet significant, the association of glycosuria with insanity, and adding to these the post-mortem evidences of transudation from the cerebral vessels, it is not to be doubted that there is a connection between the state of the brain and the voidance of sugar which must be taken into account in any theories we may form of diabetes. Whatever changes may exist in the liver and glycosuria, the remote cause is in the brain. The main suggestion from the nervous system lesion is that of loss of contractile power in the arteries. Only in some does this result in actual extravasation. Recent blood was found in eight out of twenty-two cases. The want of arterial tone found in diabetes is not, however, the terminal fact but merely a step in that direction.

British Medical Journal, December 10, 1904.

Condition of the Lower Limbs Often Mistaken for Phlebitis.—Sir William Bennett describes the general symptoms of phlebitis of the main deep venous channels as follows: Acute onset of pain or intense stiffness increased by movement; tenderness along certain definite areas increased by pressure; rapidly supervening general swelling below the seat of lesion, which "pits" on pressure, and which is increased when the erect position is assumed, or if the limb is materially dependent, subsiding on the other hand (if the phlebitis has ceased to extend), when the recumbent position is assumed and the affected part elevated; the essential part of the treatment being rest. For comparison with this, a condition of the lower limbs is met with, commencing with rapidly-oncoming pain somewhat diffusely inclined, but irregularly limited to certain areas, increased only upon slight (superficial) pressure, and completely relieved by deep or heavy pressure. There is some swelling of the limb, wholly, or in parts only, the swelling being of the nature of a general engorgement; there is no œdema; and hence no "pittting"; it is not increased by assuming the erect position, nor is it appreciably diminished in the recumbent or flat position. The swelling is for practical purposes independent of posture. The same may be said of the pain, which nevertheless, is much influenced by heat or cold, sometimes by one, and sometimes by the other. The patients, as a rule, are not neurotic, but rather the reverse. The swelling, when not involving the whole limb, is fairly limited to the areas supplied by the internal and middle cutaneous nerves, the saphenal plexus, the external cutaneous nerve in the thigh, and the musculo-cutaneous nerve at the outer side of the leg and the dorsal aspect of the foot. When the whole limb is swollen, the general contour of the normal part is preserved in striking contrast to the bolster-like limb of thrombosis. The reflexes are unaltered. Little can be said concerning the cause of the trouble. The condition may have some relation to osteo-arthritis. Possibly some vasomotor disturbance is at the root of the swelling. As to treatment, rest has no beneficial effect in these cases. The main object is to find the best means to shorten the course of the complaint. Massage, electricity, and passive movement, followed by resistance exercises are indicatd. To these may be added moderate exercise up to the point of resistance. By this is meant the point at which pain or stiffness renders exercise impossible without great effort. By these means the course of the disease is doubtless much shortened.

The Cerebrospinal Fluid in Relation to Disease of the Nervous System.—F. W. Mott declares that fortunately it is only under exceptional conditions that the cerebrospinal fluid contains microorganisms. There are, however, conditions in which microorganisms are almost invariably present, for example, cerebrospinal meningitis; and, from recent researches, it would seem that the same can be said for tuberculous meningitis. Sicard maintains that the cerebrospinal fluid in tetanic intoxication of the blood stream does not acquire any tetanizing property. This is an argument against the cerebrospinal fluid being the medium of exchange between the blood and the nervous tissues. Although it may be impossible in all cases of tuberculous meningitis to detect microscopically bacilli in the cerebrospinal fluid, yet, according to various inoculation experiments and culture experiments on blood gelose, positive results have always been obtained. Much interest has lately attached to the examination of the cerebrospinal fluid in sleeping sickness, on account of the discovery of the existence of trypanosomes in the fluid extracted by lumbar puncture. The writer has been able in a few instances, only, to find the trypanosome either in the blood or in the perivascular cell infiltrations of the central nervous system. He adds that the etiological evidence of the trypanosome being the cause of the disease, and, therefore, of the symptoms and characteristic lymphocytic reaction of sleeping sickness, is so convincing that very possibly some plasmodial or transitional form may exist in great abundance in the cerebrospinal axis which could easily be missed in sections, or forms which require a special stain, in order to disclose their existence. In general paralysis of the insane, there is evidence of chronic meningoencephalitis and lymphocytes in the cerebrospinal fluid. Under a low power in an acute case, there is a perivascular cell proliferation somewhat resembling that seen in sleeping sickness, except that it affects the cortex rather than the base of the brain. It is attended by far more neuron destruction and cell proliferation. The writer has very seldom found diplococci in the brains in this form of meningoencephalitis, although a large number of patients die with pneumonia and bronchopneumonia; whereas, in sleeping sickness, a very large proportion of the cases showed abundant evidence of diplococcal infection of the central nervous system.

Berliner klinische Wochenschrift, December 5, 1904.

Chromophorous Zones in Vital Blood Staining.—Rosin and Bibergeil describe a phenomenon observed in the course of their researches in the vital staining properties of the blood. When methylene blue, methylene azure, or combinations containing these dyes are employed, at a certain stage of the staining before the nuclei have taken up the color, some of the usually refractory red cells are seen to be stained. The cells affected are those surrounding a white cell, and it seems to make no difference whether this be a leucocyte, a lymphocyte, a myelocyte, or a mast cell, and even a mass of blood plates may produce the same phenomenon. The phenomenon is only temporary, but may be observed in pathological blood as well as in normal blood. The explanation appears to be that the leucocytes furnish enough oxygen temporarily to prevent the final reduction of the methylene blue to its leucoproduct, or that the white cells and blood plates in consequence of their great affinity for the dye attract the methylene blue to their vicinity and take it up themselves as leucoproduct until their death has taken place. During this time the erythrocytes become decolorized.

The Experimental Production of Lymphoeytic Exudates.—Wolff and von Torday believe that they have settled the question of whether or not active lmyphocytosis is possible by experiments on guinea pigs and mice. Intraperitoneal injections of tetanus toxin or diphtheria toxin, produce an exudate which, for a period of from one to twenty-four hours is made up principally of lymphocytes. The fact that this exudate can be produced artificially, and the promptness with which it appears, dispose of the two last objections to the acceptance of the possibility of active lymphocytosis, viz., that it was not possible to cause it experimentally, and that the lymphocytes might come from connective tissue cells. It was found that mice had a much greater tendency to lymphocytosis than guinea pigs; substances that in the latter animal set up only a polynucleosis, in the former produce lymphocytosis.

Münchener medizinische Wochenschrift, December 6, 1904.

A Case of Congenital Onychogryphosis.—Müller says that cases of congenital onychographosis are rare and describes an unusual one that is now under observation in the Strassburg dermatological clinic. The patient is a girl of fourteen, anæmic and sickly but without organic lesions. There is typical psoviasis on the extensor surfaces of the upper and lower extremities and the skin is everywhere dry and pale. The scalp is unusually dry and shiny, and the growth of short, thin, dry hairs is extremely scanty and irregular in distribution. The eyebrows are almost entirely missing and the eyelashes are represented by ten to fifteen little hairs scattered on the upper lid. The finger nails exhibit the most extreme degree of onychogryphosis and are from three to four times their normal thickness. The nails of the toes are affected to a less degree. Microscopical examination of the nails and hair has revealed no abnormalities of structure in either.

The Danger Attending the Use of Biehloride of Mercury in Obstetries.—Toff directs attention to the susceptibility of puerperal women to the toxic effects of bichloride. The dangers of the situation are increased by the fact that the usual evidences of mercury poisoning, salivation, and gingivitis are often now observed until poisoning has been going on for some time. Two types of intoxication are common, one in which gastrointestinal irritation is the prominent feature, and the other in which the kidneys are attacked. In cases of the first sort, diarrhœa sets in a few days after the labor, and continues together with the onset of more or less prostration and collapse, colic, etc. In such instances errors of diet, contaminated milk, etc., are apt to receive the blame and the bichloride douches are kept up till the appearance of oral symptoms proclaims the cause of the condition. If the kidneys are attacked by the poison, the case is still more serious, for in addition to albuminuria there may

be chills, fever, scanty lochia, irregular pulse, in short, a simulation of puerperal infection. Unless they have progressed too far, both types recover promptly on omission of the bichloride douches and irrigation of the uterus with saline solution. There is great variability in the susceptibility to bichloride, and some patients may be affected by even a single 1-4,000 irrigation, especially those with renal lesions. The author advises that the antiseptic should be used only in very dilute solutions, as 1-6,000 to 1-10,000, and should be followed by a douche of salt solution, to wash out any of the sublimate that might be retained in the genital canal. Albuminuria and intestinal diseases contraindicate the use of bichloride.

Deutsche medizinische Wochenschrift, December 8, 1904.

Manual Removal of the Placenta.—Ahlfeld says that the recent communications of Baisch and Wormser in which these authors have endeavored to show that better results as regards puerperal morbidity are obtained by the use of rubber gloves in manual removal of the placenta, are misleading. He ascribes the fact that the statistics of the Marburg clinic seem to show a higher percentage of temperatures in those cases to the greater care with which slight degrees of fever are noted in this institution. He also believes that such statistics give unreliable results because usually of retained placentas in maternity institutions usually occur in connection with other complications, which, of themselves, may account for a temperature, and the only way to reduce this element of error is to use the figures of larger numbers of cases than at present are available. Ahlfeld is convinced that in well-conducted institutions, the danger lies less in the hand than in the character of the contents of the genital canal, and he has usually seen temperatures only in those cases in which the nature of the labor itself was sufficient to cause a puerperal fever. The degree of contraction of the uterus is of importance and the removal of placentas completely within the uterus gives less good results than the extraction of fragments. The author also considers the attacks that have been made on his hot water and alcohol method of disinfecting the hands, and endeavors to show that it is possible to produce complete sterility of the skin with these agents.

Infection With Ankylostomum Larvæ Through the Skin.—Lambinet attained an abundant culture of ankylostomum larvæ by infecting dogs and then treating the stools according to the methods of Loos. The larvæ were washed with weak antiseptics to prevent the development of bacteria. Several hundred were injected hypodermically into a young dog. There was no local reaction, but the animal died twelve days later. The middle portion of the small intestine, not the duodenum, contained several hundred young worms of the same age and resembling those found after the same length of time in cases of mouth infections. The mucosa was covered with bloody mucus and showed numerous fresh hemorrhages.

Physiological and Pathological Albuminuria.—Senator discusses at some length the present standpoint in regard to albuminuria and especially physiological albuminuria. It is only within comparatively recent times that this condition has been received as a possibility, but now it is generally accepted that every normal urine must contain some albumin, though it may be present only in very small amounts. Now, physiological albuminuria is regarded much in the same way as physiological glycosuria, and among the causes that give rise to it in susceptible individuals are severe exertion of the lower extremities, eating and digestion of a hearty meal, menstruation, cold baths and psychical excitement. The occurrence of albuminuria is to be regarded as pathological only when it does not take place under unusual conditions alone, and does not disappear promptly on the cessation of the particular stimulus that caused it. Orthostatic albuminuria is distinctly pathological and most cases of this or cyclical albuminuria are caused by a slight irritation or inflammatory state of the kidneys which may go on to recovery or may develop into a chronic diffuse nephritis. Physiological and allied forms of albuminuria are based upon congenital or acquired predisposition of the individual, which consists in an abnormality of various organs such as the kidneys, the digestive tract, the blood-vessels, or the body fluids.

French and Italian Journals.

Cystotomy and Prostatectomy in a Patient with Calculous Prostate.—Fournier reports a case of this nature, the patient being a man of 76 years. The writer performed a cystotomy by means of which he was enabled to remove 80 vesical calculi. Ten days later, he performed prostatectomy, and determined that the ureter was filled with calculi in its prostatic portion. By means of retrograde catheterism, he was able to reestablish the permeability of the canal. Fournier believes that it is well first to do a cystotomy, in the case of patients with prostatic retention, in order that they may better support the later prostatectomy. In these cases, as in the one just cited, in which the prostatic ureter contains adherent calculi, which are very difficult to extract or push back, cystotomy and prostatectomy are two necessary operations.—*Revue de Chirurgie,* November 10, 1904.

Metaclastic Cysts of the Spleen.—Brunswic le Bihan designates cysts which follow rupture of the spleen as metaclastic cysts. Ruptures of the spleen are relatively rare in Europe. The spleen is small, and its consistence normal. Violent traumatism is necessary to cause a rupture of this organ. Unless there is surgical intervention, death is the most frequent termination of such an accident, since a free hemorrhage takes place in the peritoneal cavity. It is quite different in malarial countries. There, spleens are of large size, often enormous. The splenic pulp is fragile, but the capsule is thick and surrounded with adhesions. Sometimes even a slight injury will cause a sub-capsular rupture, or the hemorrhage is more or less limited by the adhesions. Later, the cyst gradually increases in the manner of a diffuse aneurysm. The writer has operated in two cases in which the patients had been sufferers from malaria. Both had suffered an injury with probable rupture of the kidney. The growth of the cyst dated back for several months. The same appearance was noted in the two cases. The cystic pocket contained from 8 to 10 liters of greenish liquid, which examination proved to be sterile. It contained blood and leukocytes. The wall formed by the greatly distended splenic capsule was lined by thick masses of fibrinous clots. Very strong adhesions fastened the cyst to the surrounding organs. In the first case a very difficult splenectomy was followed by death from shock on the next day. In the second case, recovery followed operation.—*Revue de Chirurgie,* November 10, 1904.

Traumatism and Affections of the Stomach.—Monprofit calls attention to the traumatic origin of certain affections of the stomach. The connection between traumatism and gastric disturbances has been well known for many years, but the writer believes that if more careful observation was given to these cases, this association would be found far more often than it is at present. He cites one of his own cases: A man was hit with great force in the upper part of the abdomen, and following this injury there developed gastric intolerance and vomiting, which lasted for several months. When the writer saw the patient, he was much emaciated, and presented all of the symptoms of gastric cancer, including a tumor in the epigrastrium. Laparotomy showed a stomach dilated, with an hypertrophied pylorus surrounded by an inflammatory area, showing the remains of hemorrhage. Posterior gastroenterostomy was performed, followed by the complete restoration of gastric functions. It is now a year since the operation, and the patient is in perfect health.—*Le Bulletin Médical,* November 16, 1904.

The Soluble Ferments and the Digestive Function of the Placenta.—Vercelli Raineri details his experiments on the digestive functions of the placenta, and formulates the following conclusions: (1) There is no doubt that the composition of the blood of the mother is different from that of the fetus. (2) The composition of the fetal blood leads us to suppose that there is a selection of the substances in the maternal blood. (3) There do not exist in the placenta soluble ferments, like those of gastric digestion, but for the fats and sugars there is a special selective action, due to the metabolic activity of the epithelial cells of the placental villi. (4) In the placental villi we have, not a function identical with that of the intestinal villi, but analogous to it, and in this sense the placenta possesses digestive activity.—*Archivio di Ostetricia e Ginecologia,* October, 1904.

Some Complications of Varicella.—Guiseppe Caccia calls attention to the fact that varicella, though ordinarily a very far from serious disease, is sometimes followed by serious complications, such as infection of the pustules by streptococci and staphylococci, kidney lesions, laryngeal and pulmonary lesions, and even nervous disturbances. Should there exist any fault of nutrition or tendency to disease, the attack of varicella may be followed by the development of other maladies of more importance. Convulsions, paralyses of various members, corea, meningitis, ophthalmoplegia externa, and encephalitis have all been observed. The author records a case in a baby of three years, healthy and of good ancestry, who, after a slight attack of varicella, developed a train of nervous symptoms which he believes to have been due to a slight encephalitis of the left cerebral hemisphere, which ended in complete recovery after four weeks. The diagnosis is based on the following symptoms: sudden onset, with vomiting, hemiparesis with tremor, disturbances of speech, slight optic neuritis, presence of albumin and leucocytes in the cerebrospinal fluid, with the complete recovery. He regards the varicella as the probable cause of the nervous lesion, combined with a predisposition to nervous disease.—*Rivista di Clinica Pediatrica,* November, 1904.

Book Reviews.

A Laboratory Guide in Elementary Bacteriology. By William Dodge Frost, PhD., Assistant Professor of Bacteriology, University of Wisconsin. Third revised edition. New York: The Macmillan Company, 1903.

This serviceable guide has required but few changes to keep it abreast of the times, and in its present edition it should prove a comfort both to instructor and student. Designed to receive the student's laboratory notes, the requisite blank pages and charts are abundantly provided, while the text is sufficiently flexible to render it easily adaptable to any course in bacteriology. The illustrations are good and thoroughly modern and the references cover literature that could be profitably read by every student.

Medical Laboratory Methods and Tests. By Herbert French, M.A., M.D. (Oxon.), M.R.C.P. (Lond.), Medical Registrar, Guy's Hospital, etc. Illustrated. Chicago: W. T. Keener & Company, 1904.

Dr. French aims to give the practising physician a very brief outline of the principal methods of examining the urine, the blood, the sputum, the gastric contents, the fæces, and the common purulent and serous fluids. In brevity the book leaves nothing to be wished for; in completeness and thoroughness it naturally lacks much. A praiseworthy feature is the emphasis placed on the possible fallacies of the various tests. The illustrations, we are sorry to say, are for the most part useless, as they are mere rough pen-and-ink diagrams. The book may prove useful for review or as a compendium, to those who have a wider knowledge of its themes than it presents.

La Chirurgie du Médiastin antérieur, par le Dr. Maurice Auvray, professeur agrégé à la Faculté de médecine de Paris, chirurgien des hôpitaux de Paris. 23 illustrations. Paris: J. and B. Baillière et fils, 1904.

This monograph by Professor Auvray presents the latest advances in the field of the surgery of the mediastinum, exclusive of the heart and the pericardium. The general technics of mediastinal operations are discussed very fully, including the methods employed by the author himself and by other operators who have written upon this subject. The operative treatment of foreign bodies in the mediastinum, in the trachea, and in the bronchi, of mediastinal abscesses, or tumors in that region, of restroternal goitre, and of aneurysms of the great vessels is then considered in detail. The surgeon will find in this work precise information upon all these subjects, offered in a concise and attractive manner. The illustrations by K. Wagner, mostly in linework, are excellent.

A Guide to Anæsthetics for the Student and General Practitioner. By Thomas D. Luke, M.B., F.R.C.S. (Ed.), Instructor in Anæsthetics (University Surgical Classes), Royal Infirmary, Anæsthetist to the Deaconess Hospital, and the Dental Hospital, Edinburgh. With 45 illustrations. Second edition. Edinburgh and London: William Green & Sons, 1905.

Within the compass of little more than a hundred pages the author has managed to compress all that the practitioner and student are likely to require on the subject of Anæsthesia. The book is, throughout, intensely practical and useful. No space is wasted on theories or discussions. This new edition includes general anæsthesia by ethyl chloride, which, in England and Scotland, has almost displaced nitrous oxide as far as general surgery is concerned. A very valuable section, and one which will appeal to every practitioner, is that on Mechanical Anæsthesia, or how the practitioner can best work single-handed. The book is small, but its value is great; it is well arranged, sufficiently illustrated, attractively written, and can be confidently recommended.

The Art of Compounding. A Textbook for Students and a Reference Work for Pharmacists at the Prescription Counter. By Wilbur L. Scoville, PhG., formerly Professor of Theory and Practice of Pharmacy in the Massachusetts College of Pharmacy, etc. Third Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son & Company, 1904.

It was with a pleasure that is rarely vouchsafed a reviewer that we perused the first edition of Professor Scoville's work in 1895. The third edition, which has now come to hand, presents the same material as the preceding editions in an enlarged and more complete manner. The book deals with the technical and practical knowledge required by those who are called upon to dispense medicines. It deals in detail with every form of prescription, from the simple solution to the most difficult and elegant form of dispensing. The book is so clearly and explicitly written that even the pharmaceutical tyro will at once seize the meaning of the directions given, and, with practice, will acquire the proper technique. To the country physician who is far from pharmacies or who wishes to dispense his own medicines, this book will be a perfect mine of knowledge. The subject matter is arranged so as to be of easy reference, and a large number of illustrative prescriptions are given. The chapter on incompatibilities is the best and most practical we have seen anywhere. In the new edition the subject matter has been made to conform to the U. S. Pharmacopœia, ninth revision, and chapters have been added on Tablets, on Sterilized Preparations, including the preparation of gauzes, catgut, etc. The subject of Emulsions is now treated with great fullness, with the latest researches on this theme as a basis, and additions have been made to various chapters.

Accidents and Emergencies, A Manual of the Treatment of Surgical and Medical Emergencies in the Absence of a Physician. By Charles W. Dulles, M.D., Fellow of the College of Physicians of Philadelphia and of the Academy of Surgery; Surgeon to the Rush Hospital, etc. Sixth edition, thoroughly revised and enlarged, with new illustrations. Philadelphia: P. Blakiston's Sons & Company, 1904.

Prompt action in emergencies may often save life or serious injury, and this manual, designed for the laity, is well adapted to serve as a guide in times of need. The text is simple enough to be easily understood by any person of average intelligence, with assuming the words-of-one-syllable type, so common in books of this class, and the measures advocated are all efficient and such as can easily be carried out by the unskilled. The subject matter for the most part is above criticism from the medical standpoint, though the author's sweeping condemnation of the Pasteur treatment seems somewhat ill-advised. The present edition has been considerably enlarged in both the letter press and illustrations.

A Textbook of Physiological Chemistry. By Olof Hammarsten, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Author's enlarged and revised fifth German edition. By John A. Mandel, Sc.D., Professor of Chemistry and Physics, and of Physiological Chemistry, in the New York University and Bellevue Hospital Medical College. Fourth edition. First thousand. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1904.

It is five years since the appearance of the former American edition of this well-known work; and during that period much has been done in the field of Physiological Chemistry. These new advances are incorporated in this edition, but the size of the book has been increased only by about seventy-five pages. This end has been attained by the judicious elimination of methods and statements that had become either superfluous or untenable. The general plan of the book is the same as before. Of late the importance of Physiological Chemistry has been recognized more than ever before, and those who require an authoritative and standard textbook on the subject will make no mistake in procuring this work.

Die Wirkungen von Arzneimitteln und Giften auf das Auge. Handbuch für die gesammte ärztliche Praxis. Von Dr. L. Lewin und Dr. H. Guillery. Band I. Mit 85 Texfiguren. Berlin: Verlag von August Hirschwald, 1905.

The volume is one of 857 pages. The therapeutics of the eye is discussed in an exhaustive manner, all of the known remedies employed in the treatment of the diseases of the eye being fully described. The introduction occupies thirty-five pages, and is devoted to a consideration of the peculiarities of the tissues of the eyes in different individuals—inherited tendencies, differences in the power of the tissues to resist disease, their behavior when subjected to the influence of remedial agencies, the possibilities of osmosis, the influence on deep structures of the absorption of various remedies, the casting off of effete and obnoxious materials, etc.

The volume is further divided into three parts. In the first part remedies that temporarily paralyze the entire or a part of the nervous system are considered. To this group belong chloroform, ether, cocaine, atropine, etc. The second part is devoted to a description of those remedies which have a toxic effect on the whole or a part of the nervous system. This group includes ethylic alcohol, ethereal oils, tobacco, etc. The third division is devoted to a description of the remedies that chemically or physically affect the albumin of the living cells. Iodoform, phosphorus, mercury, and the acids are included in the list. This division of the subject is not quite complete in this volume. There are a number of cuts, chiefly of fields of vision, illustrating the effect of certain remedies on the function of the retina.

The work when complete will be embodied in two volumes and will be the most comprehensive of all the works on this subject. It should be in the hands of all ophthalmologists.

Society Reports.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at Birmingham, Ala., December 13, 14, and 15, 1904.

The association met in the Council Chamber of the City Hall, and, in the absence of the president, Dr. Floyd W. McRae, of Atlanta, Georgia, the second vice-president, Dr. J. Shelton Horsley, of Richmond, Virginia, presided.

Addresses of welcome were delivered by Mayor Drennan and Dr. L. G. Woodson, which were responded to by Dr. W. P. Nicolson, of Atlanta, Georgia. After a brief report from Dr. John D. S. Davis, chairman of the local Committee of Arrangements, relative to entertainments, order of procedure, etc., the reading of papers was proceeded with.

A Method of Uniting Intestines of Very Small or of Unequal Caliber.—Dr. J. Shelton Horsley of Richmond, Va., said that all sutures might be divided into two general classes, the continuous and the interrupted. The continuous suture more nearly fulfilled the ideal conditions for intestinal healing than the interrupted. Serous surfaces united after being sutured on account of the hyperemia of repair, and this was dependent upon some slight injury to the peritoneum. In the case of an interrupted suture, union was obtained within the bite of the suture by hyperemia caused by pressure of the suture, by the trauma of the needle, and by the presence of the thread. Between the sutures the pressure from thin intestinal tissues was practically *nil,* so union depended solely upon extension of this hyperemia, and if this process did not extend from one stitch to another, leakage would surely occur. Continuous pressure along the entire margin of an intestinal wound could be obtained only by the continuous suture. He described nine experiments in which an area of intestine was included between two lines of sutures. In only four of these did the whole area between the rows of sutures unite, demonstrating that something besides mere approximation of serous surfaces was necessary for satisfactory union. The method of suture was difficult to describe without accompanying illustrations. The intestinal ends to be united were placed side by side with their convex borders in contact and clamped with a hemostatic forceps. Then he used a suture that passed through the whole of the intestinal wall, sewing together with a continuous stitch a crescentic area excised; then changing the stitch to a Cushing right-angled continuous suture penetrating all the coats and invaginating the remaining margins of the wound. When the first knot was reached in the suture, it was invaginated and the suture continued by two or more insertions of the needle; with the last two insertions of the needle, as secure a hold as possible was obtained without penetrating the mucosa. The very last insertion of the needle was in the reverse direction of the other insertions, so that when the knot was tied it was partly buried. The bowel was then returned to its natural position, and the mesentery sewed up with continuous stitches. A number of photographs and specimens from dogs were exhibited, demonstrating some of the advantages claimed for this method. These specimens had been filled with paraffin and then photographed; afterward the intestine was removed, and the paraffin model was also photographed, giving a very good idea of the large lumen at the site of the union.

Dr. W. P. Carr of Washington, D. C., stated that the holding of the bowel with a clamp, a rubber ligature, tape, or something of that sort, to prevent the escape of intestinal contents during operation was the only part of intestinal suture that seemed not to be as perfect as it might be. There was more or less danger of injuring the bowel by any sort of clamp or ligature which was put around it tight enough to prevent the intestinal contents from escaping. He thought it was better to hold the bowel with the fingers of an assistant when this was possible, although it facilitated the operation very much to take the bowel in a long clamp not far from the point where it was going to be sutured, as this prevented the sliding of the coats of the bowel over each other.

Dr. Herman J. Bolt of New York City personally preferred suturing to using buttons or mechanical devices for the purpose of intestinal anastomosis.

Dr. J. M. T. Finney of Baltimore, Md., said that in his experience he found that there were certain technical difficulties in the end-to-end suture which were hard to overcome. For instance, at the mesenteric border it was difficult to obtain satisfactory union; there was so much likelihood that a leak would occur there, that it had been his practice for the last two years to use almost exclusively lateral anastomosis, closing both ends. This gave more satisfactory union. He was an advocate of the interrupted suture.

Dr. A. Palmer Dudley of New York City stated that in his experience the use of the continuous as contrasted with that of the interrupted suture had been followed by fairly good results in intestinal work.

Dr. W. S. Goldsmith of Atlanta, Ga., stated that in the case of continuous sutures around the bowel leakage might result and a fistula be produced by tissue necrosis incident to the distention of the bowel on account of the application of this ligature. It was a ligature in effect around the bowel; we had distention of the gut, and the ligature did not expand; there was no elasticity about it. Therefore, the interrupted suture would be his preference.

Dr. Samuel J. Mixter of Boston said that when one was in a hurry the continuous suture was quicker. He emphasized the absolute necessity of practising these operations on lower animals before beginning to do them on patients. This was a point that was not sufficiently recognized. Every new method should be tried on some of the lower animals. So far as his experience went, very little clamping was necessary even if there was some leakage. He did not consider that there was any great danger from septic peritonitis, because the peritoneum was able to stand a great deal of soiling without great damage, and it could be washed off without producing any ill effect. This was likewise true of operations on the stomach.

Intestinal Obstruction.—Dr. Dyer F. Talley of Birmingham, Ala., said that intestinal obstruction was a condition which presented many difficulties in its early diagnosis, and it was a well-recognized fact that in acute cases the life of the patient depended on early recognition and prompt surgical intervention. There were two difficulties in the way of early operation: (1) It was hard to make a positive diagnosis in the first twenty-four hours; indeed, in some cases it was impossible to do so unless an exploratory laparotomy was made. (2) There was a tendency on the part of the patient, his friends, and also the physician, to wait until to-morrow and see what purgatives and enemata would accomplish. The author reported eight cases of intestinal obstruction that had come under his care during the last fifteen months. The details of each case were recounted with great clearness. One case showed that a laparotomy could be done without anæsthesia, and many patients who were seen late and were too weak for an anæsthetic might be operated on and relieved without a general anæsthetic. The result of operation in the eight cases were five recoveries and three deaths.

Dr. Guy Leroy Hunner of Baltimore, Md., said that from a large experience with hospital and private patients showing symptoms of intestinal obstruction, he had come to the conclusion that he would rather err on the side of operating occasionally unnecessarily than to be too late. Cases were cited in point.

Dr. W. P. Carr said the more he saw of cases of intestinal obstruction the more he was convinced that whenever there was a strong suspicion of it an exploratory operation should be made. There were so many patients who had little or no symptoms for quite a while, and others that had considerable fecal movements from the lower bowel

after obstruction had taken place, that one was apt to be misled. He had been misled a number of times.

Dr. J. Garland Sherrill of Louisville held that whenever a patient had intra-abdominal pain which was not promptly relieved, an exploration should be made; whenever a patient had a severe pain in the abdomen that ceased suddenly, there was probably gangrene of the gut, and for that reason in such a case very prompt operation was demanded. Many of these patients could be saved by opening the abdomen at once, even in the presence of shock, and in that way avoiding inflammation of the peritoneum.

Dr. Charles L. Bonifield of Cincinnati recommended changing to ether when patients could not stand chloroform, particularly in children.

Dr. W. O. Roberts of Louisville narrated the case of a child, nine months old, on whom he had operated. The little patient had been treated for dysentery. When he saw the patient there was a considerable amount of distention, with straining, and bloody mucus was being passed by the bowel. He introduced his finger into the rectum and found an intussusception. The intussusception was within two inches of the anus. He advised laparotomy, which was consented to and performed, and he found the intussusception began at the ileocecal opening, and went clear to within two inches of the anus. It was relieved very easily, but the child died in the course of twelve hours from shock. It was important in all cases of intestinal obstruction to examine the rectum carefully.

Dr. Wm. E. Parker of Hot Springs, Ark., said the general practitioner ought to be impressed with the importance of early diagnosis in these cases, and if there was any question at all to call in a surgeon, or someone who had had experience in this class of cases. He knew of no class of work in which an early diagnosis was so important, and next in importance to this was the getting into and out of the abdomen as quickly as was consistent with good work.

Dr. W. P. Nicolson of Atlanta called attention to the significance of abdominal pain. We should always bear in mind that the location of pain in the abdomen bore practically no relation to the location of the lesion itself in many instances. When a patient with a severe abdominal pain was not relieved by two or three doses of morphine, or did not remain relieved by this agent, but needed a repetition of it, the case was not one of indigestion. It was far more serious. He had had the misfortune to operate on a young woman for intestinal obstruction, and during the operation there was tremendous fecal vomiting, which was aspirated into the lungs, some of it. She left the table in good condition, with good pulse, and with indications that she was all right; but within a short time she became cyanosed, with rapid breathing, and pulse increased in rapidity; she remained conscious, but died within two hours.

Dr. Samuel J. Mixter said that, given a patient who had had intestinal obstruction for days and was in a very critical condition, he thought he could often be saved if too much was not attempted; the reason so many of these patients died was because surgeons attempted too much. Take a case of gangrene following intussusception, if a simple opening was made in the most distended loop of bowel, a tube tied in, and the intestine drained, a later operation could be done, and the patient would probably be saved; whereas if one attempted to do a resection or a serious operation at the time, the patient would surely die.

Dr. A. Palmer Dudley said that the surgeon was at a great disadvantage when he was called in to see a patient to whom morphine had been administered for the relief of pain, for the reason that it masked the symptoms. Peristalsis was arrested and the obstruction went on more rapidly. He had not given a dose of morphine in fifteen years to any patient on whom he had performed an abdominal section.

Dr. Talley, in closing, said the principal point he wanted to emphasize was the importance of early operation, because he believed that most of the patients could be saved if reached and operated upon early enough.

A Review of One Thousand Operations for Gallstone Disease, with Especial Reference to the Mortality.—This was the title of a joint paper by Drs. William J. and Charles H. Mayo of Rochester, Minn. The paper was read by Dr. Chas. H. Mayo. In one thousand operations for gallstone disease there were fifty deaths—five per cent.—counting as a death every patient operated upon who died in the hospital, without regard to cause of death or length of time thereafter; 960 for benign disease, with 4.2 per cent. mortality. In the case of more than one procedure through a single incision, only the major was counted, therefore, 101 cholecystotomies and 44 cholecystectomies in connection with common-duct operations were not included. Of 673 cases operated upon by cholecystotomy there was a mortality of 2.4 per cent. This group included most of the acute infections. In no case did the stones reform in the gall-bladder. This was the operation of choice in the average uncomplicated case, and especially if there was or had been cholangitis. Of cholecystectomy, there were 186 operations, with a mortality of 4.3 per cent. This operation was employed for special indications, such as cystic duct obstruction, thick-walled gall-bladders suspicious of malignant disease, and cholecystitis without calculi. There were 137 operations for stone in the common duct, with a mortality of 11 per cent., 7 per cent. from the operation, and 4 per cent. from secondary complications after more than three weeks. Of the cases operated upon during the quiescent period, with little jaundice and slight infection, all recovered. There were four cases with extreme icterus from obstruction, in which there were subcutaneous hemorrhages at the time of operation (purpura). All of these patients died. Of four cases of complete biliary obstruction in which the common and hepatic ducts were filled with clear cystic fluid and no bile, all the patients died. Of the cases of malignant disease, 14.6 per cent. were of the common duct. There were forty cases of malignant disease, with 22.5 per cent. mortality; two patients with cancer of the gall-bladder were now alive and well more than two years after operation; they had also had two additional favorable cases of more recent date. Of the remaining malignant cases, a few received marked palliation, but the majority were but little benefited.

Enterostomy.—Dr. J. W. Long of Greensboro, N. C., stated that the important measures to be accomplished were: (1) The drainage of gas and fæces from the intestine. (2) In mechanical obstruction, relief of distention, pain, vomiting, and toxæmia. (3) In septic conditions, depletion of the inflamed bowel and peritoneum, overcoming intestinal paralysis and sepsis. (4) Protection of the peritoneum as in typhoid perforation. (5) Nourishment of the patient by making an artificial mouth. Enterostomy was employed only in the most desperate cases, and in those in which it was indicated the patient was always in imminent peril of speedy dissolution from some of the conditions above indicated. In all forms of intestinal obstruction the patient suffered from distention and absorption of the toxins. When septic peritonitis was present, the sepsis itself produced suspension of peristalsis, which was sufficient to account for the obstruction. In mechanical obstruction, to this factor was added painful peristalsis. In recent years enterostomy had been applied to a number of conditions other than intestinal obstruction *per se*, the principal indication being feeding the patient through the fecal fistula. This operation has been applied to cases of inoperable carcinoma of the stomach, a fistula being made in the jejunum, and the patient fed through it; life was thereby prolonged, and the patient was made more comfortable. Enterostomy was also to be applied to typhoid perforation, catching up the perforated bowel and fastening it to the wound, it being more quickly done than closure of the perforation; at the same time, the bowel was drained and the patient was fed through the fistula. Dr. Long reported eight cases of enterostomy occurring in his practice

in twenty-two years, with five recoveries, or 62½ per cent. He drew the following conclusions: 1. Enterostomy is a life-saving measure, and never an operation of choice. 2. Enterostomy is not indicated when a more ideal surgical procedure is feasible. 3. In the hands of an experienced, carefully trained, competent surgeon, capable of dealing with grave emergencies, enterostomy need rarely be resorted to, but the better the surgeon, the more quickly he will adopt any measure which will save his patient. 4. Every abdominal surgeon must, according to the abundance of his material, find cases in which only enterostomy can with propriety be done. 5. When an enterostomy is indicated, to hesitate is to lose the patient; to operate promptly, dextrously, and with celerity means to tide the patient over the imminent peril, and spare him for future consideration.

Dr. James A. Goggans of Alexander City, Ala., said that drainage of the distended intestines was very important. He made it a rule, if possible, when he did a laparotomy for any trouble whatever, to drain the intestine in order to let it regain its elasticity, and move the fecal current along as it should. He commended the author of the paper for advocating enterostomy, and draining, when the intestine was greatly distended in the class of cases under consideration.

Dr. J. Garland Sherrill said that enterostomy had a place in surgery in those cases where complete surgery could not be done; but whenever a surgeon sent a patient away from the operating table with an open intestine, he subjected the profession and himself to criticism from the laymen who did not understand the condition. Therefore, he would lay it down as a rule that no enterostomy should be done in any case where it was possible to do complete surgery, and instead of widening the field for enterostomy, surgeons should strive to contract it.

Dr. I. S. Stone of Washington, D. C., said the reader of the paper must have gotten hold of a number of very difficult and delayed cases for operation. He thought his idea was simply this, that rather than let a patient die from obstruction, he would catch up a loop of bowel and make an artificial anus. This was the old-fashioned way of doing enterostomy, and Dr. Long had had as good results as most surgeons would have gotten under the same circumstances.

Dr. Long, in closing, said it would seem that he had unfortunately ran afoul of quite a number of cases in which it seemed proper to do enterostomy. These eight cases were spread over a period of more than twenty-two years of practice. He doubted if any surgeon had had a better percentage of recoveries in cases of acute intestinal obstruction by any method than that which he had reported, namely, 62½ per cent.

The Abuse of Purgatives Before and After Abdominal Section.—Dr. I. S. Stone of Washington, D. C., read a paper with this title, in which he said that purgatives should be given as evacuants, and should not produce hypercatharsis, whether administered before or after abdominal section. Bland evacuants, such as castor oil, aided by suitable enemata, would empty the bowels without causing severe exhaustion. Excessive purgation was intended not only to empty the bowels, but to perform additional service, namely, to remove collections of serum or other fluids which might be in the peritoneal cavity. A large majority of the sections made at the present time might be called minor pelvic or abdominal. In these no infection existed, nor was the intestine in any way involved. Such cases required only the mildest evacuants, with sterile diet in the preliminary treatment. Vomiting, paresis, ileus, and excessive distention after operation were frequently exaggerated and aggravated by the administration of the worse than useless cathartics which were usually given. It had been shown that patients had bowel movements (peristaltic) after surgical operations because they were ready to act, rather than because one had found any method to produce such results. Hypercatharsis did more than anything short of venesection, or the use of dangerous heart depressants, to unfit patients for prolonged anæsthesia and operation. The administration of purgatives immediately after operation appeared to cause vomiting and reversed peristalsis, and to add to the general discomfort of the patient. The temporary paralysis of the intestines in nearly every case was to be desired, and nearly all patients having been properly prepared would recover far more satisfactorily with perfect rest until normal peristalsis returned, than with the aid of all sorts and kinds of irritants intended to produce quick movements of the bowel.

A Review of the Treatment Immediately Before and After Abdominal Section.—Dr. L. S. McMurtry of Louisville said the general indications for preparatory treatment in cases of abdominal section were to cleanse the alimentary canal thoroughly without violent disturbance or exhaustion; to put all the eliminative functions in the best possible condition, and to favor in every way a tranquil state of mind and body. More than a year ago he became satisfied that to put the patient to bed for three days, or even longer, as was practised by many, was not the best course for preparatory treatment. There was a positive advantage in having the bowels cleaned out in a relatively short time, as the patient was not relaxed by purgation, and was less prone to suffer from toxic changes. Prolonged and irritating catharsis increased the nausea and vomiting of ether and chloroform anæsthesia. A prolonged period of preparatory treatment impaired the patient's strength and depressed the nervous system. Sterilization of the skin from a bacteriological standard was impossible; yet mechanical cleansing would, for all practical purposes free the skin of all active germ action, and provide for immediate primary union of wounds. In the effort to accomplish this, the important fact had been overlooked that the unbroken skin was endowed with a power of resistance to the activity of its own and other germs; but when the epidermis was cracked, denuded, and broken by irritating germicides and scrubbing with hard brushes, this natural resistance was impaired, and infection occurred. Mechanical cleansing would remove germs readily from smooth and unbroken cutaneous surfaces. For these reasons the brush and chemical germicides should be discarded, and only soap and water and alcohol should be used, applying these with gauze instead of the brush. In the after-treatment only the most simple course was necessary in average cases. The routine use of purgatives was to be avoided. The patient should be allowed to move about in bed freely, and should be given water as soon after operation as it could be retained.

Celluloid Plates for Covering Openings in the Skull After Operation.—Dr. William P. Nicolson of Atlanta, Ga., said that celluloid remained indefinitely in the tissues without irritation, and it could be easily shaped with scissors for adjustment to the opening to be covered. Its harmlessness in the tissues was demonstrated to him many years ago by the absence of any irritation from a celluloid testicle introduced into a patient's scrotum. Given such a material, one was enabled to enlarge the opening in the skull to whatever size he might desire, knowing that he could cover the opening and protect the brain from subsequent injury, or from undue protrusion from want of support. In operations for epilepsy it not only protected the brain from subsequent pressure, but left an increased space, which was measured by the thickness of the individual's skull. The author reported some cases in which celluloid plates had been used. He felt justified in making the following claims for this practice: (1) It was safe, and did not add any extra risk to the operation. (2) It not only removed the pressure and irritation, which the surgeon was endeavoring to combat, but by its resistance prevented a recurrence from the subsequent consolidation of the coverings in a false position due to atmospheric pressure. (3) It protected the patient from external influences, and not only made him feel safer, but he was actually safer. (4) It enabled surgeons to be much more untrammeled in

the amount of bone that they could remove. (5) It prevented deformity, which, especially when beyond the hair line, was necessarily great in large bone removals.

Traumatic Synovitis of the Knee Joint.—Dr. Edward A. Balloch of Washington, D. C., made a plea for earlier operative intervention in cases of traumatic synovitis. The reluctance of surgeons to open the joint was ascribed in part to a fear of sepsis, and in part to a lack of a precise knowledge as to the normal structure of the joint. Illustrative cases were cited, showing the advantages of early operative intervention. The following conclusions were reached: (1) In most, if not all, cases of traumatic arthritis of the knee, there was an injury to some of the structures of the joint. (2) Conservative measures should not be persisted in too long. Three weeks was proposed as a fair length of time for a trial of these measures. If no improvement was manifest at the end of that time, the propriety of operative intervention should be considered. (3) Arthrotomy, properly performed, was not an essentially dangerous procedure, and might do great good. (4) Early operative intervention would give a greater proportion of useful joints in a shorter space of time than any other method.

Cases in Which Early Diagnosis of Cancer of the Body of the Uterus Was Made.—Dr. Rufus B. Hall of Cincinnati reported two cases to show that an early diagnosis of primary cancer of the body of the uterus was possible, and that a diagnosis could be made while the disease was yet very limited in extent. Of the many cases of cancer of the body of the uterus coming under his observation, only these two were seen early enough to make a diagnosis while the disease was limited to a very small area. Adenocarcinoma was found to be the variety of the disease in each case. It was this form that most frequently attacked the body of the uterus, and if operated upon early, it promised great immunity from recurrence. The disease could be diagnosed in its incipiency if surgeons systematically curetted every suspicious case, and made repeated microscopical examinations of the scrapings removed from the uterus, until they confirmed or disproved the presence of malignant disease.

Origin of Adenomyoma of the Uterus.—Dr. J. Whitridge Williams of Baltimore, Md., after calling attention to the anatomical appearance of adenomyomata of the uterus, and the various theories which had been advanced according to the origin of the epithelial structures contained in them, described a uterus removed at autopsy from a woman who died just after delivery as the result of hemorrhage from placenta prævia. At the time of its removal, the uterus apparently presented the characteristic appearance of the organ immediately following delivery, except that the area of placental attachment covered two-thirds of its interior, instead of being more circumscribed and limited to the anterior or posterior wall, thus indicating in all probability that interference with its blood supply had led to a much more extensive implantation of the placenta than usual. On making a sagittal section through the uterus after hardening, numerous irregularly shaped, more or less oval areas, of a dull white appearance, varying from a millimeter in diameter to five by ten millimeters in their various dimensions, could be seen throughout the entire thickness of the uterine walls, which measured 3 cm. in their thickest parts. These areas were most abundant immediately beneath the endometrium, but could be traced outward through theentire thickness of the uterine wall to its peritoneal covering. Upon microscopical examination they were found to consist of typical decidual tissue, which was made up of the characteristic decidual cells and glandular spaces lined by cuboidal epithelium. There could be no doubt as to the origin of the decidual areas, they being derived from the uterine mucosa. Their wide distribution throughout the uterine muscle precluded the possibility of their having resulted post partum, and indicated most conclusively that they must have existed prior to the onset of pregnancy. Such being the case, the specimen afforded a beautiful example of the presence of tissue derived from the endometrium being scattered throughout the myometrium of an adult woman. In not a few cases the glandular elements in typical adenomyomata showed changes identical with those occurring in the menstruating endometrium, and the development of the decidual tissue in this case seemed to make it probable that where portions of Muellerian tissue were scattered through the myometrium, they might undergo the same changes as the normal endometrium, namely, menstruation, and decidual formation.

Development of Fibroids of the Uterus After Ablation of the Appendages.—Dr. J. Wesley Bovée of Washington, D. C., said the large number of published cases of fibroid tumors that had broken down, become infected, or undergone other changes in structure detrimental to the lives of their unfortunate possessors had swept away the old ideas as to their benignancy. Pathologists were now searching for a distinct borderline between benign and malignant soft a distinct borderline between benign and malignant soft uterine myomata. Recurrent myomata, while not so positively dangerous as cancer, must be considered malignant Between these and sarcomata there was not always a distinct difference. Five cases were cited. Of these, two were operated upon for noninfections disease, two were victims of infection, and in one the condition requiring removal of the appendages was not known. Did the sudden change in the pelvic circulation incident to the ligation of the uteroovarian blood vessels in double salpingo-oöphorectomy act as a cause of the subsequent fibroid degeneration of the uterus? This question might be reasonably answered negatively, else such degeneration might logically be seen commonly instead of rarely. Yet it was possible that hemorrhagic infarcts in the uterus might occasionally in that manner be formed that would result in hyperplasia of connective tissue, and be the origin of fibromata.

The Effect of Suspensio Uteri on Pregnancy and Labor.—Dr. Joseph Taber Johnson of Washington, D. C., in a paper with this title, contended that very few, if any, such injurious effects need be feared as had been frequently charged against the operation of suspensio uteri. That it sometimes failed to cure was true, but that was not the charge. By ventrosuspension he did not mean ventrofixation. He was free to admit that the uterus should not be securely fixed in the abdominal wound, or to the abdominal wall, in women likely to become pregnant. It was quite certain that some of the pains of pregnancy and difficulties of labor which had been charged against suspension were really the result of fixation. In over one hundred suspensions done by himself, he knew of only two pregnancies. These were both normal. In one case, the labor was so rapid that the child was born before the doctor's arrival, and he knew from recent examinations that there had been no return of the retroversion. The other woman he delivered in November last, after a five-hour normal labor, without chloroform or forceps. The author mentioned the number of suspension operations performed by other operators, and concluded by saying that when the retrodisplaced or prolapsed uterus was suspended, not fixed, according to the technique of the author of the operation, it appeared to him to be the best operation yet devised for the great majority of women suffering with this displacement, irrespective of the fact that they might become pregnant subsequently.

Typhoid Fever and Appendicitis.—Dr. John C. Oliver of Cincinnati called attention to the possibility of these diseases being so irregular in their manifestations as to be mistaken the one for the other. He cited illustrative cases in which these mistakes had been made. A case was also reported in which an attack of appendicitis was followed within a month by an attack of typhoid fever. The possibility of mistaking the perforation of a typhoid ulcer for an acute attack of appendicitis was exemplified by the report of a case of walking typhoid in which perforation of

the ileum occurred. The author's conclusions were (1) that typhoid ulcers might appear in the glandular structures of the appendix, and give rise to a typhoid appendicitis. (2) That the infiltration of the ileum and cæcum in typhoid fever might be so great as to give rise to a distinct tumor mass in the right iliac fossa. (3) That the Widal test was of but little, if any, value in the early diagnosis of the disease present. (4) That the leucocyte count proved in his series of cases to be of value in distinguishing between the two diseases. (5) That an exploratory laparotomy in typhoid fever was not devoid of danger. (6) That abdominal incision was imperative when it became necessary to establish the differential diagnosis between a typhoid perforation and fulminant appendicitis. (7) That in the absence of perforation, cases of typhoid appendicitis should not be operated upon.

The Problems Presented to the Gynecologist Twenty-five Years Ago and To-day.—Dr. P. F. Chambers of New York City said that the problems presented to the gynecologist of earlier date were entirely different from those of to-day, and as different, he had no doubt, as would be those of twenty-five years hence. To illustrate his contention, he gave the diagnoses of all the patients who were admitted to the Woman's Hospital of New York a quarter of a century ago, and the operations which were there performed for the relief of these conditions. The peritoneum was the surgeon's *bête noir*. Abdominal surgery, then in its infancy, constituted but a little part of the work of the gynecologist. This was before the days of asepsis. Antiseptic surgery was then in vogue; consequently the mortality of all abdominal work was still so great that the abdomen was never opened except in desperate cases, such as for the removal of ovarian cysts, or the ovaries in cases of intensely severe dysmenorrhea, or very large fibroids, as then advocated by Battey, Tait, and Hegar. For other causes, for which now the abdomen was readily opened, it was then a sealed book.

The Management of Acute General Peritonitis.—Dr. J. Garland Sherrill of Louisville considered two forms of infection. First, acute septic peritonitis, in which the poison was so intense that the patient died from a profound toxæmia before the local changes had progressed to the point of pus formation. The second type was general suppurative peritonitis, in which pus was found free in the peritoneal cavity without any localization of the process. The two forms resulted from infection following perforations of the alimentary canal, rupture of the urinary or gall-bladder, ileus, abdominal operations, puerperal infection, and disease of the ovaries and tubes. Many cases, especially of the septic type, resulted fatally regardless of the time they were seen or the treatment employed, while some responded to medical, and more to promptly applied surgical measures. The various methods of medical treatment were considered, and the position was taken that these cases were surgical, except when operation was refused, and the patient's condition would not permit of surgical interference. Under such circumstances the medical treatment should be planned with reference to the causative condition, if this could be determined, and a distinction should be made between perforations of the stomach and those of the intestine, and also those cases in which there was reason to believe the intestinal wall was intact. In the first, emphasis was laid upon absolute rest of the stomach to limit leakage; rectal lavage, and nutrient enemata were advised. In the second class (intestinal perforations), gastric lavage, small rectal enemata to unload the lower bowel could be employed, and opium used freely while the patient was nourished per rectum. In the third class, with an intact intestine, gastric and rectal lavage, purgation, and nutrient enemata were recommended. Heat and cold were considered the best topical applications, and the patient's position should be suited to the location of the causative lesion. In considering the surgical treatment of this disease, much stress was placed upon early operation as a measure for the prevention of general peritonitis, while the process was yet localized. The outcome of a given case would depend upon the following factors: (1) The virulence of the infection; (2) the quantity of the infecting medium; (3) the resistance of the patient; (4) the activity of the organs of elimination; (5) the time at which the patient came to operation; (6) the rapidity and thoroughness of the surgical procedure. The special technique of the operation was of less importance than the dexterity of the surgeon and the care with which he did his work.

Advances in Renal Surgery.—Dr. John B. Murphy of Chicago made a forcible plea for more conservative surgical work on the kidney and ureters in the future, saying that surgeons must consider the importance of preservation of any portion of a kidney that was still in a condition to functionate, on account of the enormous mortality associated with the removal of this organ. The mortality in the past following the removal of a kidney that was secreting practically the normal amount of urine, varied from 29 to 35 per cent. He reported six cases of conservative operations on the kidney. In cases of great dilatation of the pelvis of the kidney, it was formerly his custom to remove the kidney, until he realized that it was practically a normally secreting organ, and that the dilatation of the pelvis was due to ureteral obstruction, and that there was no good reason for taking out the kidney when the obstruction was removed. He believed that surgeons were coming to a time when they would examine the kidney carefully, and then decide, as in certain lesions of the stomach, that this or that portion shall be removed, and the remaining portion husbanded.

Four Cases of Vesical Diverticula Requiring Operation.—Dr. Hugh H. Young of Baltimore, Md., read a paper on this subject. He said that a patient died after obscure bladder symptoms, and autopsy showed seven diverticula, the largest about five inches in diameter, communicating with the bladder by small orifices. Both ureters were compressed by the diverticula, and hydroureter and hydropelvis had resulted. The patient died of uræmia. Since then the operator had had four cases of vesical diverticula, in which operation was performed with success. In two cases the diverticula were larger than an orange, in the others smaller. In one case the ureter was compressed by the diverticulum, and intermittent attacks of renal colic resulted. In one case the diverticulum lay in the urachus, and became constricted at its orifice several times a week, producing severe tenesmus in the region of the umbilicus. In three of the cases the disease developed early in life, and in only one was an enlarged prostate the cause of the diverticulum. Careful study of the literature showed that only three cases had been operated upon radically, namely, one by Czerny, excising by transverse abdominal incision, transplantation of the ureter, development of pyonephrosis, nephrectomy, and final cure; one by Riedel, suprapubic incision, death from collapse; one by Pagenstecher, parasacral extirpation, resection of ureter, kidney involvement, improvement, with fistula. The writer's four patients were all living, and in good condition. In three cases the diverticula were completely excised, but ureteral transplantation was avoided by a plastic method. Renal infection was avoided, and no fistulæ resulted.

The Ultimate Results Obtained by Conservative Perineal Prostatectomy in Seventy-five Cases.—Dr. Young also read a paper with this title. In this series there were five patients over 80 years, one 87 years of age, with one man aged 84 years, who died five weeks after the operation. Two other deaths, neither attributable to the operation, occurred, each in the third week, one in a patient walking about, and ready to go home, from pulmonary thrombosis, and the other in a man, seventy-seven years of age, who had been uræmic for several weeks, and autopsy showed double pyohydronephrosis. The innocuousness of the operation was thus shown. The use of the author's double-bladed metal tractor was of great help in steadying the prostate for the incisions, drawing it down for a complete enucleation,

enabling the operator to deliver and remove even large middle lobes without tearing away the mucous membrane of the bladder or urethra, or the ejaculatory ducts. The advisability of preserving the floor of the urethra, the veru montanum, and the ejaculatory ducts in men whose sexual powers were well preserved (and these represented over 50 per cent, of the cases), was shown by the impotence which followed, in nearly all cases, operations like Albarran's and Murphy's, in which the floor of the urethra and duct were deliberately destroyed.

When Shall We Resect in Tuberculous Disease of Joints?—Dr. C. H. Caldwell of Cincinnati read a paper on this subject. As to the joint under consideration, somewhat would depend on whether it was a single large isolated joint, such as the knee, for instance, or whether it was a smaller joint, such as the carpal or tarsal, in immediate continuity with other joints. A single tuberculous focus in the epiphysis of a long bone, which was susceptible of complete immobilization, stood a much better chance to undergo reparative change than would such a focus in the spongy bones of the wrist in the close proximity of synovial and ligamentous structures which favored dissemination and persistence of the disease. The results to be expected from conservative treatment might be divided into three classes—ideal, satisfactory, and unsatisfactory. An ideal result was when, after a reasonably long period of treatment, a cure was obtained with no limitation, or but slight limitation, of movement, and no deformity. Under satisfactory results might be classed those in which, after a reasonable period of treatment, a cure was obtained with a stiff joint, or in which a slight range of motion was possible, without shortening or malposition, and in which, if there had been abscess or sinus formation, the sinuses had healed. Under unsatisfactory results might be classed those which, after a reasonable period of treatment, either showed no tendency to get well, or might be said to have recovered with sinuses still weeping, with a tendency to fatigue on exertion, with more than an average amount of shortening, and with deformity to a greater or less degree. The absence of any active symptoms of disease—pain, increased temperature or muscular rigidity, placed these in the category of cured cases, but cured with unsatisfactory results. The results from the resection of the hip were of necessity unsatisfactory when complete, as with ablation of the head and neck of the femur, one left no *point d'appui* for the femur, and there must be a greater or less amount of give to it under the weight of the body. In tuberculosis of the knee there was but little use of wasting time with a joint in which marked osseous changes were already present, and which, in spite of conservative treatment over a period of six months, had shown no improvement. Resection of the knee in cases which had passed the period of adolescence had much to recommend it, and but little could be said against it. In those cases too prolonged delay often meant amputation. As to resection in elbow cases, one was again confronted by the fact that results were at the best far from what one might desire. In the smaller joints, such as the wrist and carpal joints, excision must depend on individual judgment. Ankle joint and tarsal excisions were, as a rule, very unsatisfactory. The deficiency in weight-bearing capacity rendered the results far more gratifying, and amputation was, as far as his observations went, too frequent a sequel to these operations.

Obliteration of the Stomach by Caustic.—Dr. Samuel J. Mixter of Boston stated that doubtless other surgeons had seen cases of constriction of the œsophagus after the ingestion of acid or strong alkalies, and also some cases of constriction of the pylorus from the same cause. It was very rare, however, to find practically the whole stomach destroyed, and this was the reason for putting the cases he had seen on record. He reported three cases in which the stomach was almost entirely obliterated by caustics.

Tumor of the Pancreas.—Dr. J. A. Goggans of Alexander City, Ala., reported two cases of this nature.

Vaginal Cesarean Section.—Dr. C. Jeff Miller of New Orleans, read a paper on this subject, in which he reported a case and summed up the advantages of the method as follows: (1) In severe eclampsia, when the woman is unconscious between the convulsions, the cervix rigid and elongated, and delivery imperative, it is always preferable to perform abdominal section, and, under proper surroundings, she may be preferable to metal dilators or manual dilatation. (2) In severe cases of accidental hemorrhage, when the cervix is closed, it is safer than the other method of accouchement forcé, owing to the rapidity with which the uterus can be emptied, and should be given preference over abdominal hysterectomy, which is generally advised. (3) It may be considered in other conditions when cesarean section is indicated, except in contracted pelvis or dystocia arising from maternal or fetal disproportion. It has not the disadvantages of an abdominal operation; the peritoneum need not be opened unless hysterectomy is to be performed for malignancy, and there is less shock than follows abdominal operations. (4) It is not more dangerous than attempting to deliver either by version, or forceps, when the os is not fully dilated, if done under strict aseptic precautions.

Dermoid Cysts and Fistulæ of the Sacrococcygeal Region.—Dr. Lewis C. Bosher of Richmond, Va., during the past few years had had occasion to operate on seven cases of dermoid cysts or fistulæ of the sacrococcygeal region. The patients sought relief either on account of the presence of annoying exudation, or after some traumatism had given rise to the formation of abscess, with the usual train of inflammatory symptoms. The cases operated on by the writer were all in male adults. After referring to the diagnosis and prognosis, the author said that the usual methods resorted to for treating inflammatory fistulous tracts would seldom result in permanent cure. Complete extirpation of the fistula and sac must be performed to prevent a recurrence. It was to be noted that this was not always possible, as in a case reported by Wette, in which complete extirpation would have involved opening the spinal canal, with serious injury to the nerves.

Hæmatoma of the Ovary.—Dr. Magnus A. Tate of Cincinnati presented a study of the cases which he had collected from the literature. Three periods of life markedly predominated as a predisposing factor in the causation of hæmatoma of the ovary: (1) Before or during birth; (2) at or near the first menstrual flow; (3) early adult or childbearing period. Scott, in operating for ovarian disease, stated that hæmatomata were frequently found. In this the author concurred, and did not believe that they were so rare as the paucity of case reports in literature would lead one to believe. In size, they varied from a hazelnut to a good-sized orange. The uncomplicated cases were free from fever, but pain was almost always present, and vaginal examination disclosed almost constant tenderness. Sometimes the ovary was fixed, and the pain was frequently severe. Schultze and Riedel reported hæmatomata in newborn infants. Winckel saw the follicular variety of hæmatoma following petroleum burns, phosphorus poisoning, typhoid fever, cerebral hemorrhage, tuberculosis, and heart failure. Edgar reported a case in which the hæmatoma ruptured, and caused a pelvic hæmatocele; and Boldt one in which the tumor ruptured, and peritonitis resulted. Two cases were reported in which the tumors became cystic, and had twisted pedicles. Garrigues gave the history of a case associated with vicarious menstruation; Janvrin, a case of dysmenorrhœa, in which, on section, there was salpingitis of both tubes, abscess of the right, and hæmatoma of the left ovary; and Murray, a case of abscess of the left ovary, and hæmatoma of the right. Kramer reported a case associated with purpura and epilepsy; and Edebohls, one with hysteroepilepsy. Wylie had a case in which electricity was the probable cause; Tate, one following a long, tedious labor; Reamy, one in which one ovary was removed, and a portion of the other, and subsequently the patient had two children. Ricketts reported one associated with a large

ovarian tumor, one with a dermoid, one with a suppurating appendix, one in which the left ovary was removed, the right being normal, and in one year later the right ovary had to be removed for a hæmatoma. Wenning operated upon a case of double hæmatoma, the patient suffering from excruciating pain when an examination was made. The age of childbearing women who were afflicted with hæmatomata of the ovaries varied from fifteen to forty years, and the left ovary seemed to be more frequently affected than the right.

Pathogenesis and Surgical Treatment of Tuberculous Peritonitis, with Report of Cases.—Dr. William E. Stokes of Salisbury, N. C., divided tuberculous peritonitis into four forms—the adhesive, suppurative, tympanitic, and ascitic. He quoted extensively from the literature of the subject, referred to the modes of infection, gave synopses of cases, histological examinations, and reported six cases. Operation was contraindicated in cases of tuberculous peritonitis, whenever there was an advanced tuberculosis of the liver, lung, kidney, intestines, or glands, or when the exudate within the peritoneal cavity was solid. What the actual changes in this infection of the peritoneum were, or what reaction was brought about in the local lesions and in the peritoneum itself by the mere abdominal incision, remained problematical. Whether it was the mechanical action brought about by the air and sunlight, or the increase of the peritoneal resistance; or whether after the operation a local reaction in the periphery of the tuberculous nodes took place, or an increased phagocytosis brought about absorption of the tuberculous product, with the formation of new connective tissue, as has been shown in experiments on animals, still remained unsettled.

Treatment of Uterine Bleeding.—Dr. H. J. Boldt of New York City, read a paper with this title, in which he supplemented his former report on the use of cotarnine hydrochlorate in various cases of uterine hemorrhage, his opinion of the therapeutic value of this agent being based on seven years' experience.

Some Points in the Technic of Aseptic Operating.—Dr. Henry T. Byford of Chicago said he did not offer any new methods, but emphasized the necessity of more thoroughness in those already used. The method he employed consisted in (1) twenty minutes' scrubbing with green soap and water; (2) three minutes' in dilute acetic or citric or oxalic acid; (3) five minutes in strong alcohol; (4) five minutes in a 1-2,000 solution of mercuric chloride in water. The author considered the use of rubber gloves open to the objection of macerating the cuticle with danger of their being punctured and allowing septic sweat to escape. He deprecated the mixing up of the steps of the preparation by using a combination of green soap and alcohol, or by dissolving the mercuric chloride in alcohol, since aqueous solutions were more efficient than alcoholic. He advised disinfection of the hands one or more times during the course of long operations. Attention was called to the necessity of unusual care in the preparation of the field of operation in operations about the pubes and vulva. He recommended absorbent rather than occlusive dressings in the treatment of the wounds after the operation.

Suprapubic Prostatectomy.—Dr. W. H. Doughty, Jr., of Augusta, Ga., reported a case of suprapubic prostatectomy, and described an improved method of after-treatment. He also narrated an unusual case of intraperitoneal hydatids.

Tracheotomy for Gunshot Wounds of the Trachea.—Dr. J. McFadden Gaston of Atlanta, Ga., discussed the subject of gunshot wounds of the trachea, and the complications that were likely to occur from septic infection or laryngeal stenosis. He reported a case of gunshot wound of the trachea in a female child, 8 years of age. The position of the incision in the trachea was lateral rather than on the anterior surface of the windpipe. The patient made an excellent recovery.

Rupture of the Diaphragm.—Dr. Geo. S. Brown of Birmingham, Ala., contributed a paper on this subject, in which he reported an interesting and instructive case in a fireman, 27 years of age, six feet tall, and weighing 190 pounds. The patient had hurt or strained his side slightly about two years before the rupture occurred. Although an operation was performed, the case terminated fatally.

Encephalomeningocele.—Dr. W. D. Haggard of Nashville reported an unique case of encephalomeningocele, in a male child, four months of age. The child weighed six pounds; the tumor weighed five pounds, and measured 23 inches in diameter one way, and 17 inches another.

Dr. Haggard also described an easy method of instituting peritoneal gauze drainage through the cul de sac.

Dr. J. B. Murfree of Murfreesboro, Tenn., read a paper on "Strangulated Hernia," and Dr. E. Denegre Martin of New Orleans, reported two cases of cancer of the appendix.

The Davis Memorial.—The monument erected by the Association to its founder, the late Dr. W. E. B. Davis, was unveiled in Capitol Park, with fitting ceremonies, Wednesday, December 14th, at 11 o'clock. About five thousand people attended these exercises, including the members of the Association. After an invocation by Rev. Dr. L. S. Handley, Dr. Chas. M. Rosser, of Dallas, Texas, was introduced, and delivered the address of presentation. The statue was unveiled by Elizabeth and Margaret Davis, the little daughters of the beloved physician. Dr. R. M. Cunningham, Acting Governor of the State of Alabama, accepted the statue in behalf of the State in an eloquent address. The statue, in behalf of the city, was accepted by Hon. John C. Forney, the representative of Mayor Drennan, who was unavoidably absent.

Officers.—*President,* Dr. Lewis C. Bosher, Richmond, Va.; *First Vice-President,* Dr. John D. S. Davis, Birmingham, Ala.; *Second Vice-President,* Dr. I. S. Stone, Washington, D. C.; *Secretary,* Dr. W. D. Haggard, Nashville, Tenn., re-elected; *Treasurer,* Dr. Charles M. Rosser, Dallas, Texas, re-elected.

Louisville, Kentucky, was selected as the place for holding the next annual meeting, in December, 1905.

THE PRACTITIONERS' SOCIETY.

One Hundred and Ninety-first Regular Meeting, Held December 2, 1904.

Dr. Charles Stedman Bull, President, in the Chair.

On What Lines Is the Treatment of Malignant Disease Advancing?—Dr. Robert Abbe read this paper. (See page 1041.)

Dr. Charles McBurney asked Dr. Abbe how many cases of carcinoma he had seen treated by radium without any beneficial effect whatever?

Dr. Abbe said he had not employed the radium in carcinoma more than half a dozen times, all of them comparatively minor cases, and he could not recall a single instance in which some improvement was not effected by it. In one case, in which three cancerous nodules recurred in the line of a mammary scar after extirpation of a carcinomatous breast, the conglomerate mass measuring about three inches by one inch, a number of applications of the radium produced a remarkable reduction, and in a letter recently received the patient stated that this improvement had continued, and that two of the nodules had entirely disappeared. Dr. Abbe said he had seen a similar effect in other cases of recurrent carcinomatous nodules of the skin, after half a dozen applications, and Dr. McCosh had recently reported a case in which twelve or fifteen typical carcinomatous nodules, the size of a bean or larger, had entirely melted away under the influence of the radium. There were cases of this kind, however, in which the treatment had proved ineffectual.

Dr. McBurney said that the experiments with radium in the treatment of malignant disease had apparently not

yet progressed sufficiently far to permit of definite conclusions to be drawn regarding its value. The results thus far obtained, however, could not fail to recall other methods that had been from time to time advocated in the treatment of this class of cases. Not very long ago, removal of both ovaries was brought forward as a physiological cure of malignant disease in the breast, and yet, of the eight cases treated by Dr. Abbe in that manner, there was only a temporary "shrinkage of the mammary tissue" in every instance, but no other improvement. The early reports following the use of the Roentgen rays were also very encouraging. Under this method, tumors "partially disappeared," "pain diminished," "the patient was more comfortable," and occasionally even a "complete cure" was reported. On the whole, however, the effect of the Roentgen rays as well as of other methods of radiant energy, was very disappointing. The future would show whether radium would prove equally disappointing. None of the methods thus far advocated had shown any specific, controlling effect on cancer, and none of them could be depended on with any certainty whatever. This conclusion, Dr. McBurney said, he considered a fair one, and he thought it was to be deplored that many cases of cancer should be subjected to the application of remedies which must still be regarded as of a purely experimental nature, and thereby lose the opportunity to be treated by the only method which surgeons regard as reliable, namely, the operative method. Many patients, he said, had been subjected to the Roentgen rays to the exclusion of operative measures until the opportunity to operate on them with success had been lost. The speaker wished not to be understood as deprecating the search for some specific new remedy in the treatment of cancer. On the contrary, he and all other surgeons, would welcome the discovery of a really valuable cure for cancer as the most important scientific advance of modern times. Experiments in this direction should, however, be made only upon inoperable cases.

Dr. Joseph D. Bryant said that Dr. Abbe's paper, and the remarks of Dr. McBurney, led him to discuss the subject in a retrospective vein. He recalled that many years ago clover flowers were looked upon as a great remedy for cancer, and many cures were attributed to it. Subsequently, turpentine became very popular for the same purpose, and following that, the introduction into the tumor of electrically charged needles. Benefit followed the employment of all these methods. Then cundurango appeared on the field, extolled by many as of great benefit. Dr. Bryant said that while he did not wish to take a pessimistic view of the subject, and while he believed that all these various agents and methods should be given a faithful trial, he was inclined to agree with Dr. McBurney that patients were encouraged thereby in a false sense of security. Instead of first trying the Roentgen rays or radium, or any other of these temporizing methods, Dr. Bryant said he was in favor of reversing the proposition, namely, operating first, and then preventing a recurrence by the use of one of these agents, providing they had the power to do it. The speaker said he failed to understand how the application of radium to a morbid growth could control or relieve the effect of the disease upon neighboring lymphatics, providing the enlargement was the result of a true extension of the malignant disease, and not a simple inflammatory process. While he was glad to encourage the employment of all these various agencies for the purpose of combating malignant disease, he did not favor their use to the exclusion of operation. He still believed there was nothing better than operation for malignant disease of a decided type, and that any special increase in the rate of operative recovery would be achieved by earlier recognition and admission of malignancy, and prompter and more thorough extirpation (if possible) of the disease.

Dr. Abbe, in closing, said he had seen very few cases of malignant disease in which he would be willing to advise the use of radium in preference to the knife. In certain types of cases, however, he thought the method should be given a fair test by those who were willing to do so, and a critical report of the results should subsequently be given. Unless such tests were made, there would be danger of losing an opportunity of learning more about the disease than we now knew.

Dr. McBurney suggested that the inoperable cases would furnish sufficient material for the purpose of testing some of these methods.

Problems Relating to Simple Ulcer of the Stomach.—Dr. Beverley Robinson said that at a recent meeting of the New York Clinical Society he read a paper on this subject (see page 1043), in which he briefly reported twenty-nine cases of ulcer of the stomach, the histories of which had been obtained for him by Dr. J. Emil Traub, of this city, from the records of St. Luke's Hospital for the past twenty years. Of these twenty-nine cases, twenty-four occurred in females, and five in males, the ages of the former ranging from 16 to 68 years, and of the latter from 23 to 70 years. Of the men, three died; one was cured; one improved. Of the women, most of them domestics, the majority gave a history of excessive tea drinking, some taking as many as ten to fifteen cups daily, and one gave a history of having taken half a glass of vinegar and water eight or ten times a day for a long time. Most of the women were anæmic, poorly nourished, markedly constipated, and nervous and irritable in temperament. Menstruation was usually irregular, and they were living amid poor hygienic surroundings. All suffered from dyspepsia, pain in the epigastrium, vomiting of food and mucus, and, in seventeen cases, of blood. Of the twenty-four female patients, one died, two were improved, and nineteen were cured. Only one of the twenty-nine cases was treated surgically. In that case, a man, a gastroenterostomy was done, and the patient died on the following day. In addition to these twenty-nine cases, Dr. Robinson referred to six cases from the records of Bellevue Hospital. Dr. G. Strack, of the hospital staff, after a careful search of the records, reported that he could find but six cases of gastric ulcer occurring in the four medical divisions of Bellevue Hospital since November, 1903, and in two of these the diagnosis was very doubtful. He found no record of any case occurring in the surgical divisions of the hospital. Dr. Robinson said that his object in bringing this subject up for discussion was to get an expression of opinion in regard to the treatment of these cases, and whether a surgical operation for an ulcer of the stomach was preferable to medicinal methods, or even justifiable.

Dr. Bryant said he could recall only one case in the Third Surgical Division of Bellevue Hospital, in which an operation had been recently done for ulcer of the stomach. In that case, the operation was done by Dr. B. Farquhar Curtis.

Dr. Edward G. Janeway said that the results of the medicinal and dietetic methods of treating hemorrhage from ulcer of the stomach were certainly better than those recently published by the Massachusetts General Hospital, which gave ten cases treated by operation, with ten deaths. With the hæmoglobin reduced to 20 per cent., the operation was to be regarded as disastrous. In such cases, the chances of the patient were better without operation; and some remarkable instances of recovery had occurred. In the treatment of the later effects of gastric ulcer, however, such as pyloric obstruction or conditions due to the presence of old cicatrices, operative interference undoubtedly often produced good results. To operate in every case simply because there was a hemorrhage from a gastric ulcer would show very poor judgment, because quite a large proportion of these patients recovered without operation, although relapses were not uncommon. Furthermore, a hemorrhage from the stomach, like that from the lungs in early phthisis, might sometimes be regarded as a life-saver, as it usually awakened the patient to a proper realization of his condition, and made him more willing to follow his physician's instructions. The advisability of operating

in even extreme cases of gastric hemorrhage was doubtful.

Dr. W. Gilman Thompson said he had had a somewhat varied experience with gastric ulcer, and had seen quite a number of cases operated on. In a recent case under his observation there was a chronic gastric ulcer, with considerable dilatation: this condition gave rise to constant distress after eating, making the patient's life practically unendurable. She became much emaciated, and was finally referred to Dr. Mayo for operation. He did a gastroenterostomy early last summer, which was followed by immediate relief, and the patient was now enjoying better health than she had for many years. In a case seen at the Presbyterian Hospital several years ago, there was a gastric ulcer with severe hemorrhage, which was operated on successfully. This patient was a man. In another case, a woman, seen in the same institution some years ago, the patient had repeated gastric hemorrhages with constant vomiting, and all the classical symptoms of gastric ulcer. The stomach was opened and carefully explored with the aid of an electric lamp, but absolutely nothing was found. After the operation she still failed to absorb her food, and died three or four weeks later of asthenia. In a case recently operated on at the Presbyterian Hospital for repeated severe gastric hemorrhages, the patient barely got off the table alive. In a case now under observation in that hospital, the patient, a woman, had successive hemorrhages for four or five days, until the amount of hæmoglobin became reduced to 35 per cent., and the number of red corpuscles to 2,000,000. An operation was urged, but refused by the family. The patient was then put on the customary treatment for gastric ulcer, and she improved so rapidly that she was now able to take solid food, and had gained considerable strength, although she was still very anæmic. She had had no further hemorrhages. Dr. Thompson said he favored operation in cases in which repeated gastric hemorrhages endangered the patient's life, or when there was a history of recurrent attacks of gastric ulcer. The speaker referred to a case that he saw with Dr. McBurney about ten years ago. The patient was a woman who had suffered from symptoms of gastric ulcer, including several severe hemorrhages. She was exceedingly neurotic, and some of her symptoms were attributed to that source. Finally, however, her pain became so severe and constant, and her general condition became so poor that she was referred to Dr. McBurney for operation. Upon opening the stomach, he found an ulcer fully 3 by 5 inches in diameter, with an enormous indurated base. Its excision would practically have amounted to removal of the entire stomach, and as the patient's condition was desperate, it was decided to do nothing more than sew up the wound. She hovered between life and death for several days, and after the operation had a hemorrhage which was so severe that it necessitated transfusion and hypodermocylsis. She finally made a perfect recovery, however, and was now enjoying excellent health, and was able to eat everything. In this instance the ulcer was actually seen, and the diagnosis was not speculative, as it was in a certain proportion of these cases. The symptoms of gastric ulcer were sometimes simulated in chlorotic conditions.

Dr. Janeway said he could recall two cases seen in consultation in extremis, in which the introduction of the stomach tube and washing out the stomach had produced perforation of an old ulcer, in both instances with fatal results. He mentioned these cases because lavage of the stomach was advocated by some in the treatment of gastric ulcer. In corroboration of the statement made by Dr. Thompson that the symptoms of gastric ulcer were sometimes simulated by other conditions, Dr. Janeway mentioned a case that had been under observation for a long time, and in which all the classical symptoms of gastric ulcer were present, including repeated hemorrhages. The patient was a woman, who had frequently been shown to medical students as a typical example of a case of gastric ulcer. She finally died of pulmonary tuberculosis, and when the stomach was opened before the class, no cicatrix could be found, and the gastric mucous membrane was apparently perfectly normal.

Dr. McBurney said that given a dozen cases of gastric ulcer in which severe and repeated hemorrhages had occurred, a larger proportion of them would probably recover if all were subjected to the usual methods of treatment than if all were operated upon. Undoubtedly there were patients whose only chance of recovery was to be found in operation. The difficulty was to select such cases at an early stage of the disease, and before the general condition had become so bad that operation had little chance of being successful.

Dr. Abbe said he had operated on only one case of ulcer of the stomach. In that instance he found a lesion which seemed to be the cause of the bleeding. This was excised. The patient got along very well for a few days, and then had a fatal secondary hemorrhage. At the autopsy, multiple ulcers of the stomach were found. The statistics of Mayo Robson in the treatment of these cases were favorable to a gastroenterostomy, and Dr. Abbe said he would be inclined to employ that method in any suitable case that might come under his care in the future. In cases of repeated hemorrhage, however, with extreme exsanguination, the patients generally had better be left alone. A gastroenterostomy, the speaker thought, was preferable to the excision of the ulcer. It operated theoretically and practically, by preventing distention of the stomach by gas, which stretched the ulcer and continued the bleeding, and also by putting the stomach peristalsis at rest, owing to its constant emptiness.

Dr. J. Emil Traub (by invitation) said that in one of the cases included in Dr. Robinson's paper, that of a man 70 years old, the autopsy disclosed an ulcer three and one-half inches in diameter, with several additional bleeding points scattered over the stomach wall. He doubted whether such a case, in which there were multiple bleeding points, would prove a favorable one for surgical interference.

The Vasomotor Factor in the Clinical Measurement of Blood Pressure.—Albert Abrams concludes that blood pressure is an expression of action of two chief factors: ventricular force and vasoconstriction. The inhalation of amly nitrate will dissipate the vasoconstrictor factor and bring into play the ventricular force, which is the real factor to be encouraged in a failing heart. The vasoconstrictor factor may and does compensate ventricular inadequacy, for it is essential in most cardioarterial diseases for the blood pressure to be maintained to afford better nutrition for the heart and to promote arterial elasticity as a means of establishing the circulation of the blood. The recognition of the ventricular and vasomotor factors in blood pressure serves as a clue in the correct administration of cardiactonics. In the individual endowed with cardiac health the removal of the vasomotor factor causes an increase in blood pressure, whereas the converse condition causes the latter to fall, and the degree of reduction is proportional to the degree of cardiac enfeeblement. Cardiac auscultation, in conjunction with the sphygmomanometer, and the inhalation of amyl nitrite constitute the ideal methods of eliciting the real condition of things. The sphygmomanometer gauges the force of the left ventricle only, while auscultation of the pulmonic valve sounds and a physical examination of the lungs are alone adequate to determine the sufficiency of the right ventricle. Cases in which there is high blood pressure without cardiac weakness, and in which after the inhalation of amyl nitrite the blood pressure remains the same, are associated with traces of albumin in the urine which is of low specific gravity and are practically instances of incipient chronic interstitial nephritis. Persistent high blood pressure, dependent upon augmented tonus of the vasomotor center, is a cogent etiological factor in arteriosclerosis independent of any other cause, and is rarely the reaction of arterial overwork. Normally, there is a postural variation in blood pressure. In the erect posture blood pressure rises owing to a compensatory arteriole contraction. In vasomotor insufficiency the postural variations are reversed, especially in neurasthenia, notably the angiopathic form. The bromides, carried to their physiological effects, will cause high blood pressure to fall, if dependent upon augmented tonus of the vasomotor center.

Therapeutic Hints.

Chlorosis with Neurasthenia.—

℞ Tinct. ferri chloride..... ℥ iiss
Hydrarg. chlor. corrosiv..... gr. ii
Liq. arsen. chloridi..... ℥ iiss

Gout.—

T. E. Satterthwaite says that there is a general treatment of gout that should underlie every variety, whether the form be acute, subacute, chronic, aberrant, or minor, and independent of special manifestations that require special treatment. Colchicum, in conjunction with the salicylates or their congeners, or the alkaline carbonates, still holds the palm in the treatment of acute gout. In the aberrant form, so varied are its manifestations there can be no specific treatment. In the other forms medicine plays a subordinate rôle to diet and hygienic remedies, though the iodides are mainly to be relied upon.—*The Post-Graduate.*

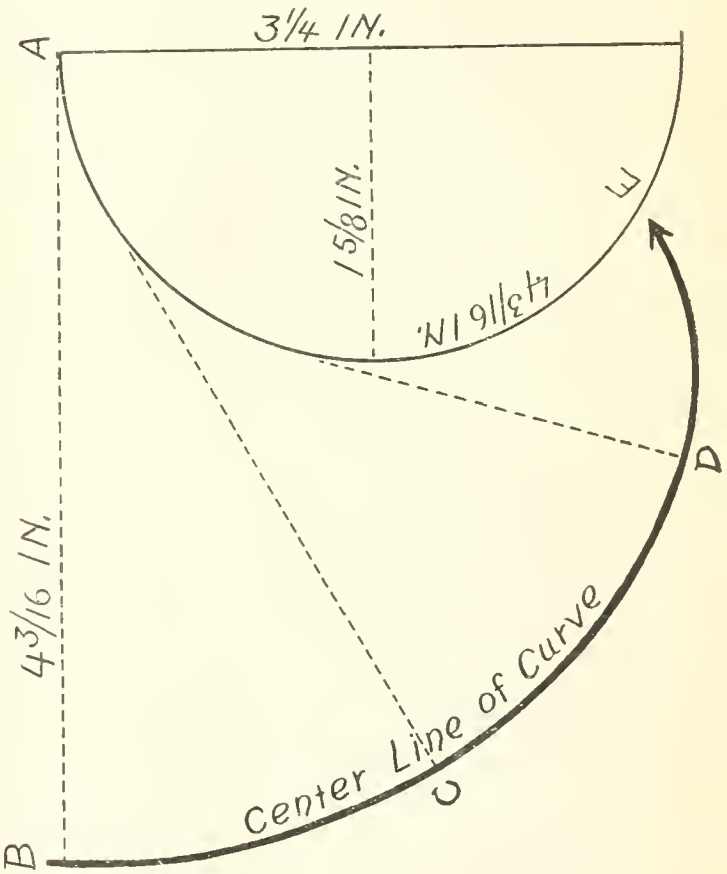
New Instruments.

CATHETERISM IN PROSTATIC RETENTION.

BY CHARLES L. SQUIRE, M.D.,
ELMIRA, N. Y.

This is the time of the year when subjects of prostatic hypertrophy are most apt to be seized with complete retention of urine from exposure of the surface of the body to cold, which produces a congestion in the already enlarged prostate and an engorgement of its blood-vessels, increasing its size and occluding its narrowed orifice, rendering catheterism difficult, painful, and often attended with hemorrhage. Acting on a recent suggestion of a colleague, I would devote a few words to the description of a curve which has been found serviceable when others have failed.



It is not a new curve, having been first described in the *American Journal of the Medical Sciences* for July, 1876. At that time a cut or pattern was given for its reproduction. It is the purpose of this article to describe how that pattern can be made at will and the correctness of the curve proven. This curve, which, by the way, does not conform to the *arc* of a circle, but is in its entire axis the shape of an *involute* of a circle, can be given to an ordinary English gum elastic catheter, No. 12, with stylet, at the bedside. To accomplish this it will be necessary to secure several articles, with which most houses are provided, namely, a cup or glass which measures three and a quarter inches across the top, a pocket tapeline, a lead pencil, and a sheet of white paper. The physician now inverts the glass upon the paper, previously placed upon a convenient table, then holds against the outside of the glass that point of the tapeline (A), four and three-sixteenths inches from the end, which is to be kept uniformly tangent by the

tip of a lead pencil (B) while the tape is being wound around the glass until the pencil comes in contact with the same (E). The mark upon the paper made by the lead pencil (B, C, D, E) will describe the curve to which the catheter with the stylet is to be made to conform, the beak of the instrument resting at the point where the curve made with the pencil meets the glass (E).

It has been the custom to give the shaft of the instrument a reverse curve, which gives to the whole a sigmoid shape, but the accuracy of the prostatic portion is all that is essential.

Three Recent Cases of Croup Due to Staphylococcus and Requiring Tracheotomy.—F. P. Anzinger reports three cases of preliminary sore throat in children, followed by severe obstructive symptoms in the larynx, and requiring tracheotomy. In none of the cases was there evidence of a pseudomembrane. The clinical symptoms in these cases pointed to a local infectious process, with elaboration of toxins. In two of the cases the diagnosis of diphtheria was entertained, and antitoxin was given, but with negative results. Bacteriological examination revealed the presence of practically pure cultures of staphylococci in the trachea and larynx. The organism in recent artificial cultures proved to be unusually pathogenic to white mice. Subsequent inoculation of the same strain of bacteria proved much less virulent. Pathogenesis was displayed only by direct inoculation into the lymph or blood circulation. The writer states that these cases may be taken as examples of cases at times diagnosed as diphtheria in which no microscopic examination is made. The failures of antitoxin are often credited to such cases. The writer finally emphasizes the importance of a careful analysis of each case, basing the diagnosis on both clinical and bacteriological evidence.—*Am. Journal of the Medical Sciences.*

Syphilis—A Non-Venereal Disease.—Nelson D. Brayton speaks of the dozens of epidemics of syphilis which have occurred involving not only thousands of individuals, but also races, the victims of which have acquired this dread disease ignorantly, or at least in ignorance of its dangers. Many patients are innocent victims of syphilis, the larger proportion of syphilis insontium, however, occurring in females. The larger number of cases of extragenital chancres appear on the face, which, next to the genital region, is the favorite seat for this hideous scourge. The lips are the most often attacked, then the tonsils, tongue, cheek, eye, ear, and nose. Bulkley gives the following general classification: 1. Syphilis œconomica, in which group fall those cases in which the disease is transmitted innocently from one to another, in the ordinary relations of domestic and industrial life. Under this group may be considered domestic, industrial, and personal transmission. Domestic transmission includes all cases of conveyance by means of spoons, forks, knives, cups, pipes, cigars, and the like. Articles of clothing may also convey the poison, as well as bedding, combs, sponges, and tooth brushes. Under industrial transmission belongs syphilis of the trades, arts, and crafts, the most striking example being that of glass blowing. Whole communities have been quickly syphilized in this way. Those engaged in trades in which instruments are used in the mouth are liable to infection. The poison may be transferred by means of stick candy. Personal transmission covers only a few varieties, but the innumerable cases in which the disease is acquired by means of kissing, biting, and other non-venereal acts, belong in this class. 2. Syphilis brephotrophica includes two classes, that relating to the nutrition of infants, and that relating to attendance upon them. 3. Syphilis technica includes three classes: *a.* The operator is the victim; *b.* the operator is the syphilifer; *c.* the operator is the medium. Dentists, physicians, surgeons, and nurses are the ones concerned in these classes. The writer has known eight physicians who have had digital chancres, acquired in their professional work. The greater number of these cases are among gynecologists and accoucheurs. A curious and unexpected method of transmission is that of the ancient practice of removing foreign bodies from the eye by the tongue. Tattooing and the sucking of recent wounds are causes of extra-genital chancres. Other methods of transmission are vaccination, dentistry, wet cupping, the use of razors, tongue depressors, surgical sounds, and specula. The main diagnostic features of the Hunterian lesion remain the same, though there may be slight variations in the chancre upon the buccal mucous membrane. Upon the lip, mouth, cheek, or tongue, there is often a pseudo-diphtheritic membrane difficult to remove. The prognosis and treatment do not differ essentially from the prognosis and treatment of the disease as it appears in the more usual situation. The writer believes that the most difficult part

of treatment is in the display of tact necessary in the management of such cases of syphilis. The social, moral, and medical obligations incurred by the physician in the treatment of syphilis are often very heavy, and call upon all of his resources to meet them. He becomes the guardian of the people's health. But the rewards for work of this kind are often great in proportion to the difficulties of the case.—*The Medical and Surgical Monitor.*

A Case of Dislocation of the Atlas.—James Hendrie Lloyd calls attention to the fact that a dislocation of the atlas may occur, and the patient continue to live for weeks and even years, as several well-authenticated cases prove. The author's patient was a man who fell on the left shoulder, striking the back of his head with great force. When examined by the writer the patient had a marked deformity in the neck. The head was twisted to one side and slightly rotated, and the deformity was most prominent on the left side. With a finger in the pharynx, the deformity could be felt as a projecting mass on the posterior wall. There was no complaint of pain, but the head was held in a very rigid and unnatural manner. The patient was paralyzed in the left upper arm. There was no paralysis in the left leg, however, nor in the right arm or leg. In fact, pressure symptoms were remarkable for their absence. There were no stigmata of hysteria present. As to sensory symptoms, one disturbance may possibly be very significant. This was a distinct area of tactile anæsthesia in the region of the distribution of the great occipital nerve of the left side. This nerve comes off from the second cervical which emerges from the spinal canal between the axis and the atlas. There was marked loss of thermic sense in the right arm and forearm. This sense was confused in the remaining parts of the right side extending from the fourth cervical vertebra. There was also analgesia of the entire right side from the region of the fourth cervical vertebra. There was no tactile anæsthesia either on the right or left side. The sensory symptoms eventually almost disappeared, but the motor paralysis of the left arm and the cervical deformity have persisted. In the skiagram shown, the atlas appears to be displaced. The vertebræ below it are in place. In summing up the features of this case the writer says that the motor paralysis of the left arm alone is extremely difficult to account for. This paralysis is of the peripheral type, as would be due to a lesion of the anterior nerve roots, for there is some muscular atrophy with faradic changes. The posterior colduns are not involved, as the absence of tactile anæsthesia shows. The writer questions if the odontoid process could be fractured allowing the atlas to slip, and also if there could be 2 lesions, one of the atlas and one lower in the spine, involving the anterior roots that go to form the brachal plexus.—*Am. Journal of the Medical Sciences.*

Pneumococcus Endocarditis.—Herbert R. Preble after a detailed study of this subject offers the following conclusions: Endocarditis complicates pneumonia in about 1 per cent. of all cases, and in 5 per cent. of the fatal cases. Endocarditis, due to the pneumococcus, makes about 25 per cent. of all cases of bacterial endocarditis. This affection may be of any degree of intensity, but in over three-fourths of the cases it is of the severe or so-called malignant type. The exudate is usually massive, but there is less disposition to ulceration and perforation of the valves than in endocarditis, due to the streptococci and staphylococci. Pneumococcus endocarditis is far more often left than right-sided, but involvement of the tricuspid and pulmonary valves occurs about 4 times as often as it does with endocarditis in general. The pneumococcus attacks the aortic valves more often than the mitral, and relatively twice as often as other organisms, commonly causing endocarditis. Infacts occur in about one-half the cases. Meningitis complicates pneumococcus endocarditis in about 60 per cent. of the cases, the prognosis, therefore, is extremely grave. Pneumococcus endocarditis is relatively twice as common in females as in males; it is more frequent after 30 years of age than before. An old heart lesion favors its development. Its clinical picture does not differ from that of any acute endocarditis. It may develop before, during, or after the pulmonary involvement, but the pneumococci may infect the endocardium with no lung involvement. The endocarditis may be afebrile. The duration varies from a few days to a few months. The pulse is usually rapid and irritable, but bradycardia is more frequent than in any other forms of acute endocarditis. Subjective symptoms referable to the heart are usually absent, except in the case of an old heart lesion. Physical signs are often entirely lacking. Leukocytosis is often absent. Blood culture will show the pneumococci. The diagnosis is difficult, impossible, in fact, in cases in which the endocarditis develops during the course of the pneumonia and ends rapidly in death. Endocarditis should always be suspected in pneumonia, which is followed by an irregular temperature not sufficiently accounted for by some other complication such as empyema. The treatment consists merely in absolute rest, with good, supporting food and stimulation as required.—*Am. Journal of Medical Sciences.*

Angioneurotic Œdema.—Roger S. Morris reports a case of this nature in which he believes for the first time a histological examination of the gastric mucosa has been made during an attack involving the stomach. The patient, a man of 21 years, has suffered from attacks of œdema, at times since he was 12 years old. The patient during this attack described by the writer became nauseated and vomited, and complained of pain in the stomach. In washing out the stomach a piece of tissue was obtained undoubtedly coming from a wound which was made by the end of the stomach tube. This bit of tissue was semitranslucent, and almost jelly-like. It was put at once into strong alcohol. It measured 13 mm. in length, by 7 mm. in breadth, by 4 mm. in thickness. It was soft, white and smooth on one surface and slightly rough and ragged on the other. Microscopic examination proved that it was gastric mucosa, probably from the pyloric end. Few parietal cells were found in the glands and numerous lymph nodes were present. It presented the picture of an extreme œdema of the interstitial tissue, the lymph spaces and vessels being enormously dilated. There was no excess of mucous formation. Numerous small round cells were present in many areas to a greater extent than usual in normal gastric mucosa. The lymph nodes showed the presence of œdema. Many of the stroma cells contained vacuoles and were spherical and swollen. From all the appearances a diagnosis was made of "extreme œdema of gastric mucosa, non-inflammatory in origin." The fall in free hydrochloric acid and in the total acidity coincident with the development of stomach symptoms in this case may have been due to œdema of the mucosa. It is possible, according to the writer, that the pain may also be explained by a stretching or pressing of the nerves or nerve endings. From the study of this case, it can be positively stated that simple œdema of the stomach wall does occur concomitantly with attacks of nausea, vomiting and gastric pain at times, at any rate, and that the probability of local œdema lying at the base of practically all of the gastrointestinal symptoms in angioneurotic œdema is greatly strengthened by this report.—*Am. Journal of the Medical Sciences.*

The Function of the Apophysis.—Guido Guerrini gives us an account of his experiments on animals to ascertain the function of the apophysis cerebri. He then gives a résumé of his findings and conclusions. The anterior lobe of the apophysis and the anterior portion of the posterior lobe have the structural characteristics of secreting structures, in the main that of secretory elements; there are two distinct functional products, one granular, staining red, and one of the nature of a plasmosoma which stains green; the origin, evolution, and action of the cells is the same as that of other secreting elements; the plasmosoma body is a form of colloid material; the two secretions react to the same stimuli; the maximum secretory activity is in adults, the same for male and female animals; in new-born animals

secretion is slight; in gestation, secretion is somewhat increased, not so in lactation; changes in metabolism do not increase secretion, starvation gradually decreases secretion; the kind of food does not influence secretion; injections of the nucleoproteid of apoyhysis or thyroid act as a stimulus to secretion; pilocarpine is an active stimulant; the blood serum of animals in which intoxications have been produced acts as a stimulant to secretion, when injected into normal animals. He concludes: (1) The apophysis is not a rudimentary organ destitute of function; (2) it has the function of elaborating two types of secretion; (3) the secretion seems not to influence trophic conditions; (4) the secretion has a generic antitoxic function.—*Lo Sperimentale*, October, 1904.

Cystic Hygroma of the Lymphatics of the Peritoneum.—Tito Cavazzani details the examination of the tumor in a case of hygroma of the peritoneal lymphatics. The most convenient classification of such tumors he considers to be as follows: 1. Derived from isolated connective tissue germs which develop to form new lymphatics. 2. The products of retention of fluids, forming cysts, resulting in a new formation of lymphatic vessels in a limited area. 3. Lymphangioma with obstructed vessels of exit, formation of large cysts, with alteration of the walls, desquamation of the endothelium, etc. The author diagnoses lymphatic angioma only when he finds abnormal production of vessels independent if obstruction. The etiology is not well known. Stasis, chronic inflammation. development of connective tissue, compression from tumors, etc., favor it. The most important factor is stasis. There must be an inflammatory reaction sufficiently acute to cause development of endotheliol cells quicker and in greater numbers than of the connective tissue cells. The specimen examined by the author was found in an operation for tubercular peritonitis. It consisted of two cysts, united by cords of vessels, and with several smaller cysts, which floated in the ascitic fluid which the abdomen contained. One of the cysts arose from the peritoneum near the umbilicus, two others from the omentum. The chronic peritoneal inflammation was the origin of the overgrowth of connective tissue and endothelial cells.—*Archivio per le Scienze Mediche*, Vol. XXVIII, Nov. 21, 1904.

History of Cerebral Localization, with Some Considerations Regarding the Subdivisions of the Areas of Representation of Cutaneous and Muscular Sensibility and of Concrete Concepts.—Charles K. Mills first speaks briefly of the history of cerebral localization, attributing the initiation of the modern era of this line of research to Francis Gall and Sir Charles Bell. Some of the results of recent studies in localization he presents as follows: In operating for prefrontal tumors, higher psychical symptoms should be the chief guide, and in the case of the left hemisphere, agraphia and aphasia, the opening should always be anterior to the main extent of the motor region. In all operations for brain tumors with dominating motor symptoms, the opening of the skull should be made so that the correlative brain exposure will be three-fourths in front and one-fourth behind the central fissure, the base of the flap being perpendicular to the lower end of that fissure. In operations for tumors having symptom-complexes, in which disorders of the muscular sense and astereognosis are dominant, the opening in the skull should be so made that the cerebral exposure will be three-fourths behind and one-fourth in front of the central fissure. When oculomotor symptoms, such as abducens paresis, lid drooping, and nystagmoid movements, are present, with symptoms pointing to the parietal lobe, the operation should be parietal or parieto-occipital, for the interference with eye movements is not basal, but probably due to disturbance of the visual motor cortex. When object blindness in any of its forms is the central feature of the symptomatology, operation should be done with a view of exposing the lower temporo-occipital convolutions. When relative or absolute hemianopsia, or hemiachromatopsia, or both, are the most important symptoms, the operation should, if possible, be with the view of reaching the mesotentorial surfaces of the occipital lobe. When forms of literal or verbal blindness are the central features of the syndrome, the angular gyrus should be the focus of the exposure. Likewise, when verbal deafness is the deciding symptom, the posterior extremities of the first and second temporal convolutions should be the objective points, while for uncomplicated verbal amnesia, the mid-temporal region should he exposed, and for note deafness or amnesia, the anterior-temporal region.—*Proceedings of the Philadelphia County Medical Society.*

What Constitutes Medical Practice.—Dr. Van Meter of Denver suggests the following comprehensive definition: Any person shall be regarded as practising medicine who shall in any manner hold himself out to the public as being engaged in the diagnosis and treatment of diseases or injuries of human beings; or who shall suggest, recommend, or prescribe any form of treatment for the intended palliation, relief or cure of any physical or mental ailment of any person, with the intention of receiving therefor, either directly or indirectly, any fee, gift, or compensation whatsoever; or who shall maintain an office for the reception, examination, and treatment of any person suffering from disease or injury of body or mind; or who shall attach the title of M.D., Surgeon, Doctor, or any other word or abbreviation to his name, indicative that such person is engaged in the practice of medicine as hereinbefore defined.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 23, 1904:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS
California, Stockton	Nov. 1–30	2	..
Illinois, East Saint Louis	Dec. 1 17	18	2

INDEX.

A.

Abbe, Robert, on what lines is the treatment of malignant disease advancing? 1041; the subtle power of radium, 321.
Abdominal aorta, ptosis of the, 590; wall, overlapping the aponeurosis in the closure of wounds of the, 1028; surgery, unavoidable calamities in, 74; surgery, immunity against infection in, 97; muscles, laceration of the, 70; inflammation, management of, 37.
Abortion, chlorate of potassium in habitual, 708; criminal, social causes of, 489.
Abrams, Albert, the stomach reflex and percussion of the stomach, 377.
Abscess, lumbar, six cases of, 66.
Academies for practical medicine in Germany, 302.
Accidental hemorrhage, treatment of, 313.
Accouchement forcé, value of the means employed for, 554.
Acetone bodies in diabetes, 673.
Acetonuria and fatty diet, 859; associated with death after anæsthesia, 106; elsewhere than in diabetes, 1031.
Acid intoxication, 458.
Acne, the curette in the treatment of, 238; vulgaris, bacteriology of, 630.
Acrodermatitis, controlled by *x*-ray, 186.
Actinomycosis, the nature of in man, 830.
Addison's disease, a case of, 1065.
Adenoids, conditions interfering with complete removal of, 238; in children, 305; remarks on, 268.
Adenopathy, treatment of tracheobronchial, 831.
Adirondack sanatorium patients, post discharge mortality among, 869.
Adolescence, mental disorders of, 715.
Age and youth in medicine, 161; treatment of the degenerations of, 466.
Agreement not to practice in a given locality, validity of, 301.
Ainhum, 651, 679.
Air passages, cancer of the upper, 514.
Albumin, absorption of in infants, 468.
Albuminuria, a case of, 105; functional, 146, 667; in the apparently healthy, 218; orthostatic, 430, 1068; retinitis of, 27.
Alcohol in the tropics, 961.
Alcoholism and drug habits, their pathology and treatment, 296; and heredity, 537; and inebriety, 373; cure of, 550; in German schools, 898; in Normandy, 370; social causes of, 421.
Aldrich, Charles A., tic, 169.
Alexander operation, results of the, 674.
Alienists, examiners of the State Board of, 262.
Alopecia areata, light treatment of, 308.
Alvarenga prize, 743.
Am Ende, C., strophanthus in lobar pneumonia, 778.
American Physicians and Surgeons, Congress of, 1021.
Amœbæ, urine containing, 356.
Amyotrophic sclerosis, after trauma, 590.
Anæmia, chronic splenic, 427; in uncinariasis, 9; pernicious, mental symptoms in, 111.
Anæsthesia, nitrous-oxide ether, 638; sterile water, in rectal diseases, 691, 717; symposium on local and general, 152, 153.
Anæsthetic apparatus and technique, improvements in, 92.
Anæsthetics, value of oxygen in combination with general, 816, 836.
Anastomosis, gastric and intestinal, a mechanical device for, 76; a new method of lateral, 708.
Aneurysm, non-fatal rupture of aortic, 910; treatment of by injections of gelatine, 309, 944; two popliteal in the same patient, 790.
Angioma of the vastus internus, 360; treatment of by boiling water, 195.
Angina pectoris, 747.
Anginas, non-diphtheritic, 619.
Anilin poisoning, 629.
Ankylosis, treated by arthroplasty, 75.
Ankylostomiasis, 350; prophylaxis of, 829, 1031.
Ankylostomum infection through the skin, 590, 1068.
Antenatal conditions, influence of, 348.
Anthrax, serumtherapy of, 307.
Antisepsis, internal, 627.
Antistreptococcus serum, the use of, 787.
Antitetanus serum, prophylactic use of, 1000.
Antitoxin, in diphtheria, 675; streptococcus and tetanus, 859.
Antituberculosis serum, Marmorek's experience with, 871.
Antivaccination revolution, 863.
Antivenene, 450.
Antrum of Highmore, empyema of the, 590.
Anuria, renal retention with, treatment of, 506.
Aortic insufficiency, trauma as a cause of, 348.
Aphasia and the speech center, 591; treatment of, 1066.
Aphonia, the treatment of spastic, 349.
Apoplexy, traumatic, 528.
Appendectomy, treatment of the stump in, 1030.
Appendicitis, a case simulating, 554; acute, drainage in, 67; and embalmed beef, 283; associated with disease of the adnexa, 266; conditions simulating acute, 684; diagnosis of, 419; hot bath in the treatment of, 900; latest cure for, 235; medical treatment of, 153; operations for, intestinal obstruction following, 426; operation for, on the eighth day of typhoid fever, 897; or intestinal occlusion by invagination, 190; pneumococcal, 108; posterior incision in, 788; predisposing causes of, 478, 679; prevention and mortality of, 759; retroperitoneal abscess in, 590; simulated by cholecystitis, 251; suppurative, 230; treatment of, 600; two thousand operations for, 430; unusual cases of, 671, 795; urinary complications of, 830; value of clinical symptoms in, 14; when to operate for, 665.
Appendix, adenocarcinoma of, 231; carcinoma of the, 870; a case of chronic cystic dilatation of the, 856; colic of, 28; extraperitoneal relations of the, 147; foreign bodies in the, met with in 1,600 necropsies, 935; new method of treating the stump of the, 910; peritonitis due to the, 389; pin in the, 146; specimen of an, 278.
Argyle symptom, the, and syphilitic meningitis, 231.
Army medical examination, change in, 61.
Arterial sclerosis, etiology and treatment, of, 153, 1018.
Arteries, chemical analysis and radiograph of calcified, 150; effect of cold on the, 911.
Arthritis, an analytical study of twenty-eight cases, 466; experimental, produced by a streptococcus from a case of rheumatism, 789; injection of sodium salicylate in multiple, 701; puerperal suppurative, 669.
Arthritis deformans and its relations to gastrointestinal diseases, 460; resemblance to paralysis agitans, 458; surgical treatment of, 38; treatment of, 154.
Ascarides simulating gallstones, 592.
Ascaris texana, a new intestinal parasite, 545.
Asepsis, 949; and antisepsis, present aspects of, 315.
Aseptic operating, 72, 1076.
Ashmead, Albert S., biology of the tubercle bacillus, 586.
Associated movements of the eyelid and lower jaw, 248.
Association neurosis, nature of, 786.
Assouan cure, the, 707.
Asthma, the climatic treatment of, 947; dermatitis in, 498; etiology of, 671; in infants, with forty-three cases, 436; tracheal traction test in, 27.
Astigmatism, variations of with age, 790.
Atheroma in rabbits, caused by adrenalin, 308.
Athletics, use and abuse of, 484.
Atrophy of the thenar eminence, bilateral, 1033; strychnine nitrate in progressive muscular, 204.
Atropine poisoning, 947.
Aural inflammations, non-operative treatment of, 190.
Auricles, pressure in the, 389.
Austin, Oliver L., the clinical features of the epidemic of dysentery at Tuckahoe, N. Y., during the summer of 1902, 206.
Autointoxication, 57, 346; intestinal, 379.
Azoöspermia, diagnosis and treatment of, 268.

B.

Babin, retirement of Dr., 1061.
Bacterial toxins, further studies of the, 426.
Bacteriology, progress in, 199, 754.
Bailey, Pearce, traumatic apoplexy, 528.
Balsam of Peru, nephritis due to, 309
Banti's disease, 628.
Bardes, Albert C., trachoma, 1052.
Barrows, Charles Clifford, prolapse of the ovary. An operation for its cure, with report of twelve cases, 601.
Barry, William F., an interesting day's work, 707.
Barstow, Donald M., a case of supposed primary tuberculosis of the pharyngeal tonsil, 578.
Baruch, Simon, the success of physical remedies in pulmonary phthisis as an index of their value in other chronic diseases, 241; prize awarded to Dr., 742.
Bathing in Japan, 245.

Hay fever, etiology of, 588; management and treatment, 94.
Haynes, Irving S., report of two fatal cases, 653.
Headache in rhinology 587.
Head cooler, a new, 358.
Health, the battle for, in the tropics, 220; seeker, the improvident, 860.
Heart, air in the, 189; and circulation in pregnancy and the puerperium, 922; disease, chronic, diet in, 188; disease, congenital, polycythæmia of, 178; disease, exercise in, 940; disease, in pregnancy, 312; electricity applied to the denuded pericardium in failure of the, 25; foreign body in the, 268; lesions, diagnosis, and treatment of, 308; murmur, significance of a, 427; orthodiagraphy and percussion of the, 109; suture of the, 502, 828.
Hebrews, physical condition of American, 078; tuberculosis among, 340.
Helprin, Benjamin Edel, dietetics in summer diarrhœa, 130.
Hemianopsia, 913.
Hemiplegia, due to lumbricoid worms, 270.
Hemorrhage, before, during, and after labor, 619; external, metabolic changes caused by, 188; medical treatment of internal, 387, 628, 1066; pulmonary treatment of, 447.
Hemorrhagic, disease of the newly-born, 1000; septicæmia, pulmonary lesions produced by the bacillus of, 539.
Hemorrhoids, internal, diagnosis and treatment of, 66; a method for preventing pain following clamp-and-cautery operations for, 338; the treatment of by currents of high tension, 108.
Henoch's purpura, gastrointestinal lesion of, 890.
Hepatic drainage, 317
Heredity and disease, 658, 880.
Hernia, autoplastic suture for, 37; of the bladder, complicating inguinal hernia, 470; in children, fourteen hundred operations for, 675; inguinal, Andrew's operation for radical cure of, 37; inguinal and femoral on the same side, 874; radical cure of, 465, 755; sciatic, 678; and traumatism, 189; treatment of, by alcohol injections, 749; ventral, silver filigree for cure of, 228.
Heroin addiction, 631.
Higgins, F. W., minus cylinders, 375.
Hip, treatment of congenital dislocation of the, 949.
Hips, elevation of the, in placenta prævia, 507.
Hodgkin's disease, a case of, 826.
Hospital, charges against, 382; construction in America, 712; new Vienna General, 63; New York State, for incipient tuberculosis, 61; problem in New York, the, 1057.
Hot-air treatment of diseases of the genitals, 448.
Hot Springs, Va., climate and waters of, 707; waters, radioactivity in, 660.
House fly, the menace of the, 341.
Hoy opaque projector, 914.
Hubbard, Ernest Valentine, illuminating gas poisoning, its rational treatment, 417.
Huber, John B., the history of tuberculosis, 645.
Hyde, B. C., icterus in secondary syphilis, 497.
Hydrastis, uses of, 787.
Hydrocephalus, chronic internal, lumbar puncture in, 267.
Hydrophobia, demonstration of the parasite of, 710; doubtful case of, 629; eosinophile formations in, 270; laboratory aids in the diagnosis of, 909; Negri's, bodies in, 191; researches on the etiology of, 30; and trauma, 549; the way by which its virus reaches the dog's saliva, 669.
Hydrotherapeutic measures, 385; in nervous diseases, 678.
Hyoscine poisoning, 701.
Hyperidrosis, treatment of, 266.
Hyper-pyrexia, puerperal, 911.
Hypnotism, dangers of, 1064.
Hypospadias, Beck's operation for, 549.
Hysteria in childhood, 668.
Hysterectomy, 316; after effects of, 636, 637, 1065; in puerperal infections, 912.
Hysteropexy, physiological or ligamentary, 591.

I.

Icterus, and diabetes of nervous origin, 590; in secondary syphilis, 497.
Ic tic, the, 462.
Illuminating gas poisoning, its treatment, 417; a study of ninety cases of, 41.
Immune hæmolysins, transmission of from fœtus to mother, 418; sera, specially prepared, 259.
Immunity, 509, 546; against streptococci, 980; the theory of, 468; Wassermann's lecture on, 543.
Incision, the suprapubic transverse, 819.
Indicanuria, complicating typhoid, 748.
Inebriety, loss of consciousness in, 713; relation of to insanity, 307.
Infant feeding, 391, 635, 708, 1015; citrate of sodium in, 387; difficult cases of, 306; natural vs. scientific, 857; a simple method for, 892.

Infant mortality in New York City, 676.
Infants, endeavor to reduce the mortality among, in Chicago, 140; pyloric stenosis in, 324.
Infants' and children's hospitals, 433; foods, addition of bicarbonate of sodium to, 1059.
Infection, by a new chromogenic bacterium, 540; cerebral, 224; and immunity, symposium on, 154; iodine and mercury in local, 27.
Inflammation, physical therapeutics in, 636.
Influenza and articular rheumatism, diagnosis of, 466; bacillus as the cause of cholecystitis, 458; in children, 466; nervous complications of, 258.
Infusoria and bacteria, antagonism of, 839.
In lighter vein, 901.
Insane, allegations against nurses of the, 221; disposal of the criminal, 713; mechanical restraint of the, 945.
Insanity, dissimulation in, 750; feigned, 869; in obstetrics and gynecology, 715.
Insufflator, a cheap, 359.
Intermittent lameness and other nervous symptoms of arterial disease, 508.
Internal secretions, present status of investigations on, 834.
Internal urethrotomy, 370.
Interrupted circulation as a remedy, 387.
Intraventricular septum, perforation of the, 1031.
Intestinal obstruction, 710, 1070; obstruction, three cases of, 68; obstruction after gastroenterostomy, 387; obstruction, diagnosis, and treatment of, 467; obstruction from gall-stones, 913; obstruction, postoperative, 949; paralysis, prevention of post-operative, 461; stenoses, 1030; surgery, 757; worms, toxic effect of, 589.
Intestine, exclusion of the, 667; syphilis of the, 357; traumatic rupture of the, 111.
Intestines, congenital absence of continuity between large and small, 990; a method for uniting, of unequal caliber, 1070.
Intoxication, diagnosis of, 268.
Intratracheal injections, 474.
Intraocular hemorrhage and systemic disease, 870.
Intubation, 748.
Intussusception, 391.
Iodides, action of, 991.
Iodine catgut, 269.
Iris, abnormal mobility of, as a diagnostic measure in nervous diseases, 229.
Iron, perchloride of, in blood poisoning, 910.
Isaac, A. E., congenital absence of vagina, operation, 818.
Isthmian Commission, Department of Health of the, 1019.
Isthmus, sanitary work on the, 140.

J.

Jacobi, A., the potassium chlorate and iron mixture, 26.
Jamaica, vomiting sickness of, 404.
Japanese army, medical department of the, 341; sanitation in the, 20; soldier, habits and diet of the, 300; treatment of wounded by the, 342.
Jaundice and its treatment, 501.
Jaw, reduction and fixation of fractures of the, 810.
Joint affections, Bier's treatment of, 590.
Joints, diseases which affect the, 712.

K.

Kakosmia, subjective, 668.
Kala-azar, 398.
Keen, W. W., age and youth in medicine, 161.
Keloid of tuberculous origin, 991.
Kempf, E. J., a cheap and serviceable insufflator, 359; primitive medicine, 288.
Kennedy, Francis S., music as a therapeutic agent, 697.
Kidney, congestion of the, 310; diagnosis and treatment of stone in the, 909; functions of the, and renal insufficiency, 110; gynecological importance of prolapsed, 641, 672; movable, 470; movable and enteroptosis, 30; nephrectomy for tuberculosis of the, 761; primary diphtheria of the, 268; stone in the, 38; studies on the capsule of the, 789; unusual effects of movable, 1066.
Kidneys, action of corrosive sublimate on the, 349; cryoscopy in disease of the, 668; experimental decapsulation of the, 146; lesions in the, discovered during nephropexy, 632.
Kingsley, Josephine, the over-educated woman and the race question, 228.
Knee-joint, anatomy and surgery of the internal derangements of the, 192.
Knockout drops of picrotoxin, 626.
Knopf, S. A., the modern tuberculosis dispensary, 125, 157; the National Association for the Study and Prevention of Tuberculosis, 26.

L.

Laboratory tests, clinical value of, 796.
Lacerations, treatment of, of pelvic floor, 117.
Lachrymal canal, congenital occlusion of the, 989.
Lambert, Samuel W., appointed dean of Columbia Medical Department, 702.
Laminectomy, a contribution, 37.
Landenberger, J. C., report of a case of chronic cystic dilatation of the vermiform appendix, 856.
Laparotomy, combined, transverse, and longitudinal incision in, 632; treatment before and after, 1072.
Laryngeal stridor, congenital, 147.
Laryngitis, chronic, some phases of, 174.
Laryngocele, 439.
Larynx, cancer of the, 28, 441, 477, 721; papilloma of the, 389, 515; post-typhoid perichondritis of the, 446, 475.
Laundry hygiene, 945.
Lazear, a tablet to Dr., 623.
Lederer, William J., the rational reduction and fixation of maxillary fractures, 810.
Leishman-Donovan body, in ulcerated surfaces, 108; nature of, 397.
Lentigo, a case of, with unilateral distribution, 229.
Leonard, Z. L., some phases of chronic laryngitis, 174.
Leper, deportation of a, 303.
Leprosy, a curable disease, 548; serum treatment of, 182.
Leucocytes, neutrophile in infectious diseases, 110; significance of, 677.
Leucocytic formula in blister serum, 631.
Leucocytosis, of pregnancy and eclampsia, 430; value of, in abdominal diagnosis, 459.
Leukæmia, acute, 276, 437, 668; a case of, with improvement, 338; a case of myelogenous, 307; in childhood, 789; investigations into the etiology of, 509; spleno-medullary, treated by the *x*-ray, 786; *x*-ray treatment of, 546, 709.
Leukanæmia, a case of, 28.
Lewis, Frank N., a case of foreign body remaining in the lens of the eye for six years with the lens otherwise clear, 214.
Lewis, H. Edwin, a clinical study of certain forms of pericarditis, with report of a pericardial effusion complicating an extensive burn of the chest, 487.
Library, movement for a medical, 60.
License requirements in Illinois, 742.
Life insurance, the medical relations of, 938.
Ligatures and sutures, materials for, 225.
Light treatment after sensibilization, 155.
Lilienthal, Howard, a method for preventing the pain following clamp and cautery operations for hemorrhoids, 338.
Lincoln, H. W., gastrostomy for stoppage at the cardia, 377.
Lipoma of the labium majus, 995.
Lipomata, painful, 790.
Liver cases, 147; cirrhosis of the, 574; primary sarcoma of the, 437; reservoir action of the, 589; Talma's operation for cirrhosis of the, 653; tropical abscess of the, 899.
Local pressure, application of continuous, 710.
Locomotor ataxia in man and wife, 738.
London, letters from, 23, 64, 102, 143, 184, 226, 264, 304, 344, 383, 424, 464, 504, 544, 584, 626, 664, 704, 744, 784, 825, 866, 906, 985, 1024, 1062.
Lorenz, a garden party given by Dr., 105.
Lumbar puncture in Sydenham's chorea, 310; value of, in meningitis, 29.
Lunacy Commission, work of the N. Y. State, 703.
Lung, percussion of the apex of the, 12; primary cancer of the, 752, 852; sequestra of the, 787.
Lupus, treatment of, by the practitioner, 990; vulgaris of the oropharynx and nasopharynx, treated by *x*-rays, 1013; vulgaris, treatment of, 748.
Lying-In Hospital, report of, 942.
Lymph cells, 548.
Lymph nodes, topography of, 426.
Lymphatic constitution, care during operations, 31; glands, influence of the, on immunity, 631; system, surgical physiology of the, 707.
Lymphocytes, nature of, 509.
Lymphocytic exudates, production of, 1067.
Lymphoid affections of the upper air tract of children, 766.
Lymphosarcoma of the mesentery, 178.

M.

McCullough, John W., post-partum hemorrhage, 908.
McIntosh, T. M., post-partum hemorrhage, 987.
McKinney, Richmond, adenoids in children, 395.

McLaughlin, W. B., the treatment of pulmonary hemorrhage, 447.
Macrocheilia, adenoma of the lips as a cause of, 788.
Maher, Stephen J., the cycle of the tubercle bacillus, 401.
Malachite green in trypanosomiasis, 947.
Malaria, 450; æstivoautumnal, 537; and ascarides, 710; arterial pressure in, 1031; influence of daylight on, 191; invasion of æstivoautumnal, 107; other causes of, than mosquitos, 808; prophylaxis against, by quinine, 639; prophylaxis of, 394; therapy and prophylaxis of, 69; tropical, 717.
Malarial infection, 746; antitoxin treatment of, 1001.
Malignant disease, on what lines is the treatment of, advancing, 1041, 1076.
Malignant growths of the upper air passages, pathology of, 960.
Malsbary, George E., rheumatism, 926.
Malta fever, 348.
Mammary gland, clinical notes on the, with report of four cases, 132.
Manges, Morris, treatment of pneumonia in adults, 929.
Mania from traumatic meningitis, 68.
Manila, letters from, 24, 745, 867, 907, 986, 1063.
Manley, Thomas H., clinical notes on the mammary gland, with report of four cases of somewhat unusual interest, 132.
Marcour, Raphael O., polymazia among enlisted men of the marine corps, 498.

Marvin, Frederic Rowland, execution by electricity, 145.
Marx, S., occipitoposterior positions, 54.
Massage, vibratory, in general practice, 197.
Mastoid, operations on the, 320; operation, fever as an indication for, 1021.
Mastoiditis, two cases of, with paralysis of facial nerve, 409.
Mayer, Emil, post-typhoid perichondritis of the larynx, 446.
Mayo, Charles H., thyroidectomy for exophthalmic goiter, based upon forty operative cases, 734.
Measles, characteristic temperature curve of, 1, 33; the otitis of, 948; polymyositis in, 388; prevention of, 539, 1065; susceptibility of the newborn to, 507.
Measurements, uniformity in pelvic and cranial, 118.
Meckel's diverticulum, 471; abdominal crisis due to, 1031.
Mediastinum, abscess of the, 550.
Medical appointments on the Isthmus of Panama, 982; journals, consolidation of, 542; lessons of the war, 380; license examination in Missouri, 141; literature, the choice of, 712; military journalism in the present day, 260; science, modern methods of, 555; students and graduates in the United States, 423; union in New York State, 142, 622.
Medical College, Dearborn, 423.
Medical Jurisprudence, officers of the Society of, 1021.
Medicine and hygiene, state, progress in, 197; and therapeutics, progress in, 195; primitive, 288.
Medico-legal cases, 587.
Melancholia, remarks on, 1007, 1034.
Melancholias, discussion of the, 1033.
Membranes, repose in relation to premature rupture of the, 830.
Memory and consciousness, temporary loss of, 870.
Meniere's disease, nature of, 829.
Meningeal infection by the diplococcus pneumoniæ, 427.
Meningitis, cerebrospinal, see *Cerebrospinal;* due to the pneumococcus lanceolatus, 160; in infants, a new bacterium causing, 428; lumbar puncture in, 389; tuberculous, 679.
Meningoencephalitis, hemorrhagic, 355.
Menorrhagia, in typhoid fever, 465.
Menstrual disorders, causes of, 546; precocity, a case of, 664.
Menstruation, disturbances of, 747.
Mental overstrain at puberty, gynecological aspects of, 506; phenomena and visceral disease, 840; therapeutics, 345.
Meralgia paræsthetica, a case of, 191.
Mercurial injections in nervous diseases, 1066.
Mercury, idiosyncrasy against, 618; manometers, pocket, 990.
Metatarso-tarsal valgus, relation of, to boots, 908.
Metastatic lymph currents from the thoracic to the abdominal cavity, 549.
Meteorism, post-operative, 937.
Methyl alcohol, properties of, 908.
Middle ear, injuries to the, 549.
Military attaches, medical, 741.
Military Surgeons of the U. S., Association of the, 661.
Milk, 557; adulteration, permissive, 163; bacteria in grocery, 1020; Chicago, 141; distribution of pasteurized, 503; for infant feeding, 787; influence of the state of health on the freezing point of, 631; law in Chicago, a new, 100; sickness in Illinois, 462; sterilized or plain, 913.
Miller, Charles C., internal urethrotomy in the treatment of stricture of the membranous urethra, 370.
Mind cure, from the standpoint of the general practitioner, 345.
Minus cylinders, 375.
Mistake of a drug clerk, fatal, 342.
Missouri State University School of Medicine, 423.
Mitchell, Louis J., a series of foreign bodies in the vermiform appendix met with in 1,600 necropsies, 935.
Mitral regurgitation, 587; stenosis in advanced life, 230; stenosis, recurrent laryngeal nerve paralysis in, 737; stenosis, with insufficient physical signs, 913.
Morphine in cardiac disease, 269; in cerebral injury, 68; habit, treatment of the, 714; habit, symptomatology of the, 307.
Morris, Robert T., the idea of gross cleanliness in surgery, and its harmful results, 528.
Morton, Henry H., perineal prostatectomy, with report of ten cases, 561.
Moser, W., a case of chronic fibrinous bronchitis, with especial reference to the treatment of this disease, 216.
Mosquito bites, treatment of, 948; campaigns against the, 350; reduction, 557.
Mosquitos, extermination of, 542; and malaria, 717; ricinus and pawpaw plants as deterrents to, 220.
Mundorff, George T., a suggestion for increasing the value of the cystoscope in cases of hæmaturia, 186.
Murder habit, the, 220.
Murdoch, Frank H., the indications for surgical intervention in chronic gastric ulcer, 529.
Murray, Grace Peckham, rectal constipation in women, 201, 236.
Mushrooms, symptoms in acute poisoning by, 819.
Mutation, theory of in medicine, 107.
Myelitis, hemorrhagic, 356; unusual forms of, 546.
Myocardial disease, recognition and treatment of, 267; insufficiency in children, 435.
Myocardium, disease of the, 587.
Myokymia, primary, 67.
Myomectomy, abdominal, 898.
Myopia, treatment of, 871.
Myositis, two cases of infective, 870.

N.

Nævi, linear, 385.
Name, illegal use of a surgeon's, 702.
Narcotic drug users, a plea for, 348.
Nasal affections, value of ointments in, 472; fossæ, large foreign body in the, 30; hydrorrhœa, 472; polyps, the origin of, 829; septum, facial asymmetry, causing deformities of the, 474; suppuration, 741, 759; surgery, collodion dressing in, 831; surgery of to-day, 472.
Nasopharyngitis, lithæmic, 666.
Nasopharynx, four unusual tumors in the, 474.
Natural resistance, conservation of, in surgery, 597.
Nauheim Springs, radioactive substances in the, 149.
Navy, the personnel of the, 581.
Neoplasms, the nucleus in, 226; origin of, 620.
Nephritis, chronic, a discussion on, 275; chronic, surgical treatment of, 66; cured by decapsulation, 392; erysipelas complicating, 13; a possible cause of high-tension pulse in, 281; postdiphtheritic, 948; simulating diabetes, 589; surgical treatment of, 25, 98, 181, 707, 736; therapeutics of, 191; tonsilitis a cause of acute, 360.
Nephrotomy, therapeutic value of, 191.
Nerve defects, bridging of, 77, 1030.
Nerve trunks, perforating wounds of, 219.
Nerves, results in secondary suture of, 77.
Nervous diseases and eye strain, 599; diseases, notes on some uncommon forms of, 121, 156; exhaustion in infants, 432; symptoms in children due to refractive and muscular errors, 988; symptoms following operation, 531; system, tuberculosis of the, 663.
Neuralgia, nerve blocking in, 636; of the inferior dental nerve, operation for, 874; spasmodic, treated with bromide, 787; trigeminal, intracranial neurectomy for, 37.
Neurasthenia, the mental disorder of, 1040; the passing of, 237.
Neurology, physiological principle in, 559, 1028.
Neuron theory, 388.
Neuropathology and internal medicine, 260.
Neuroses of the upper air tract, 475; radiant light bath in the treatment of, 187.
Newton, Richard Cole, the true education of mind and body, 84.
New York, water supply of, 624.
Nodules, evanescent, subcutaneous with fever, 548.
Noise, unhealthfulness of, 108.
Noma, bacteriology of, 830.
Norstrom, Gustaf, the study of sprain and its treatment by massage, 812.
Nose, accidental vaccina of the, 108; adenocarcinoma of 514; and throat, fatal operations on the, 472; pus in the, 1065; secreting mechanism of the, 471; treatment of fracture of the, 948.
Notifiable diseases in Philadelphia, 141.
Nucleus in neoplasms, the, 226.
Nurses, American in Japan, 420.
Nurses' bureau, 753.

Nydegger, James A., two cases of chronic nephritis treated surgically, 736.

O.

Obesity, 948; some aspects of, 218.

Piroplasmosis, human, 398, 509.
Placenta, chorioangioma of the, 831; circumscribed infection of the, 597; ferments of the, 1068; manual removal of the, 1068.
Plastic operations, results of four, 1036.
Plecker, W. A., the climate of Tidewater, Va., 331.
Pleural effusion and pneumothorax, treatment of tuberculous, 276; fluids, examination of, 665.
Pleurisy, chronic, 549; tuberculous, 714.
Pneumococcic pyæmia, 667.
Pneumonia Commission, 624, 663.
Pneumonia, a disseminated form in children, 667; etiology of, 418; herpes zoster in, 109; incubation of, 231; lobar, treatment of, 147; lobar in infancy, 118; cases of, 433; meteorism in, 347; meteorological conditions in the causation of, 427; post-operative, with experiments upon its pathogeny, 31; pathogenesis of, 149; problem, the, 1000; strophanthus in, 778; treatment of, 107, 849, 929; treatment of heart failure in, 989.
Polak, John O., brief notes on the management of occipitoposterior positions of the vertex, 55.
Pollak, Alfred W., three cases of primary malignant tumor of the lung, 852.
Polyarthritis diplococci, 309.
Polydipsia and polyuria, hysterical of eleven years' duration, 29.
Polymazia among enlisted men, 498.
Pooley, Thomas R., a case of conglomerate tubercle of the choroid, 847.
Portal vein, artificial anastomoses for, 468.
Post-graduate instruction in America, 754; medical study in Paris and in Berlin, 184.
Post-mortem examinations for medical-legal purposes, 508; temperature, 949.
Post-partum hemorrhage, 820, 908, 987.
Pott's disease, plaster apparatus in the treatment of, 710.
Powell, Junius L., are there other causes of malaria than mosquitos? 808.
Pregnancy, the circulation during, 940; complicated by ovarian cyst with twisted pedicle, 235; extrauterine, cases of, 34, 306, 533, 758; extrauterine, diagnosis of, 945; extrauterine, study of, 314; heart disease in, 312; ovarian, 114; propriety, indications and methods for the termination of, 36; pyelitis complicating, 81, 115; tubal, three cases of, 996; vaginal hysterectomy for cancer during, 550.
Preservatives and adulterants in foods, influence of, on public health, 914; effect of, on health, 782.
Preventive medicine and school children, 987.
Progeria, a form of senilism, 741.
Prostate, anatomy of, and suprapubic prostatectomy, 189; cause of enlarged, 318; light treatment of the, 364; operations on the, 756; rôle of the, in urinary disease, 693.
Prostatectomy, operative methods, 38, 1068; perineal, 561; report of fifty cases of, 38; suprapubic, 70, 248; ultimate results of perineal, 1074.
Prostatic hypertrophy, does gonorrhœa cause, 147; hypertrophy, present attitude regarding treatment of, 1055; retention, catheterism in, 1079; operation, Freyer's, 318.
Prostatitis, chronic, 827.
Proteids, protective value of, 589.
Pruritus ani, 427, 709; treatment of, with the *x*-ray, 716.
Pseudo-hermaphrodism, 235.
Pseudoleukæmia, in a young child, 508.
Psittacosis, three cases of, 708.
Psychiatry, relation of to other sciences, 559.
Public Health and Marine Hospital Service, work of the, 19; examinations of, 62.
Public health, science, 555, 556; work, the need of, 587.
Public-house trust, the British, 582.
Pudic nerve, reflexes caused by, 387.
Puerperal fever, bacteriological results in, 1030; fever, treatment of, 871; infection, prevention of, 314; pyæmia, prognosis and treatment of, 189.
Puerperium, myelitic symptoms, during the, 347.
Pulmonary streptothricosis, 789.
Pulmonary tuberculosis, coal-dust in, 1040; congestion as a cause of death, 1064; dangers of the microscope in early diagnosis of, 988; early diagnosis of, 708; home treatment of, 108, 945; larynx in early, 27; pulmonary infusions for the diagnosis and treatment of, 190; route of infection in, 1029; success of physical remedies in, 241.
Pulse, continued slow, 110; high-tension, cause of in nephritis, 281.
Pulsus paradoxus, significance of the, 349.
Punton, John, why railroad and similar corporations lose their damage suits, 612.
Purgatives, abuse of in laparotomies, 1072.
Purpura, convalescentium, following measles, 787; hemorrhagica, retropharyngeal blood cyst in, 629.
Pus studies, 749.
Pyelitis, acute, of infancy, 434; complicating pregnancy, 81, 115.
Pyæmia, artificial suppuration in, 829.
Pyloric stenosis in infants, 324.
Pylorus, congenital stenosis of the, 392.
Pyothorax, a new operation for, 213.

Q.

Quadruplets, 667.
Quackery, the repression of, 661.
Quarantine regulations, plea for Federal control of, 260.
